The first example is, of course, the Navier–Stokes system, which describes the motion of a viscous incompressible fluid in a bounded domain $\Omega$ (we will only consider here the two-dimensional case $\Omega \subset \mathbb{R}^2$, since the adequate formulation in three dimensions is still an open problem):

$$\begin{cases} \partial_t u - (u, \nabla_x)u = \nu\Delta_x u + \nabla_x p + g(x) \\ \operatorname{div} u = 0, u|_{t=0} = u_0, u|_{\partial\Omega} = 0 \end{cases} \qquad [6]$$

Here, $u(t,x) = (u_1(t,x), u_2(t,x))$ is the unknown velocity vector, $p = p(t,x)$ is the unknown pressure, $\Delta_x$ is the Laplacian with respect to $x$, $\nu > 0$ and $g$ are given kinematic viscosity and external forces, respectively, and $(u, \nabla_x)u$ is the inertial term ($[(u,\nabla_x)u]_i = \sum_{j=1}^{2} u_j \partial_{x_j} u_i$, $i = 1, 2$). The unique global solvability of [6] has been proved by Ladyzhenskaya. Thus, this equation generates an infinite-dimensional DS in the phase space $\Phi$ of divergence-free square-integrable vector fields.

The second example is the damped nonlinear wave equation in $\Omega \subset \mathbb{R}^n$:

$$\begin{gathered} \partial_t^2 u + \gamma\partial_t u - \Delta_x u + f(u) = 0 \\ u|_{\partial\Omega} = 0, \quad u|_{t=0} = u_0, \quad \partial_t u|_{t=0} = u_0' \end{gathered} \qquad [7]$$

which models, for example, the dynamics of a Josephson junction driven by a current source (sine-Gordon equation). It is known that, under natural sign and growth assumptions on the nonlinear interaction function $f$, this equation generates a DS in the energy phase space $E$ of pairs of functions $(u, \partial_t u)$ such that $\partial_t u$ and $\nabla_x u$ are square integrable.

The last class of equations that we will consider here consists of reaction–diffusion systems in a domain $\Omega \subset \mathbb{R}^n$:

$$\partial_t u = a\Delta_x u - f(u), \quad u|_{t=0} = u_0 \qquad [8]$$

(endowed with Dirichlet ($u|_{\partial\Omega} = 0$) or Neumann ($\partial_n u|_{\partial\Omega} = 0$) boundary conditions), which describes some chemical reaction in $\Omega$. Here, $u = (u^1, \ldots, u^N)$ is an unknown vector-valued function which describes the concentrations of the reactants, $f(u)$ is a given interaction function, and $a$ is a diffusion matrix. It is known that, under natural assumptions on $f$ and $a$, these equations also generate an infinite-dimensional DS, for example, in the phase space $\Phi := [L^\infty(\Omega)]^n$.

We emphasize once more that the phase spaces $\Phi$ in all these examples are appropriate infinite-dimensional function spaces. Nevertheless, it was observed in experiments that, up to a transient process, the trajectories of the DS considered are localized inside a "very thin" invariant subset of the phase space having a complicated geometric structure which, thus, accumulates all the nontrivial dynamics of the system. It was conjectured a little later that these invariant sets are, in some proper sense, finite dimensional and that the dynamics restricted to these sets can be effectively described by a finite number of parameters. Thus (when this conjecture is true), in spite of the infinite-dimensional initial phase space, the effective dynamics (reduced to this invariant set) is finite dimensional and can be studied by using the algorithms and concepts of the classical finite-dimensional DS theory. In particular, this means that the infinite dimensionality plays here only the role of (possibly essential) technical difficulties, which cannot, however, produce any new dynamical phenomena which are not observed in the finite-dimensional theory.

The above finite-dimensional reduction principle of dissipative PDEs in bounded domains has been given solid mathematical grounds (based on the concept of the so-called global attractor) over the

last three decades, starting from the pioneering papers of Ladyzhenskaya. This theory is considered in more detail here.

The finite-dimensional reduction theory has some limitations. Of course, the first and most obvious restriction of this principle is the effective dimension of the reduced finite-dimensional DS. Indeed, it is known that, typically, this dimension grows at least linearly with respect to the volume $\mathrm{vol}(\Omega)$ of the spatial domain $\Omega$ of the DS considered (and the growth of the size of $\Omega$ is the same (up to a rescaling) as the decay of the viscosity coefficient $\nu$ or the diffusion matrix $a$, see eqns [6]–[8]). So, for sufficiently large domains $\Omega$, the reduced DS can be too large for reasonable investigations.

The next, less obvious, but much more essential, restriction is the growing spatial complexity of the DS. Indeed, as shown by Babin–Buinimovich, the spatial complexity of the system (e.g., the number of topologically different equilibria) grows exponentially with respect to $\mathrm{vol}(\Omega)$. Thus, even in the case of relatively small dimensions, the reduced system can be out of reasonable investigations, due to its extremely complicated structure.

Therefore, the approach based on the finite-dimensional reduction does not look so attractive for large domains. It seems, instead, more natural, at least from the physical point of view, to replace large bounded domains by their limit unbounded ones (e.g., $\Omega = \mathbb{R}^n$ or cylindrical domains). Of course, this approach requires a systematic study of dissipative DSs associated with PDEs in unbounded domains.

The dynamical study of PDEs in unbounded domains started from the pioneering paper of Kolmogorov–Petrovskij–Piskunov, in which the traveling wave solutions of reaction–diffusion equations in a strip were constructed and the convergence of the trajectories (for specific initial data) to this traveling wave solutions were established. Starting from this, many results on the dynamics of PDE in unbounded domains have been obtained. However, for a long period, the general features of such dynamics remained completely unclear. The main problems arising here are:

1. the essential infinite dimensionality of the DS considered (absence of any finite-dimensional reduction), which leads to essentially new dynamical effects that are not observed in finite-dimensional theories;
2. the additional spatial "unbounded" directions lead to the so-called spatial chaos and the interaction between spatial and temporal chaotic modes generates the spatio-temporal chaos, which also has no analog in finite dimensions.

Nevertheless, several ideas are mentioned in the following which (from authors' point of view) were the most important for the development of these topics. The first one is the pioneering paper of Kirchgässner, in which dynamical methods were applied to the study of the spatial structure of solutions of elliptic equations in cylinders (which can be considered as equilibria equations for evolution PDEs in unbounded cylindrical domains). The second is the Sinai–Buinimovich model of spacetime chaos in discrete lattice DSs. Finally, the third is the adaptation of the concept of a global attractor to unbounded domains by Abergel and Babin–Vishik.

We note that the situation on the understanding of the general features of the dynamics in unbounded domains, however, seems to have changed in the last several years, due to the works of Collet–Eckmann and Zelik. This is the reason why a section of this review is devoted to a more detailed discussion on this topic.

Other important questions are the object of current studies and we only briefly mention some of them. We mention for instance, the study of attractors for nonautonomous systems (i.e., systems in which the time appears explicitly). This situation is much more delicate and is not completely understood; notions of attractors for such systems have been proposed by Chepyzhov–Vishik, Haraux and Kloeden–Schmalfuss. We also mention that theories of (global) attractors for non-well-posed problems have been proposed by Babin–Vishik, Ball, Chepyzhov–Vishik, Melnik–Valero, and Sell.

## Global Attractors and Finite-Dimensional Reduction

### Global Attractors: The Abstract Setting

As already mentioned, one of the main concepts of the modern theory of DSs in infinite dimensions is that of the global attractor. We give below its definition for an abstract semigroup $S(t)$ acting on a metric space $\Phi$, although, without loss of generality, the reader may think that $(S(t), \Phi)$ is just a DS associated with one of the PDEs ([6]–[8]) described in the introduction.

To this end, we first recall that a subset $K$ of the phase space $\Phi$ is an attracting set of the semigroup $S(t)$ if it attracts the images of all the bounded subsets of $\Phi$, that is, for every bounded set $B$ and every $\varepsilon > 0$, there exists a time $T$ (depending in general on $B$ and $\varepsilon$) such that the image $S(t)B$ belongs to the

$\varepsilon$-neighborhood of $K$ if $t \geq T$. This property can be rewritten in the equivalent form

$$\lim_{t\to\infty} \mathrm{dist}_H(S(t)B, K) = 0 \qquad [9]$$

where $\mathrm{dist}_H(X, Y) := \sup_{x\in\mathbb{X}} \inf_{y\in\mathbb{Y}} d(x, y)$ is the nonsymmetric Hausdorff distance between subsets of $\Phi$.

The following definition of a global attractor is due to Babin–Vishik.

**Definition 1** A set $\mathcal{A} \subset \Phi$ is a global attractor for the semigroup $S(t)$ if

(i) $\mathcal{A}$ is compact in $\Phi$;
(ii) $\mathcal{A}$ is strictly invariant: $S(t)\mathcal{A} = \mathcal{A}$, for all $t \geq 0$;
(iii) $\mathcal{A}$ is an attracting set for the semigroup $S(t)$.

Thus, the second and third properties guarantee that a global attractor, if it exists, is unique and that the DS reduced to the attractor contains all the nontrivial dynamics of the initial system. Furthermore, the first property indicates that the reduced phase space $\mathcal{A}$ is indeed "thinner" than the initial phase space $\Phi$ (we recall that, in infinite dimensions, a compact set cannot contain, e.g., balls and should thus be nowhere dense).

In most applications, one can use the following attractor's existence theorem.

**Theorem 1** *Let a DS $(S(t), \Phi)$ possess a compact attracting set and the operators $S(t): \Phi \to \Phi$ be continuous for every fixed t. Then, this system possesses the global attractor $\mathcal{A}$ which is generated by all the trajectories of $S(t)$ which are defined for all $t \in \mathbb{R}$ and are globally bounded.*

The strategy for applying this theorem to concrete equations of mathematical physics is the following. In a first step, one verifies a so-called dissipative estimate which has usually the form

$$\|S(t)u_0\|_\Phi \leq Q(\|u_0\|_\Phi)\,\mathrm{e}^{-\alpha t} + C_*, \quad u_0 \in \Phi \qquad [10]$$

where $\|\cdot\|_\Phi$ is a norm in the function space $\Phi$ and the positive constants $\alpha$ and $C_*$ and the monotonic function $Q$ are independent of $t$ and $u_0 \in \Phi$ (usually, this estimate follows from energy estimates and is sometimes even used in order to "define" a dissipative system). This estimate obviously gives the existence of an attracting set for $S(t)$ (e.g., the ball of radius $2C_*$ in $\Phi$), which is, however, noncompact in $\Phi$. In order to overcome this problem, one usually derives, in a second step, a smoothing property for the solutions, which can be formulated as follows:

$$\|S(1)u_0\|_{\Phi_1} \leq Q_1(\|u_0\|_\Phi), \quad u_0 \in \Phi \qquad [11]$$

where $\Phi_1$ is another function space which is compactly embedded into $\Phi$. In applications, $\Phi$ is usually the space $L^2(\Omega)$ of square integrable functions, $\Phi_1$ is the Sobolev space $H^1(\Omega)$ of the functions $u$ such that $u$ and $\nabla_x u$ belong to $L^2(\Omega)$ and estimate [11] is a classical smoothing property for solutions of parabolic equations (for hyperbolic equations, a slightly more complicated asymptotic smoothing property should be used instead of [11]).

Since the continuity of the operators $S(t)$ usually arises no difficulty (if the uniqueness is proven), then the above scheme gives indeed the existence of the global attractor for most of the PDEs of mathematical physics in bounded domains.

### Dimension of the Global Attractor

In this subsection, we start by discussing one of the basic questions of the theory: in which sense is the dynamics on the global attractor finite dimensional? As already mentioned, the global attractor is usually not a manifold, but has a rather complicated geometric structure. So, it is natural to use the definitions of dimensions adopted for the study of fractal sets here. We restrict ourselves to the so-called fractal (or box-counting, entropy) dimension, although other dimensions (e.g., Hausdorff, Lyapunov, etc.) are also used in the theory of attractors.

In order to define the fractal dimension, we first recall the concept of Kolmogorov's $\varepsilon$-entropy, which comes from the information theory and plays a fundamental role in the theory of DSs in unbounded domains considered in the next section.

**Definition 2** Let $\mathcal{A}$ be a compact subset of a metric space $\Phi$. For every $\varepsilon > 0$, we define $N_\varepsilon(K)$ as the minimal number of $\varepsilon$-balls which are necessary to cover $\mathcal{A}$. Then, Kolmogorov's $\varepsilon$-entropy $\mathcal{H}_\varepsilon(\mathcal{A}) = \mathcal{H}_\varepsilon(\mathcal{A}, \Phi)$ of $\mathcal{A}$ is the digital logarithm of this number, $\mathcal{H}_\varepsilon(\mathcal{A}) := \log_2 N_\varepsilon(\mathcal{A})$. We recall that $\mathcal{H}_\varepsilon(\mathcal{A})$ is finite for every $\varepsilon > 0$, due to the Hausdorff criterium. The fractal dimension $d_\mathrm{f}(\mathcal{A}) \in [0, \infty]$ of $\mathcal{A}$ is then defined by

$$d_\mathrm{f}(\mathcal{A}) := \limsup_{\varepsilon\to 0} \mathcal{H}_\varepsilon(\mathcal{A}) / \log_2 1/\varepsilon \qquad [12]$$

We also recall that, although this dimension coincides with the usual dimension of the manifold for Lipschitz manifolds, it can be noninteger for more complicated sets. For instance, the fractal dimension of the standard ternary Cantor set in [0, 1] is $\ln 2 / \ln 3$.

The so-called Mané theorem (which can be considered as a generalization of the classical Yitni embedding theorem for fractal sets) plays an important role in the finite-dimensional reduction theory.

**Theorem 2** *Let $\Phi$ be a Banach space and $\mathcal{A}$ be a compact set such that $d_f(\mathcal{A}) < N$ for some $N \in \mathbb{N}$. Then, for "almost all" $(2N+1)$-dimensional planes $L$ in $\Phi$, the corresponding projector $\Pi_L : \Phi \to L$ restricted to the set $\mathcal{A}$ is a Hölder continuous homeomorphism.*

Thus, if the finite fractal dimensionality of the attractor is established, then, fixing a hyperplane $L$ satisfying the assumptions of the Mané theorem and projecting the attractor $\mathcal{A}$ and the DS $S(t)$ restricted to $\mathcal{A}$ onto this hyperplane ($\bar{\mathcal{A}} := \Pi_L \mathcal{A}$ and $\bar{S}(t) := \Pi_L \circ S(t) \circ \Pi_L^{-1}$), we obtain, indeed, a reduced DS $(\bar{S}(t), \bar{\mathcal{A}})$ which is defined on a finite-dimensional set $\bar{\mathcal{A}} \subset L \sim \mathbb{R}^{2N+1}$. Moreover, this DS will be Hölder continuous with respect to the initial data.

### Estimates on the Fractal Dimension

Obviously, good estimates on the dimension of the attractors in terms of the physical parameters are crucial for the finite-dimensional reduction described above, and (consequently) there exists a highly developed machinery for obtaining such estimates. The best-known upper estimates are usually obtained by the so-called volume contraction method, which is based on the study of the evolution of infinitesimal $k$-dimensional volumes in the neighborhood of the attractor (and, if the DS considered contracts the $k$-dimensional volumes, then the fractal dimension of the attractor is less than $k$). Lower bounds on the dimension are usually based on the observation that the global attractor always contains the unstable manifolds of the (hyperbolic) equilibria. Thus, the instability index of a properly constructed equilibrium gives a lower bound on the dimension of the attractor.

In the following, several estimates for the classes of equations given in the introduction are formulated, beginning with the most-studied case of the reaction–diffusion system [8]. For this system, sharp upper and lower bounds are known, namely

$$C_1 \mathrm{vol}(\Omega) \le d_f(\mathcal{A}) \le C_2 \mathrm{vol}(\Omega) \qquad [13]$$

where the constants $C_1$ and $C_2$ depend on $a$ and $f$ (and, possibly, on the shape of $\Omega$), but are independent of its size. The same types of estimates also hold for the hyperbolic equation [7]. Concerning the Navier–Stokes system [6] in general two-dimensional domains $\Omega$, the asymptotics of the fractal dimension as $\nu \to 0$ is not known. The best-known upper bound has the form $d_f(\mathcal{A}) \le C\nu^{-2}$ and was obtained by Foias–Temam by using the so-called Lieb–Thirring inequalities. Nevertheless, for periodic boundary conditions, Constantin–Foias–Temam and Liu obtained upper and lower bounds of the same order (up to a logarithmic correction):

$$C_1 \nu^{-4/3} \le d_f(\mathcal{A}) \le C_2 \nu^{-4/3}(1 + \ln(\nu^{-1}))^{1/3} \qquad [14]$$

### Global Lyapunov Functions and the Structure of Global Attractors

Although the global attractor has usually a very complicated geometric structure, there exists one exceptional class of DS for which the global attractor has a relatively simple structure which is completely understood, namely the DS having a global Lyapunov function. We recall that a continuous function $\mathcal{L} : \Phi \to \mathbb{R}$ is a global Lypanov function if

1. $\mathcal{L}$ is nonincreasing along the trajectories, that is, $\mathcal{L}(S(t)u_0) \le \mathcal{L}(u_0)$, for all $t \ge 0$;
2. $\mathcal{L}$ is strictly decreasing along all nonequilibrium solutions, that is, $\mathcal{L}(S(t)u_0) = \mathcal{L}(u_0)$ for some $t > 0$ and $u_0$ implies that $u_0$ is an equilibrium of $S(t)$.

For instance, in the scalar case $N = 1$, the reaction–diffusion equations [8] possess the global Lyapunov function $\mathcal{L}(u_0) := \int_\Omega [a|\nabla_x u_0(x)|^2 + F(u_0(x))]\mathrm{d}x$, where $F(v) := \int_0^v f(u)\,\mathrm{d}u$. Indeed, multiplying eqn [8] by $\partial_t u$ and integrating over $\Omega$, we have

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathcal{L}(u(t)) = -2\|\partial_t u(t)\|^2_{L^2(\Omega)} \le 0 \qquad [15]$$

Analogously, in the scalar case $N = 1$, multiplying the hyperbolic equation [7] by $\partial_t u(t)$ and integrating over $\Omega$, we obtain the standard global Lyapunov function for this equation.

It is well known that, if a DS posseses a global Lyapunov function, then, at least under the generic assumption that the set $\mathcal{R}$ of equilibria is finite, every trajectory $u(t)$ stabilizes to one of these equilibria as $t \to +\infty$. Moreover, every complete bounded trajectory $u(t)$, $t \in \mathbb{R}$, belonging to the attractor is a heteroclinic orbit joining two equilibria. Thus, the global attractor $\mathcal{A}$ can be described as follows:

$$\mathcal{A} = \bigcup_{u_0 \in \mathcal{R}} \mathcal{M}^+(u_0) \qquad [16]$$

where $\mathcal{M}^+(u_0)$ is the so-called unstable set of the equilibrium $u_0$ (which is generated by all heteroclinic orbits of the DS which start from the given equilibrium $u_0 \in \mathcal{A}$). It is also known that, if the equilibrium $u_0$ is hyperbolic (generic assumption), then the set $\mathcal{M}^+(u_0)$ is a $\kappa$-dimensional submanifold of $\Phi$, where $\kappa$ is the instability index of $u_0$. Thus, under the generic hyperbolicity assumption on the equilibria, the

attractor $\mathcal{A}$ of a DS having a global Lyapunov function is a finite union of smooth finite-dimensional submanifolds of the phase space $\Phi$. These attractors are called regular (following Babin–Vishik).

It is also worth emphasizing that, in contrast to general global attractors, regular attractors are robust under perturbations. Moreover, in some cases, it is also possible to verify the so-called transversality conditions (for the intersection of stable and unstable manifolds of the equilibria) and, thus, verify that the DS considered is a Morse–Smale system. In particular, this means that the dynamics restricted to the regular attractor $\mathcal{A}$ is also preserved (up to homeomorphisms) under perturbations.

A disadvantage of the approach of using a regular attractor is the fact that, except for scalar parabolic equations in one space dimension, it is usually extremely difficult to verify the "generic" hyperbolicity and transversality assumptions for concrete values of the physical parameters and the associated hyperbolicity constants, as a rule, cannot be expressed in terms of these parameters.

### Inertial Manifolds

It should be noted that the scheme for the finite-dimensional reduction described above has essential drawbacks. Indeed, the reduced system $(\bar{S}(t), \bar{A})$ is only Hölder continuous and, consequently, cannot be realized as a DS generated by a system of ODEs (and reasonable conditions on the attractor $\mathcal{A}$ which guarantee the Lipschitz continuity of the Mané projections are not known). On the other hand, the complicated geometric structure of the attractor $\mathcal{A}$ (or $\bar{A}$) makes the use of this finite-dimensional reduction in computations hazardous (in fact, only the heuristic information on the number of unknowns which are necessary to capture all the dynamical effects in approximations can be extracted).

In order to overcome these problems, the concept of an inertial manifold (which allows one to embed the global attractor into a smooth manifold) has been suggested by Foias–Sell–Temam. To be more precise, a Lipschitz finite-dimensional manifold $\mathbb{M} \subset \Phi$ is an inertial manifold for the DS $(S(t), \Phi)$ if

1. $\mathbb{M}$ is semiinvariant, that is, $S(t)\mathbb{M} \subset \mathbb{M}$, for all $t \geq 0$;
2. $\mathbb{M}$ satisfies the following asymptotic completeness property: for every $u_0 \in \Phi$, there exists $v_0 \in \mathbb{M}$ such that

$$\|S(t)u_0 - S(t)v_0\|_\Phi \leq Q(\|u_0\|_\Phi)e^{-\alpha t} \qquad [17]$$

where the positive constant $\alpha$ and the monotonic function $Q$ are independent of $u_0$.

We can see that an inertial manifold, if it exists, confirms in a perfect way the heuristic conjecture on the finite dimensionality formulated in the introduction. Indeed, the dynamics of $S(t)$ restricted to an inertial manifold can be, obviously, described by a system of ODEs (which is called the inertial form of the initial PDE). On the other hand, the asymptotic completeness gives (in a very strong form) the equivalence of the initial DS $(S(t), \Phi)$ with its inertial form $(S(t), \mathbb{M})$. Moreover, in turbulence, the existence of an inertial manifold would yield an exact interaction law between the small and large structures of the flow.

Unfortunately, all the known constructions of inertial manifolds are based on a very restrictive condition, the so-called spectral gap condition, which requires arbitrarily large gaps in the spectrum of the linearization of the initial PDE and which can usually be verified only in one space dimension. So, the existence of an inertial manifold is still an open problem for many important equations of mathematical physics (including in particular the two-dimensional Navier–Stokes equations; some nonexistence results have also been proven by Mallet–Paret).

### Exponential Attractors

We first recall that Definition 1 of a global attractor only guarantees that the images $S(t)B$ of all the bounded subsets converge to the attractor, without saying anything on the rate of convergence (in contrast to inertial manifolds, for which this rate of convergence can be controlled). Furthermore, as elementary examples show, this convergence can be arbitrarily slow, so that, until now, we have no effective way for estimating this rate of convergence in terms of the physical parameters of the system (an exception is given by the regular attractors described earlier for which the rate of convergence can be estimated in terms of the hyperbolicity constants of the equilibria. However, even in this situation, it is usually very difficult to estimate these constants for concrete equations). Furthermore, there exist many physically relevant systems (e.g., the so-called slightly dissipative gradient systems) which have trivial global attractors, but very rich and physically relevant transient dynamics which are automatically forgotten under the global-attractor approach. Another important problem is the robustness of the global attractor under perturbations. In fact, global attractors are usually only upper semicontinuous under

perturbations (which means that they cannot explode) and the lower semicontinuity (which means that they cannot also implode) is much more delicate to prove and requires some hyperbolicity assumptions (which are usually impossible to verify for concrete equations).

In order to overcome these difficulties, Eden–Foias–Nicolaenko–Temam have introduced an intermediate object (between inertial manifolds and global attractors), namely an exponential attractor (also called an inertial set).

**Definition 3** A compact set $\mathcal{M} \subset \Phi$ is an exponential attractor for the DS $(S(t), \Phi)$ if

(i) $\mathcal{M}$ has finite fractal dimension: $d_f(\mathcal{M}) < \infty$;
(ii) $\mathcal{M}$ is semi-invariant: $S(t)\mathcal{M} \subset \mathcal{M}$, for all $t \geq 0$;
(iii) $\mathcal{M}$ attracts exponentially the images of all the bounded sets $B \subset \phi$:

$$\mathrm{dist}_H(S(t)B, \mathcal{M}) \leq Q(\|B\|_\Phi)e^{-\alpha t} \qquad [18]$$

where the positive constant $\alpha$ and the monotonic function $Q$ are independent of $B$.

Thus, on the one hand, an exponential attractor remains finite dimensional (like the global attractor) and, on the other hand, estimate [18] allows one to control the rate of attraction (like an inertial manifold). We note, however, that the relaxation of strict invariance to semi-invariance allows this object to be nonunique. So, we have here the problem of the "best choice" of the exponential attractor. We also mention that an exponential attractor, if it exists, always contains the global attractor.

Although the initial construction of exponential attractors is based on the so-called squeezing property (and requires Zorn's lemma), we formulate below a simpler construction, due to Efendiev–Miranville–Zelik, which is similar to the method proposed by Ladyzhenskaya to verify the finite dimensionality of global attractors. This is done for discrete times and for a DS generated by iterations of some map $S:\Phi \to \Phi$, since the passage from discrete to continuous times usually arises no difficulty (without loss of generality, the reader may think that $S = S(1)$ and $(S(t), \Phi)$ is one of the DS mentioned in the introduction).

**Theorem 3** *Let the phase space $\Phi_0$ be a closed bounded subset of some Banach space $H$ and let $H_1$ be another Banach space compactly embedded into $H$. Assume also that the map $S:\Phi_0 \to \Phi_0$ satisfies the following "smoothing" property*:

$$\|Su_1 - Su_2\|_{H_1} \leq K\|u_1 - u_2\|_H, \quad u_1, u_2 \in \Phi_0 \qquad [19]$$

*for some constant $K$ independent of $u_i$. Then, the DS $(S, \Phi_0)$ possesses an exponential attractor.*

In applications, $\Phi_0$ is usually a bounded absorbing/attracting set whose existence is guaranteed by the dissipative estimate [10], $H := L^2(\Omega)$ and $H_1 := H^1(\Omega)$. Furthermore, estimate [19] simply follows from the classical parabolic smoothing property, but now applied to the equation of variations (as in [11], hyperbolic equations require a slightly more complicated analogue of [19]). These simple arguments show that exponential attractors are as general as global attractors and, to the best of our knowledge, exponential attractors exist indeed for all the equations of mathematical physics for which the finite dimensionality of the global attractor can be established. Moreover, since $\mathcal{A} \subset \mathcal{M}$, this scheme can also be used to prove the finite dimensionality of global attractors.

It is finally worth emphasizing that the control on the rate of convergence provided by [18] makes exponential attractors much more robust than global attractors. In particular, they are upper and lower semicontinuous under perturbations (of course, up to the "best choice," since they are not unique), as shown by Efendiev–Miranville–Zelik.

## Essentially Infinite-Dimensional Dynamical Systems – The Case of Unbounded Domains

As already mentioned in the introduction, the theory of dissipative DS in unbounded domains is developing only now and the results given here are not as complete as for bounded domains. Nevertheless, we indicate below several of the most interesting (from our point of view) results concerning the general description of the dynamics generated by such problems by considering a system of reaction–diffusion equations [8] in $\mathbb{R}^n$ with phase space $\Phi = L^\infty(\mathbb{R}^n)$ as a model example (although all the results formulated below are general and depend weakly on the choice of equation).

### Generalization of the Global Attractor and Kolmogorov's $\varepsilon$-Entropy

We first note that Definition 1 of a global attractor is too strong for equations in unbounded domains. Indeed, as seen earlier, the compactness of the attractor is usually based on the compactness of the embedding $H^1(\Omega) \subset L^2(\Omega)$, which does not hold in unbounded domains. Furthermore, an attractor, in the sense of Definition 1, does not exist for most of the interesting examples of eqns [8] in $\mathbb{R}^n$.

It is natural to use instead the concept of the so-called locally compact global attractor which is well adapted to unbounded domains. This attractor $\mathcal{A}$ is only bounded in the phase space $\Phi = L^\infty(\mathbb{R}^n)$, but its restrictions $\mathcal{A}|_\Omega$ to all bounded domains $\Omega$ are compact in $L^\infty(\Omega)$. Moreover, the attraction property should also be understood in the sense of a local topology in $L^\infty(\mathbb{R}^n)$. It is known that this generalized global attractor $\mathcal{A}$ exists indeed for problem [8] in $\mathbb{R}^n$ (of course, under some "natural" assumptions on the nonlinearity $f$ and the diffusion matrix $a$). As for bounded domains, its existence is based on the dissipative estimate [10], the smoothing property [11], and the compactness of the embedding $H^1_{\mathrm{loc}}(\mathbb{R}^n) \subset L^2_{\mathrm{loc}}(\mathbb{R}^n)$ (we need to use the local topology only to have this compactness).

The next natural question that arises here is how to control the "size" of the attractor $\mathcal{A}$ if its fractal dimension is infinite (which is usually the case in unbounded domains). One of the most natural ways to handle this problem (which was first suggested by Chepyzhov–Vishik in the different context of uniform attractors associated with nonautonomous equations in bounded domains and appears as extremely fruitful for the theory of dissipative PDE in unbounded domains) is to study the asymptotics of Kolmogorov's $\varepsilon$-entropy of the attractor. Actually, since the attractor $\mathcal{A}$ is compact only in a local topology, it is natural to study the entropy of its restrictions, say, to balls $B^R_{x_0}$ of $\mathbb{R}^n$ of radius $R$ centered at $x_0$ with respect to the three parameters $R, x_0$, and $\varepsilon$. A more or less complete answer to this question is given by the following estimate:

$$\mathcal{H}_\varepsilon(\mathcal{A}|_{B^R_{x_0}}) \le C(R + \log_2 1/\varepsilon)^n \log_2 1/\varepsilon \qquad [20]$$

where the constant $C$ is independent of $\varepsilon \le 1$, $R$, and $x_0$. Moreover, it can be shown that this estimate is sharp for all $R$ and $\varepsilon$ under the very weak additional assumption that eqn [8] possesses at least one exponentially unstable spatially homogeneous equilibrium.

Thus, formula [20] (whose proof is also based on a smoothing property for the equation of variations) can be interpreted as a natural generalization of the heuristic principle of finite dimensionality of global attractors to unbounded domains. It is also worth recalling that the entropy of the embedding of a ball $\mathcal{B}_k$ of the space $C^k(B^R_{x_0})$ into $C(B^R_{x_0})$ has the asymptotic $\mathcal{H}_\varepsilon(\mathcal{B}) \sim C_R(1/\varepsilon)^{n/k}$, which is essentially worse than [20]. So, [20] is not based on the smoothness of the attractor $\mathcal{A}$ and, therefore, reflects deeper properties of the equation.

## Spatial Dynamics and Spatial Chaos

The next main difference with bounded domains is the existence of unbounded spatial directions which can generate the so-called spatial chaos (in addition to the "usual" temporal chaos arising under the evolution). In order to describe this phenomenon, it is natural to consider the group $\{T_h, h \in \mathbb{R}^n\}$ of spatial translations acting on the attractor $\mathcal{A}$:

$$(T_h u_0)(x) := u_0(x+h), \quad T_h : \mathcal{A} \to \mathcal{A} \qquad [21]$$

as a DS (with multidimensional "times" if $n > 1$) acting on the phase space $\mathcal{A}$ and to study its dynamical properties.

In particular, it is worth noting that the lower bounds on the $\varepsilon$-entropy that one can derive imply that the topological entropy of this spatial DS is infinite and, consequently, the classical symbolic dynamics with a finite number of symbols is not adequate to clarify the nature of chaos in [21]. In order to overcome this difficulty, it was suggested by Zelik to use Bernoulli shifts with an infinite number of symbols, belonging to the whole interval $\omega \in [0, 1]$. To be more precise, let us consider the Cartesian product $\mathbb{M}_n := [0,1]^{\mathbb{Z}^n}$ endowed with the Tikhonov topology. Then, this set can be interpreted as the space of all the functions $v : \mathbb{Z}^n \to [0,1]$, endowed with the standard local topology. We define a DS $\{\mathcal{T}_l, l \in \mathbb{Z}^n\}$ on $\mathbb{M}_n$ by

$$(\mathcal{T}_l v)(m) := v(m+l), \quad v \in \mathbb{M}_n,\ l, m \in \mathbb{Z}^n \qquad [22]$$

Based on this model, the following description of spatial chaos was obtained.

**Theorem 4** *Let eqn [8] in $\Omega = \mathbb{R}^n$ possess at least one exponentially unstable spatially homogeneous equilibrium. Then, there exist $\alpha > 0$ and a homeomorphic embedding $\tau : \mathbb{M}_n \to \mathcal{A}$ such that*

$$T_{\alpha l} \circ \tau(v) = \tau \circ \mathcal{T}_l(v), \quad \forall l \in \mathbb{Z}^n,\ v \in \mathbb{M}_n \qquad [23]$$

Thus, the spatial dynamics, restricted to the set $\tau(\mathbb{M}_n)$, is conjugated to the symbolic dynamics on $\mathbb{M}_n$. Moreover, there exists a dynamical invariant (the so-called mean toplogical dimension) which is always finite for the spatial DS [22] and strictly positive for the Bernoulli scheme $\mathbb{M}_n$. So, the embedding [23] clarifies, indeed, the nature of chaos arising in the spatial DS [21].

## Spatio-Temporal Chaos

To conclude, we briefly discuss an extension of Theorem 4, which takes into account the temporal modes and, thus, gives a description of the spatio-temporal chaos. In order to do so, we first note

that the spatial DS [21] commutes obviously with the temporal evolution operators $S(t)$ and, consequently, an extended $(n+1)$-parametric semigroup $\{\mathbb{S}(t,h), (t,h) \in \mathbb{R}_+ \times \mathbb{R}^n\}$ acts on the attractor:

$$\mathbb{S}(t,h) := S(t) \circ T_h, \qquad \mathbb{S}(t,h) : \mathcal{A} \to \mathcal{A} \\ t \in \mathbb{R}_+, \quad h \in \mathbb{R}^n \qquad [24]$$

Then, this semigroup (interpreted as a DS with multidimensional times) is responsible for all the spatio-temporal dynamical phenomena in the initial PDE [8] and, consequently, the question of finding adequate dynamical characteristics is of a great interest. Moreover, it is also natural to consider the subsemigroups $\mathbb{S}_{V_k}(t,h)$ associated with the $k$-dimensional planes $V_k$ of the spacetime $\mathbb{R}_+ \times \mathbb{R}^n$, $k < n+1$.

Although finding an adequate description of the dynamics of [24] seems to be an extremely difficult task, some particular results in this direction have already been obtained. Thus, it has been proved by Zelik that the semigroup [24] has finite topological entropy and the entropy of its subsemigroups $\mathbb{S}_{V_k}(t,h)$ is usually infinite if $k < n+1$. Moreover (adding a natural transport term of the form $(L, \nabla_x)u$ to eqn [8]), it was proved that the analog of Theorem 4 holds for the subsemigroups $\mathbb{S}_{V_n}(t,h)$ associated with the $n$-dimensional hyperplanes $V_n$ of the spacetime. Thus, the infinite-dimensional Bernoulli shifts introduced in the previous subsection can be used to describe the temporal evolution in unbounded domains as well.

In particular, as a consequence of this embedding, the topological entropy of the initial purely temporal evolution semigroup $S(t)$ is also infinite, which indicates that (even without considering the spatial directions) we have indeed here essential new levels of dynamical complexity which are not observed in the classical DS theory of ODEs.

## Introduction

Since they were introduced by Witten in 1988, topological quantum field theories (TQFTs) have had a tremendous impact in mathematical physics (see Birmingham *et al.* (1991) and Cordes *et al.* for a review). These quantum field theories are constructed in such a way that the correlation functions of certain operators provide topological invariants of the spacetime manifold where the theory is defined. This means that one can use the methods and insights of quantum field theory in order to obtain information about topological invariants of low-dimensional manifolds.

Historically, the first TQFT was Donaldson–Witten theory, also called topological Yang–Mills theory. This theory was constructed by Witten (1998) starting from $\mathcal{N}=2$ super Yang–Mills by a procedure called

"topological twisting." The resulting model is topological and the famous Donaldson invariants of 4-manifolds are then recovered as certain correlation functions in the topological theory. The analysis of Witten (1998) did not indicate any new method to compute the invariants, but in 1994 the progress in understanding the nonperturbative dynamics of $\mathcal{N}=2$ theories (Seiberg and Witten 1994 a, b) led to an alternative way of computing correlation functions in Donaldson–Witten theory. As Witten (1994) showed, Donaldson–Witten theory can be reduced to another, simpler topological theory consisting of a twisted abelian gauge theory coupled to spinor fields. This theory leads to a different set of 4-manifold invariants, the so-called "Seiberg–Witten invariants," and Donaldson invariants can be expressed in terms of these invariants through Witten's "magic formula." The connection between Seiberg–Witten and Donaldson invariants was streamlined and extended by Moore and Witten by using the so-called $u$-plane integral (Moore and Witten 1998). This has led to a rather complete understanding of Donaldson–Witten theory from a physical point of view.

In this article we provide a brief review of Donaldson–Witten theory. First, we describe the construction of the model, from both a mathematical and a physical point of view, and state the main results for the Donaldson–Witten generating functional. In the next section, we present the basic results of the $u$-plane integral of Moore and Witten and sketch how it can be used to solve Donaldson–Witten theory. In the final section, we mention some generalizations of the basic framework. For a complete exposition of Donaldson–Witten theory, the reader is referred to the book by Labastida and Mariño (2005). A short review of the $u$-plane integral can be found in Mariño and Moore (1998a).

## Donaldson–Witten Theory: Basic Construction and Results

### Donaldson–Witten Theory According to Donaldson

Donaldson theory as formulated in Donaldson (1990), Donaldson and Kronheimer (1990), and Friedman and Morgan (1991) starts with a principal $G=\mathrm{SO}(3)$ bundle $V\to X$ over a compact, oriented, Riemannian 4-manifold $X$, with fixed instanton number $k$ and Stiefel–Whitney class $w_2(V)$ (SO(3) bundles on a 4-manifold are classified up to isomorphism by these topological data). The moduli space of anti-self-dual (ASD) connections is then defined as

$$\mathcal{M}_{\mathrm{ASD}}=\{A:F^+(A)=0\}/\mathcal{G} \qquad [1]$$

where $F^+(A)$ is the self-dual part of the curvature, and $\mathcal{G}$ is the group of gauge transformations. To construct the Donaldson polynomials, one considers the universal bundle

$$\boldsymbol{P}=(V\times\mathcal{A}^*)/(\mathcal{G}\times G) \qquad [2]$$

where $\mathcal{A}^*$ is the space of irreducible $G$-connections on $V$. This is a $G$-bundle over $\mathcal{B}^*\times X$, where $\mathcal{B}^*=\mathcal{A}^*/\mathcal{G}$ is the space of irreducible connections modulo gauge transformations, and as such has a Pontrjagin class

$$p_1(\boldsymbol{P})\in H^*(\mathcal{B}^*)\otimes H^*(X) \qquad [3]$$

One can then obtain differential forms on $\mathcal{B}^*$ by taking the slant product of $p_1(\boldsymbol{P})$ with homology classes in $X$. In this way we obtain the Donaldson map:

$$\mu: H_i(X)\longrightarrow H^{4-i}(\mathcal{B}^*) \qquad [4]$$

After restriction to $\mathcal{M}_{\mathrm{ASD}}$, we obtain the following differential forms on the moduli space of ASD connections:

$$\begin{aligned} x\in H_0(X)&\to\mathcal{O}(x)\in H^4(\mathcal{M}_{\mathrm{ASD}})\\ S\in H_2(X)&\to I_2(S)\in H^2(\mathcal{M}_{\mathrm{ASD}})\end{aligned} \qquad [5]$$

If the manifold $X$ has $b_1(X)\neq 0$, there are also cohomology classes associated to 1-cycles and 3-cycles, but we will not consider them here.

We can now formally define the Donaldson invariants as follows. Consider the space

$$\boldsymbol{A}(X)=\mathrm{Sym}(H_0(X)\oplus H_2(X)) \qquad [6]$$

with a typical element written as $x^\ell S_{i_1}\cdots S_{i_p}$. The Donaldson invariant corresponding to this element of $\boldsymbol{A}(X)$ is the following intersection number:

$$\begin{aligned}&\mathcal{D}_X^{w_2(V),k}(x^\ell S_{i_1}\cdots S_{i_p})\\ &\quad=\int_{\mathcal{M}_{\mathrm{ASD}}}\mathcal{O}^\ell\wedge I_2(S_{i_1})\wedge\cdots\wedge I_2(S_{i_p})\end{aligned} \qquad [7]$$

where $\mathcal{M}_{\mathrm{ASD}}$ is the moduli space of ASD connections with second Stiefel–Whitney class $w_2(V)$ and instanton number $k$. The integral in [7] will be different from zero only if the degrees of the forms add up to $\dim(\mathcal{M}_{\mathrm{ASD}})$.

It is very convenient to pack all Donaldson invariants in a generating functional. Let $\{S_i\}_{i=1,\ldots,b_2}$ be a basis of 2-cycles. We introduce the formal sum

$$S=\sum_{i=1}^{b_2}v_iS_i \qquad [8]$$

where $v_i$ are complex numbers. We then define the Donaldson–Witten generating functional as

$$Z_{\mathrm{DW}}^{w_2(V)}(p, v_i) = \sum_{k=0}^{\infty} \mathcal{D}_X^{w_2(V),k}(\mathrm{e}^{px+S}) \qquad [9]$$

where on the right-hand side we are summing over all instanton numbers, that is, we are summing over all topological configurations of the SO(3) gauge field with a fixed $w_2(V)$. This gives a formal power series in $p$ and $v_i$.

For $b_2^+(X) > 1$, the generating functional [9] is a diffeomorphism invariant of $X$; therefore, it is potentially a powerful tool in four-dimensional topology. When $b_2^+(X) = 1$, Donaldson invariants are metric dependent. The metric dependence can be described in more detail as follows. Define the period point as the harmonic 2-form satisfying

$$*\omega = \omega, \qquad \omega^2 = 1 \qquad [10]$$

which depends on the conformal class of the metric. As the conformal class of the metric varies, $\omega$ describes a curve in the cone

$$V_+ = \{\omega \in H^2(X, \boldsymbol{R}) : \omega^2 > 0\} \qquad [11]$$

Let $\zeta \in H^2(X)$ satisfy

$$\zeta \equiv w_2(V) \bmod 2, \quad \zeta^2 < 0, \ (\zeta, \omega) = 0 \qquad [12]$$

Such an element $\zeta$ defines a "wall" in $V_+$:

$$W_\zeta = \{\omega : (\zeta, \omega) = 0\} \qquad [13]$$

The complements of these walls are called "chambers," and the cone $V_+$ is then divided in chambers separated by walls. A class $\zeta$ satisfying [12] is the first Chern class associated to a reducible solution of the ASD equations, and it causes a singularity in moduli space: the Donaldson invariants jump when we pass through such a wall. Therefore, when $b_2^+(X) = 1$, Donaldson invariants are metric independent in each chamber. A basic problem in Donaldson–Witten theory is to determine the jump in the generating function as we cross a wall,

$$Z_+^\zeta(p, S) - Z_-^\zeta(p, S) = WC_\zeta(p, S) \qquad [14]$$

The jump term $WC_\zeta(p, S, \delta)$ is usually called the "wall-crossing" term.

The basic goal of Donaldson theory is to study the properties of the generating functional [9] and to compute it for different 4-manifolds $X$. On the mathematical side, many results have been obtained on $Z_{\mathrm{DW}}$, and some of them can be found in Donaldson and Kronheimer (1990), Friedman and Morgan (1991), Stern (1998), and Göttsche (1996). On the other hand, Donaldson theory can be formulated as a topological field theory, and many of these results can be obtained by using quantum field theory techniques. This will be our main focus for the rest of the article.

### Donaldson–Witten Theory According to Witten

Witten (1988) constructed a twisted version of $\mathcal{N} = 2$ super Yang–Mills theory which has a nilpotent Becchi–Rouet–Stora–Tyutin (BRST) charge (modulo gauge transformations)

$$\overline{\mathcal{Q}} = \epsilon^{\dot{\alpha}\dot{A}} Q_{\dot{\alpha}\dot{A}} \qquad [15]$$

where $Q_{\dot{\alpha}\dot{A}}$ are the supersymmetric (SUSY) charges. Here $\dot{\alpha}$ is a chiral spinor index and $A$ has its origin in the SU(2) $\mathcal{R}$-symmetry. The field content of the theory is the standard twisted $\mathcal{N} = 2$ vector multiplet:

$$A, \psi_\mu = \psi_{\alpha\dot{\alpha}}, \phi, \quad D_{\mu\nu}^+, \chi_{\mu\nu}^+ = \overline{\psi}_{\dot{\alpha}\dot{\beta}}, \quad \overline{\phi}, \eta = \overline{\psi}^{\dot{\alpha}}{}_{\dot{\alpha}} \quad [16]$$

where $(1/2) D_{\mu\nu}^+ \, \mathrm{d}x^\mu \, \mathrm{d}x^\nu$ is a self-dual 2-form derived from the auxiliary fields, etc. All fields are valued in the adjoint representation of the gauge group. After twisting, the theory is well defined on any Riemannian 4-manifold, since the fields are naturally interpreted as differential forms and the $\overline{\mathcal{Q}}$ charge is a scalar (Witten 1988).

The observables of the theory are $\overline{\mathcal{Q}}$ cohomology classes of operators, and they can be constructed from 0-form observables $\mathcal{O}^{(0)}$ using the descent procedure. This amounts to solving the equations

$$d\mathcal{O}^{(i)} = \{\overline{\mathcal{Q}}, \mathcal{O}^{(i+1)}\}, \quad i = 0, \ldots, 3 \qquad [17]$$

The integration over $i$-cycles $\gamma^{(i)}$ in $X$ of the operators $\mathcal{O}^{(i)}$ is then an observable. These descent equations have a canonical solution: the 1-form-valued operator $K_{\alpha\dot{\alpha}} = -\mathrm{i}\delta_\alpha^A Q_{\dot{\alpha}\dot{A}}/4$ verifies

$$d = \{\overline{\mathcal{Q}}, K\} \qquad [18]$$

as a consequence of the supersymmetry algebra. The operators $\mathcal{O}^{(i)} = K^i \mathcal{O}^{(0)}$ solve the descent equations [17] and are canonical representatives. When the gauge group is SU(2), the observables are obtained by the descent procedure from the operator

$$\mathcal{O} = \mathrm{tr}(\phi^2) \qquad [19]$$

The topological descendant $\mathcal{O}^{(2)}$ is given by

$$\mathcal{O}^{(2)} = -\frac{1}{2}\mathrm{tr}\left(\frac{1}{\sqrt{2}}\phi(F_{\mu\nu}^- + D_{\mu\nu}^+) - \frac{1}{4}\psi_\mu\psi_\nu\right)\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \quad [20]$$

and the resulting observable is

$$I_2(S) = \int_S \mathcal{O}^{(2)} \qquad [21]$$

$\mathcal{O}$ and $I_2(S)$ correspond to the cohomology classes in [5]. One of the main results of Witten (1988) is that the semiclassical approximation in the twisted $\mathcal{N}=2$ Yang–Mills theory is exact. The semiclassical evaluation of correlation functions of the observables above leads directly to the definition of Donaldson invariants, and the generating functional [9] can be written as a correlation function of the twisted theory. One then has

$$Z_{\mathrm{DW}}^{w_2(V)}(p,S) = \left\langle \exp\left(p\mathcal{O} + I_2(S)\right)\right\rangle \qquad [22]$$

### Results for the Donaldson–Witten Generating Function

The basic results that have emerged from the physical approach to Donaldson–Witten theory are the following.

1. The Donaldson–Witten generating functional is in general the sum of the two terms,

$$Z_{\mathrm{DW}} = Z_u + Z_{\mathrm{SW}} \qquad [23]$$

(We have omitted the Stiefel–Whitney class for convenience.) The first term, $Z_u$, is called the "$u$-plane integral." It is given by a complicated integral over $\mathbf{C}$ which can be written, in turn, as an integral over a fundamental domain of the congruence subgroup $\Gamma^0(4)$ of $\mathrm{SL}(2,\mathbf{Z})$. $Z_u$ depends only on the cohomology ring of $X$, and therefore does not contain any information beyond the one provided by classical topology. Finally, $Z_u$ vanishes if $b_2^+(X) > 1$, and it is responsible for the wall-crossing behavior of $Z_{\mathrm{DW}}$ when $b_2^+(X)=1$.

2. The second term of [23], $Z_{\mathrm{SW}}$, is called the Seiberg–Witten contribution. This contribution involves the Seiberg–Witten invariants of $X$, which are obtained by considering the moduli problem defined by the Seiberg–Witten monopole equations (Witten 1994b):

$$\begin{aligned} F^+_{\dot\alpha\dot\beta} + 4\mathrm{i}\bar{M}_{(\dot\alpha}M_{\dot\beta)} &= 0 \\ D_L^{\alpha\dot\alpha}M_{\dot\alpha} &= 0 \end{aligned} \qquad [24]$$

In these equations, $M_{\dot\alpha}$ is a section of the spinor bundle $S^+\otimes L^{1/2}$, $L$ is the determinant line bundle of a $\mathrm{Spin}_c$ structure on $X$, $F^+_{\dot\alpha\dot\beta} = \bar\sigma^{\mu\nu}_{\dot\alpha\dot\beta}F^+_{\mu\nu}$ is the self-dual part of the curvature of a U(1) connection on $L$, and $D_L$ is the Dirac operator for the bundle $S^+\otimes L^{1/2}$. The solutions of these equations modulo gauge equivalence form the moduli space $\mathcal{M}_S W$, and the Seiberg–Witten invariants are defined by integrating suitable differential forms on this moduli space. We will label $\mathrm{Spin}_c$ structures by the class $\lambda = c_1(L^{1/2}) \in H^2(X,\mathbf{Z}) + w_2(X)/2$. We say that $\lambda$ is a Seiberg–Witten basic class if the corresponding Seiberg–Witten invariants are not all zero. If $\mathcal{M}_S W$ is zero dimensional, the Seiberg–Witten invariant depends only on the $\mathrm{Spin}_c$ structure associated to $\lambda = c_1(L^{1/2})$, and is denoted by $\mathrm{SW}(\lambda)$.

3. A manifold $X$ is said to be of Seiberg–Witten simple type if all the Seiberg–Witten basic classes have a zero-dimensional moduli space. For simply connected 4-manifolds of Seiberg–Witten simple type and with $b_2^+(X) > 1$, Witten determined the Seiberg–Witten contribution and proposed the following "magic formula" for $Z_{\mathrm{DW}}$ (Witten 1994b):

$$Z_{\mathrm{DW}} = 2^{1+7\chi/4+11\sigma/4}\sum_\lambda \mathrm{e}^{2\mathrm{i}\pi(\lambda_0\cdot\lambda+\lambda_0^2)}\Big[\mathrm{e}^{2p+S^2/2}\mathrm{e}^{2(S,\lambda)} + \mathrm{i}^{\chi_h - w_2(V)^2}\mathrm{e}^{-2p-S^2/2}\mathrm{e}^{-2\mathrm{i}(S,\lambda)}\Big]\mathrm{SW}(\lambda) \qquad [25]$$

In this equation, $\chi,\sigma$ are the Euler characteristic and signature of $X$, respectively, $\chi_{\mathrm{h}} = (\chi+\sigma)/4$ is the holomorphic Euler characteristic of $X$, and $\lambda_0$ is an integer lifting of $w_2(V)$. This formula generalizes previous results by Witten (1994a) for Kähler manifolds. It also follows from this formula that the Donaldson–Witten generating function of simply connected 4-manifolds of Seiberg–Witten simple type and with $b_2^+(X) > 1$ satisfies

$$\left(\frac{\partial^2}{\partial p^2} - 4\right)Z_{\mathrm{DW}} = 0$$

which is the Donaldson simple type condition introduced by Kronheimer and Mrowka (1994).

4. Using the $u$-plane integral, one can find explicit expressions for $Z_{\mathrm{DW}}$ in more general situations (like non-simply-connected manifolds or manifolds which are not of Seiberg–Witten simple type).

In the next section we explain the formalism of the $u$-plane integral introduced by Moore and Witten (1998), which makes possible a detailed derivation of the above results.

## The $u$-Plane Integral

### Definition of the $u$-Plane Integral

The evaluation of the Donaldson–Witten generating function can be made by using the results of Seiberg and Witten (1994 a, b) on the low-energy dynamics of SU(2), $\mathcal{N}=2$ Yang–Mills theory. In their work, Seiberg and Witten determined the exact low-energy effective action of the model up to two derivatives.

From a physical point of view, there are certainly corrections to this effective action which are difficult to evaluate. Fortunately, the computation in the twisted version of the theory can be done by just considering the Seiberg–Witten effective action. This is because the correlation functions in the twisted theory are invariant under rescalings of the metric, so we can evaluate them in the limit of large distances or equivalently of very low energies. The effective action up to two derivatives is sufficient for that purpose.

One way of describing the main result of the work of Seiberg and Witten is that the moduli space of $\bar{\mathcal{Q}}$-fixed points of the twisted SO(3) $\mathcal{N}=2$ theory on a compact 4-manifold has two branches, which we refer to as the Coulomb and Seiberg–Witten branches. On the Coulomb branch the expectation value

$$u = \frac{\langle \mathrm{tr}\,\phi^2 \rangle}{16\pi^2}$$

breaks $\mathrm{SO(3)} \to \mathrm{U(1)}$ via the standard Higgs mechanism. The Coulomb branch is simply a copy of the complex $u$-plane. The low-energy effective theory on this branch is simply the abelian $\mathcal{N}=2$ gauge theory. However, at two points, $u=\pm 1$, there is a singularity where the moduli space meets a second branch, the Seiberg–Witten branch. At these points, the effective action is given by the magnetic dual of the U(1), $\mathcal{N}=2$ gauge theory coupled to a monopole matter hypermultiplet. Therefore, this branch consists of solutions to the Seiberg–Witten equations [24].

Since the manifold $X$ is compact, the partition function of the twisted theory is a sum over "all" vacuum states. Equation [23] then follows. In this equation, $Z_u$ comes from "integrating over the $u$-plane," while $Z_{\mathrm{SW}}$ corresponds to the points $u=\pm 1$. As we stated before, $Z_u$ vanishes for manifolds of $b_2^+(X) > 1$, but once this piece has been determined an argument originally presented at Moore and Witten (1998) allows one to derive the form of $Z_{\mathrm{SW}}$ as well for arbitrary $b_2^+(X) \geq 1$.

The computation of $Z_u$ is presented in detail in Moore and Witten (1998). The starting point of the computation is the untwisted low-energy theory, which has been described in detail in Seiberg and Witten (1994 a, b) and Witten (1995). It is an $\mathcal{N}=2$ theory characterized by a prepotential $\mathcal{F}$ which depends on an $\mathcal{N}=2$ vector multiplet. The effective gauge coupling is given by $\tau(a)=\mathcal{F}''(a)$, where $a$ is the scalar component of the vector multiplet. The Euclidean Lagrange density for the $u$-plane theory can be obtained simply by twisting the physical theory. It can be written as

$$\begin{aligned} &\frac{\mathrm{i}}{6\pi} K^4 \mathcal{F}(a) + \frac{1}{16\pi}\left\{\overline{\mathcal{Q}}, \overline{\mathcal{F}}''\chi(D+F_+)\right\} \\ &\quad - \frac{\mathrm{i}\sqrt{2}}{32\pi}\left\{\overline{\mathcal{Q}}, \overline{\mathcal{F}}' d * \psi\right\} - \frac{\sqrt{2}\mathrm{i}}{3\times 2^5\pi} \\ &\quad \times \left\{\mathcal{Q}, \overline{\mathcal{F}}'''\chi_{\mu\nu}\chi^{\nu\lambda}\chi_\lambda{}^{\mu}\right\}\sqrt{g}d^4x \\ &\quad + \mathcal{A}(u)\mathrm{tr}R\wedge R + \mathcal{B}(u)\mathrm{tr}R\wedge\tilde{R} \end{aligned} \qquad [26]$$

where $\mathcal{A}(u), \mathcal{B}(u)$ describe the coupling to gravity, and after integration of the corresponding differential forms we obtain terms proportional to the signature $\sigma$ and Euler characteristic $\chi$ of $X$. The data of the low-energy effective action can be encoded in an elliptic curve of the form

$$y^2 = x^3 - ux^2 + \tfrac{1}{4}x \qquad [27]$$

and $\tau$ is the modulus of the curve. The monodromy group of this curve is $\Gamma^0(4)$. All the quantities involved in the action can be obtained by integrating a certain meromorphic differential on the curve, and they can be expressed in terms of modular forms.

As for the operators, we have $u=\mathcal{O}(P)$ by definition. We may then obtain the 2-observables from the descent procedure. The result is that $I(S)\to \tilde{I}(S)=\int_S K^2 u = \int_S (\mathrm{d}u/\mathrm{d}a)(D_+ + F_-)+\cdots$. Here $D_+$ is the auxiliary field. Although one has $I(S)\to\tilde{I}(S)$ in going from the microscopic theory to the effective theory, it does not necessarily follow that $I(S_1)I(S_2)\to\tilde{I}(S_1)\tilde{I}(S_2)$ because there can be contact terms. If $S_1$ and $S_2$ intersect, then in passing to the low-energy theory we integrate out massive modes. This can induce delta function corrections to the operator product expansion modifying the mapping to the low-energy theory as follows:

$$\exp(I(S)) \to \exp\left(\tilde{I}(S) + S^2 T(u)\right) \qquad [28]$$

where $T(u)$ is the contact term. Such contact terms were observed in Witten (1994a) and studied in detail in Losev *et al.* (1998). It can be shown that

$$T(u) = -\frac{1}{24}E_2(\tau)\left(\frac{\mathrm{d}u}{\mathrm{d}a}\right)^2 + \frac{1}{3}u \qquad [29]$$

where $E_2(\tau)$ is Eisenstein's series and $\mathrm{d}a/\mathrm{d}u$ is one of the periods of the elliptic curve [27].

The final result of Moore and Witten is the following expression:

$$Z_u(p,S) = \int_C \frac{\mathrm{d}u\,\mathrm{d}\bar{u}}{y^{1/2}}\mu(\tau)\mathrm{e}^{2pu+S^2\hat{T}(u)}\Psi \qquad [30]$$

Here,

$$\mu(\tau) = \frac{\mathrm{d}\bar{\tau}}{\mathrm{d}\bar{u}}\left(\frac{\mathrm{d}a}{\mathrm{d}u}\right)^{1-(1/2)\chi}\Delta^{\sigma/8}$$
$$\hat{T}(u) = T(u) + \frac{(\mathrm{d}u/\mathrm{d}a)^2}{8\pi y} \qquad [31]$$

where $y = \mathrm{Im}\,\tau$ and $\Delta$ is the discriminant of the curve [27]. The quantity $\Psi$ is essentially a Narain–Siegel theta function associated to the lattice $H^2(X, \boldsymbol{Z})$. Notice that this lattice is Lorentzian and has signature $(1, (-1)^{b_2^-(X)})$ (since $b_2^+(X) = 1$). The self-dual projection of a 2-form $\lambda$ can be done with the period point $\omega$ as $\lambda_+ = (\lambda, \omega)\omega$. The lattice is shifted by half the second Stiefel–Whitney class of the bundle, $w_2(V)$, that is,

$$\Gamma = H^2(X, \boldsymbol{Z}) + \tfrac{1}{2} w_2(V)$$

and

$$\Psi = \exp\left[-\frac{1}{8\pi y}\left(\frac{\mathrm{d}u}{\mathrm{d}a}\right)^2 S_-^2\right] \mathrm{e}^{2\pi \mathrm{i}\lambda_0^2} \sum_{\lambda\in\Gamma} (-1)^{(\lambda-\lambda_0)\cdot w_2(X)}$$
$$\times \left[(\lambda, \omega) + \frac{\mathrm{i}}{4\pi y}\frac{\mathrm{d}u}{\mathrm{d}a}(S, \omega)\right]$$
$$\times \exp\left[-\mathrm{i}\pi\bar{\tau}(\lambda_+)^2 - \mathrm{i}\pi\tau(\lambda_-)^2 - \mathrm{i}\frac{\mathrm{d}u}{\mathrm{d}a}(S, \lambda_-)\right] \qquad [32]$$

Here, $w_2(X)$ is the second Stiefel–Whitney class of $X$, and $\lambda_0$ is a choice of lifting of $w_2(V)$ to $H^2(X, \boldsymbol{Z})$. This expression can be extended to the non-simply-connected case (see Mariño and Moore (1999) and Moore and Witten (1998)). The study of the $u$-plane integral leads to a systematic derivation of many important results in Donaldson–Witten theory. We will discuss in detail two such applications, Göttsche's wall-crossing formula and Witten's "magic formula."

### Wall-Crossing Formula

As shown by Moore and Witten, the $u$-plane integral is well defined and does not depend on the period point (hence on the metric on $X$) except for discontinuous behavior at walls. There are two kinds of walls, associated, respectively, to the singularities at $u = \infty$ (the semiclassical region of the underlying Yang–Mills theory) and at $u = \pm 1$, given by

$$u = \infty\colon\ \lambda_+ = 0, \lambda \in H^2(X, \boldsymbol{Z}) + \tfrac{1}{2} w_2(V)$$
$$u = \pm 1\colon\ \lambda_+ = 0, \lambda \in H^2(X, \boldsymbol{Z}) + \tfrac{1}{2} w_2(X) \qquad [33]$$

The first type of walls is precisely the one that appears in Donaldson theory on manifolds of $b_2^+(X) = 1$. The discontinuity of the $u$-plane integral at these walls can be easily computed from eqn [33]:

$$\mathrm{WC}_{\zeta=2\lambda}(p, S)$$
$$= -\frac{\mathrm{i}}{2}(-1)^{(\lambda-\lambda_0, w_2(X))}\mathrm{e}^{2\pi\mathrm{i}\lambda_0^2}\Big[q^{-\lambda^2/2} h_\infty(\tau)^{-2}\vartheta_4^\sigma f_\infty^{-1}$$
$$\times \exp\{2pu_\infty + S^2 T_\infty - \mathrm{i}(\lambda, S)/h_\infty\}\Big]_{q^0} \qquad [34]$$

This expression involves the modular forms $h_\infty, f_{2\infty}, u_\infty$, and $T_\infty$ (the subscript $\infty$ refers to the fact that they are computed at the "electric" frame which is appropriate for the Seiberg–Witten curve at $u \to \infty$). They can be written in terms of Jacobi theta functions $\vartheta_i(q)$, with $q = \mathrm{e}^{2\pi\mathrm{i}\tau}$, and their explicit expression is

$$h_\infty(q) = \tfrac{1}{2}\vartheta_2(q)\vartheta_3(q)$$
$$f_\infty(q) = \frac{\vartheta_2(q)\vartheta_3(q)}{2\vartheta_4^8(q)}$$
$$u_\infty(q) = \frac{\vartheta_2^4(q) + \vartheta_3^4(q)}{2(\vartheta_2(q)\vartheta_3(q))^2} \qquad [35]$$
$$T_\infty(q) = -\frac{1}{24}\frac{E_2(q)}{h_\infty^2(q)} + \frac{1}{3}u_\infty(q)$$

The subindex $q^0$ means that in the expansion in $q$ of the modular forms, we pick the constant term. The formula [34] agrees with the formula of Göttsche (1996) for the wall crossing of the Donaldson–Witten generating functional.

### The Seiberg–Witten Contribution and Witten's Magic Formula

At $u = \pm 1, Z_u$ jumps at the second type of walls [33], which are called Seiberg–Witten (SW) walls. In fact, these walls are labeled by classes $\lambda \in H^2(X; \boldsymbol{Z}) + (1/2)w_2(X)$, which correspond to Spin$_c$ structures on $X$. At these walls, the Seiberg–Witten invariants have wall-crossing behavior. Since the Donaldson polynomials do not jump at SW walls, it must happen that the change of $Z_u$ at $u = \pm 1$ is canceled by the change of $Z_{\mathrm{SW}}$. As shown by Moore and Witten, this actually allows one to obtain a precise expression for $Z_{\mathrm{SW}}$ for general 4-manifolds of $b_2^+(X) \geq 1$.

On general grounds, $Z_{\mathrm{SW}}$ is given by the sum of the generating functionals at $u = \pm 1$. These involve a magnetic $\mathrm{U}(1), \mathcal{N} = 2$ vector multiplet coupled to a hypermultiplet (the monopole field). The twisted

Lagrangian for such a system involves the magnetic prepotential $\widetilde{\mathcal{F}}_D(a_D)$, and it can be written as

$$\{\bar{\mathcal{Q}}, W\} + \frac{\mathrm{i}}{16\pi}\tilde{\tau}_D F\wedge F + p(u)\mathrm{tr}R\wedge *R + \ell(u)\mathrm{tr}R\wedge R - \frac{\mathrm{i}\sqrt{2}}{32\pi}\frac{\mathrm{d}\tilde{\tau}_D}{\mathrm{d}a_D}(\psi\wedge\psi)\wedge F + \frac{\mathrm{i}}{3\times 2^7\pi}\frac{\mathrm{d}^2\tilde{\tau}_D}{\mathrm{d}a_D^2}\psi\wedge\psi\wedge\psi\wedge\psi \quad [36]$$

where $\tilde{\tau}_D = \widetilde{\mathcal{F}}_D''(a_D)$. Using the cancellation of wall crossings, one can actually compute the functions $\widetilde{\mathcal{F}}_D(a_D), p(u), \ell(u)$ and determine the precise form of the Seiberg–Witten contributions. One finds that a $\mathrm{Spin}_c$ structure $\lambda$ at $u=1$ gives the following contribution to the Donaldson–Witten generating functional:

$$Z_{\mathrm{SW}}^{u=1,\lambda} = \frac{\mathrm{SW}(\lambda)}{16}\mathrm{e}^{2\mathrm{i}\pi(\lambda_0^2-\lambda_0\cdot\lambda)} \times\left[q_D^{-\lambda^2/2}\frac{\vartheta_2^{8+\sigma}}{a_D h_M}\left(-2\mathrm{i}\frac{a_D}{h_M^2}\right)^{\chi_{\mathrm{h}}} \times\exp\left(2pu_M + \mathrm{i}(\lambda,S)/h_M + S^2 T_M\right)\right]_{q_D^0} \quad [37]$$

Here, $a_D, h_M, u_M$, and $T_M$ are modular forms that can be expressed as well in terms of Jacobi theta functions $\vartheta_i(q_D)$, where $q_D = \exp(2\pi\mathrm{i}\tau_D)$. The subscript $M$ refers to the monopole point, and they are related by an $S$-transformation to the quantities obtained in the "electric" frame at $u\to\infty$. Their explicit expression is

$$\begin{aligned} a_D(q_D) &= -\frac{\mathrm{i}}{6}\frac{2E_2(q_D)-\vartheta_3^4(q_D)-\vartheta_4^4(q_D)}{\vartheta_3(q_D)\vartheta_4(q_D)} \\ h_M(q_D) &= \frac{1}{2\mathrm{i}}\vartheta_3(q_D)\vartheta_4(q_D) \\ u_M(q_D) &= \frac{1}{2}\frac{\vartheta_3^4(q_D)+\vartheta_4^4(q_D)}{(\vartheta_3(q_D)\vartheta_4(q_D))^2} \\ T_M(q) &= -\frac{1}{24}\frac{E_2(q_D)}{h_M^2(q_D)} + \frac{1}{3}u_M(q_D) \end{aligned} \quad [38]$$

The contribution at $u=-1$ is related to the contribution at $u=1$ by a $u\to -u$ symmetry:

$$Z_{u=-1}(p,S) = \mathrm{e}^{-2\pi\mathrm{i}\lambda_0^2}\mathrm{i}^{(\chi+\sigma)/4} Z_{u=1}(-p,-\mathrm{i}S) \quad [39]$$

If the manifold has $b_2^+(X) > 1$ and is of Seiberg–Witten simple type, [37] reduces to

$$(-1)^{\chi_{\mathrm{h}}} 2^{1+7\chi/4+11\sigma/4}\mathrm{e}^{2p+S^2/2}\mathrm{e}^{-2(S,\lambda)} \times \mathrm{e}^{2\mathrm{i}\pi(\lambda_0^2-\lambda_0\cdot\lambda)}\mathrm{SW}(\lambda) \quad [40]$$

This leads to Witten's "magic formula" [25] which expresses the Donaldson invariants in terms of Seiberg–Witten invariants.

### Other Applications of the $u$-Plane Integral

The $u$-plane integral makes possible to derive other results on the Donaldson–Witten generating functional.

*The blow-up formula*. This relates the function $Z_{\mathrm{DW}}$ on $X$ to $Z_{\mathrm{DW}}$ on the blown-up manifold $\widehat{X}$. The $u$-plane integral leads directly to the general blow-up formula of Fintushel and Stern (1996).

*Direct evaluations*. The $u$-plane integral can be evaluated directly in many cases, and this leads to explicit formulas for the Donaldson–Witten generating functional of certain 4-manifolds with $b_2^+(X)=1$, on certain chambers, and in terms of modular forms. For example, there are explicit formulas for the Donaldson–Witten generating functional of product ruled surfaces of the form $S^2\times\Sigma_g$ in the limiting chambers in which $S^2$ or $\Sigma_g$ are very small (Moore and Witten 1998, Mariño and Moore 1999). Moore and Witten (1998) have also derived an explicit formula for the Donaldson invariants of $\boldsymbol{CP}^2$ in terms of Hurwitz class numbers.

## Extensions of Donaldson–Witten Theory

Donaldson–Witten theory is a twisted version of SU(2), $\mathcal{N}=2$ Yang–Mills theory. The twisting of more general $\mathcal{N}=2$ gauge theories, involving other gauge groups and/or matter content, leads to other topological field theories that give interesting generalizations of Donaldson–Witten theory. We now briefly list some of these extensions and their most important properties.

*Higher-rank theories*. The extension of Donaldson–Witten to other gauge groups has been studied in detail in Mariño and Moore (1998b) and Losev *et al.* (1998). One can study the higher-rank generalization of the $u$-plane integral, and as shown in Mariño and Morre (1998b), this leads to a fairly explicit formula for the Donaldson–Witten generating function in the SU($N$) case, for manifolds with $b_2^+ > 1$ and of Seiberg–Witten simple type. Mathematically, higher-rank generalizations of Donaldson theory turn out to be much more complicated, but they can be studied. In particular, higher-rank generalizations of the Donaldson invariants can be defined and computed (Kronheimer 2004), and the results so far agree with the predictions of Mariño and Moore (1998b). Unfortunately it seems that these higher-rank generalizations do not contain new topological information, besides the one encoded in the Seiberg–Witten invariants.

*Theories with matter*. Twisted SU(2), $\mathcal{N}=2$ theories with hypermultiplets lead to generalizations of Donaldson–Witten theory involving nonabelian

monopole equations (see Mariño (1997) and Labastida and Mariño (2005) for a review of these models and some of their properties). The $u$-plane integral leads to explicit formulas for the generating functionals of these theories, which for manifolds of $b_2^+ > 1$ can be written in terms of Seiberg–Witten invariants. Again, no new topological information seems to be encoded in these theories. One can however exploit new physical phenomena arising in the theories with hypermultiplets (in particular, the presence of superconformal points) to obtain new information about the Seiberg–Witten invariants (see Mariño *et al.* (1999) for these developments).

*Vafa–Witten theory*. The so-called Vafa–Witten theory is a close cousin of Donaldson–Witten theory, and was introduced by Vafa and Witten (1994) as a topological twist of $\mathcal{N}=4$ Yang–Mills theory. In some cases, the partition function of this theory counts the Euler characteristic of the moduli space of instantons on the 4-manifold $X$. For a review of some properties of this theory, see Lozano (1999).

# Duality in Topological Quantum Field Theory

**C Lozano**, INTA, Madrid, Spain
**J M F Labastida**, CSIC, Madrid, Spain

## Introduction

There have been many exciting interactions between physics and mathematics in the past few decades. A prominent role in these interactions has been played by certain field theories, known as topological quantum field theories (TQFTs). These are quantum field theories whose correlation functions are metric independent and, in fact, compute certain mathematical invariants (Birmingham *et al.* 1991, Cordes *et al.* 1996, Labastida and Lozano 1998).

Well-known examples of TQFTs are, in two dimensions, the topological sigma models (Witten 1988a), which are related to Gromov–Witten invariants and enumerative geometry; in three dimensions, Chern–Simons theory (Witten 1989), which is related to knot and link invariants; and in four dimensions, topological Yang–Mills theory (or Donaldson–Witten theory) (Witten 1988b), which is related to the Donaldson invariants. The two- and four-dimensional theories above are examples of cohomological (also Witten-type) TQFTs. As such, they are related to an underlying supersymmetric quantum field theory (the $\mathcal{N}=2$ nonlinear sigma model, and the $\mathcal{N}=2$ supersymmetric Yang–Mills theory, respectively) and there is no difference between the topological and the standard version on flat space. However, when one considers curved spaces, the topological version differs from the supersymmetric theory on flat space in that some of the fields have modified Lorentz transformation properties (spins). This unconventional spin assignment is also known as twisting, and it comes about basically to preserve supersymmetry on curved space. In fact, the twisting gives rise to at least one nilpotent scalar supercharge $\mathcal{Q}$, which is a certain linear combination of the original (spinor) supersymmetry generators.

In these theories the energy momentum tensor is $\mathcal{Q}$-exact, that is,

$$T_{\mu\nu} = \{\mathcal{Q}, \Lambda_{\mu\nu}\}$$

for some $\Lambda_{\mu\nu}$, which (barring potential anomalies) leads to the statement that the correlation functions of operators in the cohomology of $\mathcal{Q}$ are all metric independent. Furthermore, the corresponding path integrals are localized to field configurations that are annihilated by $\mathcal{Q}$, and this typically leads to some moduli problem related to the computation of certain mathematical invariants.

On the other hand, in Chern–Simons theory, as a representative of the so-called Schwarz-type topological theories, the topological character is manifest: one starts with an action which is explicitly independent of the metric on the 3-manifold, and thus correlation functions of metric-independent operators are topological invariants as long as quantization does not introduce any undesired metric dependence.

Even though the primary motivation for introducing TQFTs may be to shed light onto awkward mathematical problems, they have proved to be a valuable tool to gain insight into many questions of interest in physics as well. One such question where TQFTs can (and in fact do) play a role is duality. In what follows, an overview of the manifestations of duality is provided in the context of TQFTs.

## Duality

The notion of duality is at the heart of some of the most striking recent breakthroughs in physics and mathematics. In broad terms, a duality (in physics) is an equivalence between different (and often complementary) descriptions of the same physical system. The prototypical example is electric–magnetic (abelian) duality. Other, more sophisticated, examples are the various string-theory dualities, such as $T$-duality (and its more specialized realization, mirror symmetry) and strong/weak coupling $S$-duality, as well as field theory dualities such as Montonen–Olive duality and Seiberg–Witten effective duality.

Also, the original 't Hooft conjecture, stating that SU($N$) gauge theories are equivalent (or dual), at large $N$, to string theories, has recently been revived by Maldacena (1998) by explicitly identifying the string-theory duals of certain (supersymmetric) gauge theories.

One could wonder whether similar duality symmetries work for TQFTs as well. As noted in the following, this is indeed the case.

In two dimensions, topological sigma models come under two different versions, known as types A and B, respectively, which correspond to the two different ways in which $\mathcal{N}=2$ supersymmetry can be twisted in two dimensions. Computations in each model localize on different moduli spaces and, for a given target manifold, give different results, but it turns out that if one considers mirror pairs of Calabi–Yau manifolds,

computations in one manifold with the A-model are equivalent to computations in the mirror manifold with the B-model.

Also, in three dimensions, a program has been initiated to explore the duality between large $N$ Chern–Simons gauge theory and topological strings, thereby establishing a link between enumerative geometry and knot and link invariants (Gopakumar and Vafa 1998).

Perhaps the most impressive consequences of the interplay between duality and TQFTs have come out in four dimensions, on which we will focus in what follows.

## Duality in Twisted $\mathcal{N}=2$ Theories

As mentioned above, topological Yang–Mills theory (or Donaldson–Witten theory) can be constructed by twisting the pure $\mathcal{N}=2$ supersymmetric Yang–Mills theory with gauge group SU(2). This theory contains a gauge field $A$, a pair of chiral spinors $\lambda_1$, $\lambda_2$, and a complex scalar field $B$. The twisted theory contains a gauge field $A$, bosonic scalars $\lambda$, $\phi$, a Grassman-odd scalar $\eta$, a Grassman-odd vector $\psi$, and a Grassman-odd self-dual 2-form $\chi$.

On a 4-manifold $X$, and for gauge group $G$, the twisted action has the form

$$\begin{aligned}\mathcal{S} = \int_X \mathrm{d}^4x\sqrt{g}\,\mathrm{tr}\Big(& F^{+^2} - \mathrm{i}\chi^{\mu\nu}D_\mu\psi_\nu + \mathrm{i}\eta D_\mu\psi^\mu \\ &+\frac{1}{4}\phi\{\chi_{\mu\nu},\chi^{\mu\nu}\} + \frac{\mathrm{i}}{4}\lambda\{\psi_\mu,\psi^\mu\} - \lambda D_\mu D^\mu\phi \\ &+\frac{\mathrm{i}}{2}\phi\{\eta,\eta\} + \frac{1}{8}[\lambda,\phi]^2\Big)\end{aligned} \qquad [1]$$

where $F^+$ is the self-dual part of the Yang–Mills field strength $F$. The action [1] is invariant under the transformations generated by the scalar supercharge $\mathcal{Q}$:

$$\begin{aligned}\{\mathcal{Q},A_\mu\} &= \psi_\mu, & \{\mathcal{Q},\chi_{\mu\nu}\} &= F^+_{\mu\nu} \\ \{\mathcal{Q},\psi\} &= \mathrm{d}_A\phi, & \{\mathcal{Q},\eta\} &= \mathrm{i}[\lambda,\phi] \\ \{\mathcal{Q},\phi\} &= 0, & \{\mathcal{Q},\lambda\} &= \eta\end{aligned} \qquad [2]$$

In these transformations, $\mathcal{Q}^2$ is a gauge transformation with gauge parameter $\phi$, modulo field equations. Observables are, therefore, related to the $G$-equivariant cohomology of $\mathcal{Q}$ (i.e., the cohomology of $\mathcal{Q}$ restricted to gauge invariant operators). Auxiliary fields can be introduced so that the action [1] is $\mathcal{Q}$-exact, that is,

$$\mathcal{S} = \{\mathcal{Q},\Lambda\} \qquad [3]$$

for $\Lambda$ a certain functional of the fields of the theory which comes under the name of gauge fermion, a BRST-inspired terminology which reflects the formal resemblance of topological cohomological field theories with some aspects of the BRST approach to the quantization of gauge theories. Before constructing the topological observables of the theory, we begin by pointing out that for each independent Casimir of the gauge group $G$ it is possible to construct an operator $W_0$, from which operators $W_i$ can be defined recursively through the descent equations $\{\mathcal{Q},W_i\}=\mathrm{d}W_{i-1}$. For example, for the quadratic Casimir,

$$W_0 = \frac{1}{8\pi^2}\mathrm{tr}(\phi^2) \qquad [4]$$

which generates the following family of operators:

$$\begin{aligned}W_1 &= \frac{1}{4\pi^2}\mathrm{tr}(\phi\psi) \\ W_2 &= \frac{1}{4\pi^2}\mathrm{tr}\left(\frac{1}{2}\psi\wedge\psi + \phi\wedge F\right) \\ W_3 &= \frac{1}{4\pi^2}\mathrm{tr}(\psi\wedge F)\end{aligned} \qquad [5]$$

Using these one defines the following observables:

$$\mathcal{O}^{(k)} = \int_{\gamma_k} W_k \qquad [6]$$

where $\gamma_k \in H_k(X)$ is a $k$-cycle on the 4-manifold $X$. The descent equations imply that they are $\mathcal{Q}$-closed and depend only on the homology class of $\gamma_k$.

Topological invariants are constructed by taking vacuum expectation values of products of the operators $\mathcal{O}^{(k)}$:

$$\begin{aligned}&\left\langle \mathcal{O}^{(k_1)}\mathcal{O}^{(k_2)}\cdots\mathcal{O}^{(k_p)}\right\rangle \\ &\quad = \int \mathcal{O}^{(k_1)}\mathcal{O}^{(k_2)}\cdots\mathcal{O}^{(k_p)}\,\mathrm{e}^{-\mathcal{S}/e^2}\end{aligned} \qquad [7]$$

where the integration has to be understood on the space of field configurations modulo gauge transformations, and $e$ is a coupling constant. Standard arguments show that due to the $\mathcal{Q}$-exactness of the action $\mathcal{S}$, the quantities obtained in [7] are independent of $e$. This implies that the observables of the theory can be obtained either in the weak-coupling limit $e\to 0$ (also short-distance or ultraviolet regime, since the $\mathcal{N}=2$ theory is asymptotically free), where perturbative methods apply, or in the strong-coupling (also long-distance or infrared) limit $e\to\infty$, where one is forced to consider a nonperturbative approach.

In the weak-coupling limit one proves that the correlation functions [7] descend to polynomials in the product cohomology of the moduli space of anti-self-dual (ASD) instantons $H_{k_1}(\mathcal{M}_{\mathrm{ASD}})\times H_{k_2}(\mathcal{M}_{\mathrm{ASD}})\times\cdots\times H_{k_p}(\mathcal{M}_{\mathrm{ASD}})$, which are precisely

the Donaldson polynomial invariants of $X$. However, the weak- coupling analysis does not add any new ingredient to the problem of the actual computation of the invariants. The difficulties that one has to face in the field theory representation are similar to those in ordinary Donaldson theory.

Nevertheless, the field theory connection is very important since in this theory the strong- and weak-coupling limits are exact, and therefore the door is open to find a strong-coupling description which could lead to a new, simpler representation for the Donaldson invariants.

This alternative strategy was pursued by Witten (1994a), who found the strong-coupling realization of the Donaldson–Witten theory after using the results on the strong-coupling behavior of $\mathcal{N}=2$ supersymmetric gauge theories which he and Seiberg (Seiberg and Witten 1994a–c) had discovered. The key ingredient in Witten's derivation was to assume that the strong-coupling limit of Donaldson–Witten theory is equivalent to the "sum" over the twisted effective low-energy descriptions of the corresponding $\mathcal{N}=2$ physical theory. This "sum" is not entirely a sum, as in general it has a part which contains a continuous integral. The "sum" is now known as integration over the $u$-plane after the work of Moore and Witten (1998). Witten's (1994a) assumption can be simply stated as saying that the weak-/strong-coupling limit and the twist commute. In other words, to study the strong-coupling limit of the topological theory, one first untwists, then works out the strong-coupling limit of the physical theory and, finally, one twists back. From such a viewpoint, the twisted effective (strong-coupling) theory can be regarded as a TQFT dual to the original one. In addition, one could ask for the dual moduli problem associated to this dual TQFT. It turns out that in many interesting situations ($b_2^+(X)>1$) the dual moduli space is an abelian system corresponding to the Seiberg–Witten or monopole equations (Witten 1994a). The topological invariants associated with this new moduli space are the celebrated Seiberg–Witten invariants.

Generalizations of Donaldson–Witten theory, with either different gauge groups and/or additional matter content (such as, e.g., twisted $\mathcal{N}=2$ Yang–Mills multiplets coupled to twisted $\mathcal{N}=2$ matter multiplets) are possible, and some of the possibilities have in fact been explored (see Moore and Witten (1998) and references therein). The main conclusion that emerges from these analyses is that, in all known cases, the relevant topological information is captured by the Seiberg–Witten invariants, irrespectively of the gauge group and matter content of the theory under consideration. These cases are not reviewed here, but rather the attention is turned to the twisted theories which emerge from $\mathcal{N}=4$ supersymmetric gauge theories.

## Duality in Twisted $\mathcal{N}=4$ Theories

Unlike the $\mathcal{N}=2$ supersymmetric case, the $\mathcal{N}=4$ supersymmetric Yang–Mills theory in four dimensions is unique once the gauge group $G$ is fixed. The microscopic theory contains a gauge or gluon field, four chiral spinors (the gluinos) and six real scalars. All these fields are massless and take values in the adjoint representation of the gauge group. The theory is finite and conformally invariant, and is conjectured to have a duality symmetry exchanging strong and weak coupling and exchanging electric and magnetic fields, which extends to a full SL(2, $\mathbb{Z}$) symmetry acting on the microscopic complexified coupling (Montonen and Olive 1977)

$$\tau=\frac{\theta}{2\pi}+\frac{4\pi \mathrm{i}}{e^2} \tag{8}$$

As in the $\mathcal{N}=2$ case, the $\mathcal{N}=4$ theory can be twisted to obtain a topological model, only that, in this case, the topological twist can be performed in three inequivalent ways, giving rise to three different TQFTs (Vafa and Witten 1994). A natural question to answer is whether the duality properties of the $\mathcal{N}=4$ theory are shared by its twisted counterparts and, if so, whether one can take advantage of the calculability of topological theories to shed some light on the behavior and properties of duality.

The answer is affirmative, but it is instructive to clarify a few points. First, as mentioned above, the topological observables in twisted $\mathcal{N}=2$ theories are independent of the coupling constant $e$, so the question arises as to how the twisted $\mathcal{N}=4$ theories come to depend on the coupling constant. As it turns out, twisted $\mathcal{N}=2$ supersymmetric gauge theories have an off-shell formulation such that the TQFT action can be expressed as a $\mathcal{Q}$-exact expression, where $\mathcal{Q}$ is the generator of the topological symmetry. Actually, this is true only up to a topological $\theta$-term $\int_X \mathrm{tr}(F\wedge F)$,

$$\begin{aligned}\mathcal{S}=&\frac{1}{2e^2}\int_X \sqrt{g}\,\mathrm{d}^4x\{\mathcal{Q},\Lambda\}\\&-2\pi \mathrm{i}\tau\frac{1}{16\pi^2}\int_X \mathrm{tr}(F\wedge F)\end{aligned} \tag{9}$$

for some $\Lambda$. However, the $\mathcal{N}=2$ supersymmetric gauge theories possess a global U(1) chiral symmetry which is generically anomalous, so one can actually

get rid of the $\theta$-term with a chiral rotation. As a result of this, the observables in the topological theory are insensitive to $\theta$-terms (and hence to $\tau$ and $e$) up to a rescaling.

On the other hand, in $\mathcal{N}=4$ supersymmetric gauge theories $\theta$-terms are observable. There is no chiral anomaly and these terms cannot be shifted away as in the $\mathcal{N}=2$ case. This means that in the twisted theories one might have a dependence on the coupling constant $\tau$, and that – up to anomalies – this dependence should be holomorphic (resp. antiholomorphic if one reverses the orientation of the 4-manifold). In fact, on general grounds, one would expect for the partition functions of the twisted theories on a 4-manifold $X$ and for gauge group $G$ to take the generic form

$$Z_X(G) = q^{-c(X,G)} \sum_k q^k \chi(\mathcal{M}_k) \qquad [10]$$

where $q = e^{2\pi i \tau}$, $c$ is a universal constant (depending on $X$ and $G$), $k = (1/16\pi^2)\int_X \mathrm{tr}(F \wedge F)$ is the instanton number, and $\chi(\mathcal{M}_k)$ encodes the topological information corresponding to a sector of the moduli space of the theory with instanton number $k$.

Now we can be more precise as to how we expect to see the Montonen–Olive duality in the twisted $\mathcal{N}=4$ theories. First, under $\tau \to -1/\tau$ the gauge group $G$ gets exchanged with its dual group $\hat{G}$. Correspondingly, the partition functions should behave as modular forms

$$Z_G(-1/\tau) = \pm\kappa(X, G)\tau^w Z_{\hat{G}}(\tau) \qquad [11]$$

where $\kappa$ is a constant (depending on $X$ and $G$), and the modular weight $w$ should depend on $X$ in such a way that it vanishes on flat space.

In addition to this, in the $\mathcal{N}=4$ theory all the fields take values in the adjoint representation of $G$. Hence, if $H^2(X, \pi_1(G)) \neq 0$, it is possible to consider nontrivial $G$/Center($G$) gauge configurations with discrete magnetic 't Hooft flux through the 2-cycles of $X$. In fact, $G$/Center($G$) bundles on $X$ are classified by the instanton number and a characteristic class $v \in H^2(X, \pi_1(G))$. For example, if $G = \mathrm{SU}(2)$, we have $\hat{G} = \mathrm{SU}(2)/\mathbb{Z}_2 = \mathrm{SO}(3)$ and $v$ is the second Stiefel–Whitney class $w_2(E)$ of the gauge bundle $E$. This Stiefel–Whitney class can be represented in de Rham cohomology by a class in $H^2(X, \mathbb{Z})$ defined modulo 2, that is, $w_2(E)$ and $w_2(E) + 2\omega$, with $\omega \in H^2(X, \mathbb{Z})$, represent the same 't Hooft flux, so if $w_2(E) = 2\lambda$, for some $\lambda \in H^2(X, \mathbb{Z})$, then the gauge configuration is trivial in SO(3) (it has no 't Hooft flux).

Similarly, for $G = \mathrm{SU}(N)$ (for which $\hat{G} = \mathrm{SU}(N)/\mathbb{Z}_N$), one can fix fluxes in $H^2(X, \mathbb{Z}_N)$ (the corresponding Stiefel–Whitney class is defined modulo $N$). One has, therefore, a family of partition functions $Z_v(\tau)$, one for each magnetic flux $v$. The SU($N$) partition function is obtained by considering the zero flux partition function (up to a constant factor), while the (dual) $\mathrm{SU}(N)/\mathbb{Z}_N$ partition function is obtained by summing over all $v$, and both are to be exchanged under $\tau \to -1/\tau$. The action of SL(2, $\mathbb{Z}$) on the $Z_v$ should be compatible with this exchange, and thus the $\tau \to -1/\tau$ operation mixes the $Z_v$ by a discrete Fourier transform which, for $G = \mathrm{SU}(N)$ reads

$$Z_v(-1/\tau) = \pm\kappa(X, G)\tau^w \sum_u e^{2\pi i u \cdot v/N} Z_u(\tau) \qquad [12]$$

We are now in a position to examine the (three) twisted theories in some detail. For further details and references, the reader is referred to Lozano (1999).

The first twisted theory considered here possesses only one scalar supercharge (and hence comes under the name of "half-twisted theory"). It is a nonabelian generalization of the Seiberg–Witten abelian monopole theory, but with the monopole multiplets taking values in the adjoint representation of the gauge group. The theory can be perturbed by giving masses to the monopole multiplets while still retaining its topological character. The resulting theory is the twisted version of the mass-deformed $\mathcal{N}=4$ theory, which preserves $\mathcal{N}=2$ supersymmetry and whose low-energy effective description is known. This connection with $\mathcal{N}=2$ theories, and its topological character, makes it possible to go to the long-distance limit and compute in terms of the twisted version of the low-energy effective description of the supersymmetric theory. Below, we review how the $u$-plane approach works for gauge group SU(2).

The twisted theory for gauge group SU(2) has a U(1) global symmetry (the ghost number) which has an anomaly $-3(2\chi + 3\sigma)/4$ on gravitational backgrounds (i.e., on curved manifolds). Nontrivial topological invariants are thus obtained by considering the vacuum expectation value of products of observables with ghost numbers adding up to $-3(2\chi + 3\sigma)/4$. The relevant observables for this theory and gauge group SU(2) or SO(3) are precisely the same as in the Donaldson–Witten theory (eqns [4] and [5]). In addition to this, it is possible to enrich the theory by including sectors with nontrivial nonabelian electric and magnetic 't Hooft fluxes which, as pointed out above, should behave under SL(2, $\mathbb{Z}$) duality in a well-defined fashion.

The generating function for these correlation functions is given as an integration over the moduli space of vacua of the physical theory (the $u$-plane), which, for generic values of the mass parameter, forms a one-dimensional complex compact manifold (described by a complex variable customarily denoted by $u$, hence the name), which parametrizes a family of elliptic curves that encodes all the relevant information about the low-energy effective description of the theory. At a generic point in the moduli space of vacua, the only contribution to the topological correlation functions comes from a twisted $\mathcal{N}=2$ abelian vector multiplet. Additional contributions come from points in the moduli space where the low-energy effective description is singular (i.e., where the associated elliptic curve degenerates).

Therefore, the total contribution to the generating function thus consists of an integration over the moduli space with the singularities removed – which is nonvanishing for $b_2^+(X)=1$ (Moore and Witten 1998) only – plus a discrete sum over the contributions of the twisted effective theories at each of the three singularities of the low-energy effective description (Seiberg and Witten 1994a, b, c). The effective theory at a given singularity contains, together with the appropriate dual photon multiplet, one charged hypermultiplet, which corresponds to the state becoming massless at the singularity. The complete effective action for these massless states also contains certain measure factors and contact terms among the observables, which reproduce the effect of the massive states that have been integrated out as well as incorporate the coupling to gravity (i.e., explicit nonminimal couplings to the metric of the 4-manifold). How to determine these *a priori* unknown functions was explained in Moore and Witten (1998). The idea is as follows. At points on the $u$-plane where the (imaginary part of the) effective coupling diverges, the integral is discontinuous at anti-self-dual abelian gauge configurations. This is commonly referred to as "wall crossing." Wall crossing can take place at the singularities of the moduli space – the appropriate local effective coupling $\tau_{\text{eff}}$ diverges there – and, in the case of the asymptotically free theories, at the point at infinity – the effective electric coupling diverges owing to asymptotic freedom.

On the other hand, the final expression for the invariants can exhibit a wall-crossing behavior at most at $u\to\infty$, so the contribution to wall crossing from the integral at the singularities at finite values of $u$ must cancel against the contributions coming from the effective theories there, which also display wall-crossing discontinuities. Imposing this cancelation fixes almost completely the unknown functions in the contributions to the topological correlation functions from the singularities. The final result for the contributions from the singularities (which give the complete answer for the correlation functions when $b_2^+(X)>1$) is written explicitly and completely in terms of the fundamental periods $\mathrm{d}a/\mathrm{d}u$ (written in the appropriate local variables) and the discriminant of the elliptic curve comprising the Seiberg–Witten solution for the physical theory. For simply connected spin 4-manifolds of simple type the generating function is given by

$$
\begin{aligned}
\langle \mathrm{e}^{p\mathcal{O}+I(S)}\rangle_v &= 2^{(\nu/2+(2\chi+3\sigma)/8)} m^{-(3\nu+7\sigma)/8}(\eta(\tau))^{-12\nu} \\
&\times\Bigg\{(\kappa_1)^{\nu}\left(\frac{\mathrm{d}a}{\mathrm{d}u}\right)_1^{-(\nu+\sigma/4)} \mathrm{e}^{2pu_1+S^2T_1} \\
&\times\sum_x \delta_{[x/2],v}\, n_x\, \mathrm{e}^{(\mathrm{i}/2)(\mathrm{d}u/\mathrm{d}a)_1 x\cdot S} \\
&+2^{-b_2/2}(-1)^{\sigma/8}(\kappa_2)^{\nu}\left(\frac{\mathrm{d}a}{\mathrm{d}u}\right)_2^{-(\nu+\sigma/4)} \\
&\times \mathrm{e}^{2pu_2+S^2T_2}\sum_x(-1)^{v\cdot x/2} n_x\, \mathrm{e}^{(\mathrm{i}/2)(\mathrm{d}u/\mathrm{d}a)_2 x\cdot S} \\
&+2^{-b_2/2}\mathrm{i}^{-v^2}(\kappa_3)^{\nu}\left(\frac{\mathrm{d}a}{\mathrm{d}u}\right)_3^{-(\nu+\sigma/4)} \mathrm{e}^{2pu_3+S^2T_3} \\
&\times\sum_x(-1)^{v\cdot x/2} n_x \mathrm{e}^{(\mathrm{i}/2)(\mathrm{d}u/\mathrm{d}a)_3 x\cdot S}\Bigg\}
\end{aligned}
\qquad [13]
$$

where $x$ is a Seiberg–Witten basic class (and $n_x$ is the corresponding Seiberg–Witten invariant), $m$ is the mass parameter of the theory, $\nu=(\chi+\sigma)/4$, $v\in H^2(X,\mathbb{Z}_2)$ is a 't Hooft flux, $S$ is the formal sum $S=\Sigma_a\alpha_a\Sigma_a$ (and, correspondingly, $I(S)=\sum_a \alpha_a I(\Sigma_a)$, with $I(\Sigma_a)=\int_{\Sigma_a} W_2$), where $\{\Sigma_a\}_{a=1,\ldots,b_2(X)}$ form a basis of $H_2(X)$ and $\alpha_a$ are constant parameters, while $\eta(\tau)$ is the Dedekind function, $\kappa_i=(\mathrm{d}u/\mathrm{d}q_{\text{eff}})_{u=u_i}$ (with $q_{\text{eff}}=\exp(2\pi\mathrm{i}\tau_{\text{eff}})$, and $\tau_{\text{eff}}$ is the ratio of the fundamental periods of the elliptic curve), and the contact terms $T_i$ have the form

$$
T_i=-\frac{1}{12}\left(\frac{\mathrm{d}u}{\mathrm{d}a}\right)_i^2+E_2(\tau)\frac{u_i}{6}+\frac{m^2}{72}E_4(\tau) \qquad [14]
$$

with $E_2$ and $E_4$ the Einstein series of weights 2 and 4, respectively. Evaluating the quantities in [13] gives the final result as a function of the physical parameters $\tau$ and $m$, and of topological data of $X$ as the Euler characteristic $\chi$, the signature $\sigma$ and the basic classes $x$. The expression [13] has to be understood as a formal power series in $p$ and $\alpha_a$, whose coefficients give the vacuum expectation values of products of $\mathcal{O}=W_0$ and $I(\Sigma_a)$.

The generating function [13] has nice properties under the modular group. For the partition function $Z_v$,

$$\begin{aligned} Z_v(\tau+1) &= (-1)^{\sigma/8} \mathrm{i}^{-v^2} Z_v(\tau) \\ Z_v(-1/\tau) &= 2^{-b_2/2}(-1)^{\sigma/8}\left(\frac{\tau}{\mathrm{i}}\right)^{-\chi/2} \\ &\quad \times \sum_w (-1)^{w\cdot v} Z_w(\tau) \end{aligned} \qquad [15]$$

Also, with $Z_{\mathrm{SU}(2)} = 2^{-1} Z_{v=0}$ and $Z_{\mathrm{SO}(3)} = \sum_v Z_v$,

$$\begin{aligned} Z_{\mathrm{SU}(2)}(\tau+1) &= (-1)^{\sigma/8} Z_{\mathrm{SU}(2)}(\tau) \\ Z_{\mathrm{SO}(3)}(\tau+2) &= Z_{\mathrm{SO}(3)}(\tau) \\ Z_{\mathrm{SU}(2)}(-1/\tau) &= (-1)^{\sigma/8} 2^{-\chi/2} \tau^{-\chi/2} Z_{\mathrm{SO}(3)}(\tau) \end{aligned} \qquad [16]$$

Notice that the last of these three equations corresponds precisely to the strong–weak coupling duality transformation conjectured by Montonen and Olive (1977).

As for the correlation functions, one finds the following behavior under the inversion of the coupling:

$$\begin{aligned} &\left\langle \frac{1}{8\pi^2} \mathrm{tr}\phi^2 \right\rangle_\tau^{\mathrm{SU}(2)} = \langle \mathcal{O} \rangle_\tau^{\mathrm{SU}(2)} = \frac{1}{\tau^2} \langle \mathcal{O} \rangle_{-1/\tau}^{\mathrm{SO}(3)} \\ &\left\langle \frac{1}{8\pi^2} \int_S \mathrm{tr}(2\phi F + \psi \wedge \psi) \right\rangle_\tau^{\mathrm{SU}(2)} = \langle I(S) \rangle_\tau^{\mathrm{SU}(2)} \\ &\quad = \frac{1}{\tau^2} \langle I(S) \rangle_{-1/\tau}^{\mathrm{SO}(3)} \\ &\langle I(S) I(S) \rangle_\tau^{\mathrm{SU}(2)} = \left(\frac{\tau}{\mathrm{i}}\right)^{-4} \langle I(S) I(S) \rangle_{-1/\tau}^{\mathrm{SO}(3)} \\ &\qquad + \frac{\mathrm{i}}{2\pi} \frac{1}{\tau^3} \langle \mathcal{O} \rangle_{-1/\tau}^{\mathrm{SO}(3)} \sharp(S \cap S) \end{aligned} \qquad [17]$$

Therefore, as expected, the partition function of the twisted theory transforms as a modular form, while the topological correlation functions turn out to transform covariantly under SL(2, $\mathbb{Z}$), following a pattern which can be reproduced with a far more simple topological abelian model.

The second example considered next is the Vafa–Witten (1994) theory. This theory possesses two scalar supercharges, and has the unusual feature that the virtual dimension of its moduli space is exactly zero (it is an example of balanced TQFT), and therefore the only nontrivial topological observable is the partition function itself. Furthermore, the twisted theory does not contain spinors, so it is well defined on any compact, oriented 4-manifold.

Now this theory computes, with the subtleties explained in Vafa and Witten (1994), the Euler characteristic of instanton moduli spaces. In fact, in this case in the generic partition function [10],

$$Z_X(G) = q^{-c(X,G)} \sum_k q^k \chi(\mathcal{M}_k) \qquad [18]$$

$\chi(\mathcal{M}_k)$ is the Euler characteristic of a suitable compactification of the $k$th instanton moduli space $\mathcal{M}_k$ of gauge group $G$ in $X$.

As in the previous example, it is possible to consider nontrivial gauge configurations in $G$/Center ($G$) and compute the partition function for a fixed value of the 't Hooft flux $v \in H^2(X, \pi_1(G))$. In this case, however, the Seiberg–Witten approach is not available, but, as conjectured by Vafa and Witten, one can nevertheless carry out computations in terms of the vacuum degrees of freedom of the $\mathcal{N}=1$ theory which results from giving bare masses to all the three chiral multiplets of the $\mathcal{N}=4$ theory. It should be noted that a similar approach was introduced by Witten (1994b) to obtain the first explicit results for the Donaldson–Witten theory just before the far more powerful Seiberg–Witten approach was available.

As explained in detail by Vafa and Witten (1994), the twisted massive theory is topological on Kähler 4-manifolds with $h^{2,0} \neq 0$, and the partition function is actually invariant under the perturbation. In the long-distance limit, the partition function is given as a finite sum over the contributions of the discrete massive vacua of the resulting $\mathcal{N}=1$ theory. In the case at hand, it turns that, for $G = \mathrm{SU}(N)$, the number of such vacua is given by the sum of the positive divisors of $N$. The contribution of each vacuum is universal (because of the mass gap), and can be fixed by comparing with known mathematical results (Vafa and Witten 1994). However, this is not the end of the story. In the twisted theory, the chiral superfields of the $\mathcal{N}=4$ theory are no longer scalars, so the mass terms cannot be invariant under the holonomy group of the manifold unless one of the mass parameters be a holomorphic 2-form $\omega$. (Incidentally, this is the origin of the constraint $h^{(2,0)} \neq 0$ mentioned above.) This spatially dependent mass term vanishes where $\omega$ does, and we will assume as in Vafa and Witten (1994) and Witten (1994b) that $\omega$ vanishes with multiplicity 1 on a union of disjoint, smooth complex curves $C_i, i = 1, \ldots, n$ of genus $g_i$ which represent the canonical divisor $K$ of $X$. The vanishing of $\omega$ introduces corrections involving $K$ whose precise form is not known *a priori*. In the $G = \mathrm{SU}(2)$ case, each of the $\mathcal{N}=1$ vacua bifurcates along each of the components $C_i$ of the canonical divisor into two strongly coupled massive vacua. This vacuum degeneracy is believed to stem from the spontaneous breaking of a $\mathbb{Z}_2$ chiral symmetry which is unbroken in bulk (see, e.g., Vafa and Witten (1994) and Witten (1994b)).

The structure of the corrections for $G = \mathrm{SU}(N)$ (see [19] below) suggests that the mechanism at work in this case is not chiral symmetry breaking.

Indeed, near any of the $C_i$'s, there is an $N$-fold bifurcation of the vacuum. A plausible explanation for this degeneracy could be found in the spontaneous breaking of the center of the gauge group (which for $G=\mathrm{SU}(N)$ is precisely $\mathbb{Z}_N$). In any case, the formula for SU($N$) can be computed (at least when $N$ is prime) along the lines explained by Vafa and Witten (1994) and assuming that the resulting partition function satisfies a set of nontrivial constraints which are described below.

Then, for a given 't Hooft flux $v \in H^2(X, \mathbb{Z}_N)$, the partition function for gauge group SU($N$) (with prime $N$) is given by

$$Z_v = \left(\sum_{\boldsymbol{\varepsilon}} \delta_{v, w_N(\boldsymbol{\varepsilon})} \prod_{i=1}^{n} \prod_{\lambda=0}^{N-1} \left(\frac{\chi_\lambda}{\eta}\right)^{(1-g_i)\delta_{\varepsilon_i,\lambda}}\right) \times \left(\frac{1}{N^2} G(q^N)\right)^{\nu/2} + N^{1-b_1} \times \sum_{m=0}^{N-1}\left[\prod_{i=1}^{n}\left(\sum_{\lambda=0}^{N-1}\left(\frac{\chi_{m,\lambda}}{\eta}\right)^{1-g_i} \mathrm{e}^{(2\mathrm{i}\pi/N)\lambda v\cdot[C_i]_N}\right)\right] \times \mathrm{e}^{\mathrm{i}\pi((N-1)/N)mv^2}\left(\frac{G(\alpha^m q^{1/N})}{N^2}\right)^{\nu/2} \quad [19]$$

where $\alpha = \exp(2\pi \mathrm{i}/N), G(q) = \eta(q)^{24}$ (with $\eta(q)$ the Dedekind function), $\chi_\lambda$ are the SU($N$) characters at level 1 and $\chi_{m,\lambda}$ are certain linear combinations thereof. $[C_i]_N$ is the reduction modulo $N$ of the Poincaré dual of $C_i$, and

$$w_N(\boldsymbol{\varepsilon}) = \sum_{i=1}^{n} \varepsilon_i [C_i]_N \quad [20]$$

where $\varepsilon_i = 0, 1, \ldots, N-1$ are chosen independently.

Equation [19] has the expected properties under the modular group:

$$Z_v(\tau+1) = \mathrm{e}^{(\mathrm{i}\pi/12)N(2\chi+3\sigma)}\mathrm{e}^{-\mathrm{i}\pi((N-1)/N)v^2} Z_v(\tau)$$
$$Z_v(-1/\tau) = N^{-b_2/2}\left(\frac{\tau}{\mathrm{i}}\right)^{-\chi/2} \times \sum_u \mathrm{e}^{(2\mathrm{i}\pi u\cdot v/N)} Z_u(\tau) \quad [21]$$

and also, with $Z_{\mathrm{SU}(N)} = N^{b_1-1} Z_0$ and $Z_{\mathrm{SU}(N)/\mathbb{Z}_N} = \sum_v Z_v$,

$$Z_{\mathrm{SU(N)}}(-1/\tau) = N^{-\chi/2}\left(\frac{\tau}{\mathrm{i}}\right)^{-\chi/2} Z_{\mathrm{SU}(N)/\mathbb{Z}_N}(\tau) \quad [22]$$

which is, up to some correction factors that vanish in flat space, the original Montonen–Olive conjecture!

There is a further property to be checked which concerns the behavior of [19] under blow-ups. This property was heavily used by Vafa and Witten (1994) and demanding it in the present case was essential in deriving the above formula. Blowing up a point on a Kähler manifold $X$ replaces it with a new Kähler manifold $\widehat{X}$ whose second cohomology lattice is $H^2(\widehat{X}, \mathbb{Z}) = H^2(X, \mathbb{Z}) \oplus I^-$, where $I^-$ is the one-dimensional lattice spanned by the Poincaré dual of the exceptional divisor $B$ created by the blow-up. Any allowed $\mathbb{Z}_N$ flux $\widehat{v}$ on $\widehat{X}$ is of the form $\widehat{v} = v \oplus r$, where $v$ is a flux in $X$ and $r = \lambda B$, $\lambda = 0, 1, \ldots, N-1$. The main result concerning [19] is that under blowing up a point on a Kähler 4-manifold with canonical divisor as above, the partition functions for fixed 't Hooft fluxes have a factorization as

$$Z_{\widehat{X},\widehat{v}}(\tau_0) = Z_{X,v}(\tau_0)\frac{\chi_\lambda(\tau_0)}{\eta(\tau_0)} \quad [23]$$

Precisely the same behavior under blow-ups of the partition function [19] has been proved for the generating function of Euler characteristics of instanton moduli spaces on Kähler manifolds. This should not come as a surprise since, as mentioned above, on certain 4-manifolds, the partition function of Vafa–Witten theory computes the Euler characteristics of instanton moduli spaces. Therefore, [19] can be seen as a prediction for the Euler numbers of instanton moduli spaces on those 4-manifolds.

Finally, the third twisted $\mathcal{N}=4$ theory also possesses two scalar supercharges, and is believed to be a certain deformation of the four-dimensional BF theory, and as such it describes essentially intersection theory on the moduli space of complexified gauge connections. In addition to this, the theory is "amphicheiral," which means that it is invariant to a reversal of the orientation of the spacetime manifold. The terminology is borrowed from knot theory, where an oriented knot is said to be amphicheiral if, crudely speaking, it is equivalent to its mirror image. From this property, it follows that the topological invariants of the theory are completely independent of the complexified coupling constant $\tau$.

# Dynamical Systems and Thermodynamics

**A Carati, L Galgani and A Giorgilli**, Università di Milano, Milan, Italy

## Introduction

The relations between thermodynamics and dynamics are dealt with by statistical mechanics. For a given dynamical system of Hamiltonian type in a classical framework, it is usually assumed that a dynamical foundation for equilibrium statistical mechanics, namely for the use of the familiar Gibbs ensembles, is guaranteed if one can prove that the system is ergodic, that is, has no integrals of motion apart from the Hamiltonian itself. One of the main consequences is then that classical mechanics fails in explaining thermodynamics at low temperatures (e.g., the specific heats of crystals or of polyatomic molecules at low temperatures, or the black body problem), because the classical equilibrium ensembles lead to equipartition of energy for a system of weakly coupled oscillators, against Nernst's third principle. This is actually the problem that historically led to the birth of quantum mechanics, equipartition being replaced by Planck's law. At a given temperature $T$, the mean energy of an oscillator of angular frequency $\omega$ is not $k_B T$ ($k_B$ being the Boltzmann constant), and thus is not independent of frequency (equipartition), but decreases to zero exponentially fast as frequency increases.

Thus, the problem of a dynamical foundation for classical statistical mechanics would be reduced to ascertaining whether the Hamiltonian systems of physical interest are ergodic or not. It is just in this spirit that many mathematical works were recently addressed at proving ergodicity for systems of hard spheres, or more generally for systems which are expected to be not only ergodic but even hyperbolic. However, a new perspective was opened in the year 1955, with the celebrated paper of Fermi, Pasta, and Ulam (FPU), which constituted the last scientific work of Fermi.

The FPU paper was concerned with numerical computations on a system of $N$ (actually, 32 or 64) equal particles on a line, each interacting with the two adjacent ones through nonlinear springs, certain boundary conditions having been assigned (fixed ends). The model mimics a one-dimensional crystal (or also a string), and can be described in the familiar way as a perturbation of a system of $N$ normal modes, which diagonalize the corresponding linearized system. The initial conditions corresponded to the excitation of only a few low-frequency modes, and it was expected that energy would rather quickly flow to the high-frequency modes, thus establishing equipartition of energy, in agreement with the predictions of classical equilibrium statistical mechanics. But this did not occur within the available computation times, and the

energy rather appeared to remain confined within a packet of low-frequency modes having a certain width, as if being in a state of apparent equilibrium of a nonstandard type. This fact can be called "the FPU paradox." In the words of Ulam, written as a comment in *Fermi's Collected Papers*, this is described as follows: "The results of the computations were interesting and quite surprising to Fermi. He expressed the opinion that they really constituted a little discovery in providing intimations that the prevalent beliefs in the universality of mixing and thermalization in nonlinear systems may not be always justified."

The FPU paper immediately had a very strong impact on the theory of dynamical systems, because it motivated all the modern theory of infinite-dimensional integrable systems and solitons (KdV equation), starting from the works of Zabusky and Kruskal (1965). But in this way the FPU paradox was somehow enhanced, because the FPU system turned out to be associated to the class of integrable systems, namely the systems having a number of integrals of motion equal to the number of degrees of freedom, which are in a sense the most antithermodynamic systems. The merit of establishing a bridge towards ergodicity goes to Izrailev and Chirikov (1966). Making reference to the most advanced results then available in the perturbation theory for nearly integrable systems (KAM theory), these authors pointed out that ergodicity, and thus equipartition, would be recovered if one took initial data with a sufficiently large energy. And this was actually found to be the case. Moreover, it turned out that their work, and its subsequent completion by Shepelyanski, was often interpreted as supporting the conjecture that the FPU paradox would disappear in the thermodynamic limit (infinitely many particles, with finite density and energy density). The opposite conjecture was advanced in the year 1970 by Bocchieri, Scotti, Bearzi, and Loinger, and its relevance for the relations between classical and quantum mechanics was immediately pointed out by Cercignani, Galgani, and Scotti. A long debate then followed. Possibly, some misunderstandings occurred, because in the discussions concerning the dynamical aspects of the problem reference was generally made to notions involving infinite times. In fact, it had not yet been conceived that the FPU equilibrium might actually be an apparent one, corresponding to some type of intermediate metaequilibrium state. This was for the first time suggested by researchers in Parisi's group in the year 1982. The analogy of such a situation with that occurring in glasses was pointed out more recently.

In the present article, the state of the art of the FPU problem is discussed. The thesis of the present authors is that the FPU phenomenon survives in the thermodynamic limit, in the last mentioned sense, namely that at sufficiently low temperatures there exists a kind of metaequilibrium state surviving for extremely long times. The corresponding thermodynamics turns out to be different from the standard one predicted by the equilibrium ensembles, inasmuch as it presents qualitatively some quantum-like features (typically, specific heats in agreement with Nernst's third principle). The key point, with respect to equilibrium statistical mechanics, is that the internal thermodynamic energy should be identified not with the whole mechanical energy, but only with a suitable fraction of it, to be identified through its dynamical properties, as was suggested more than a century ago by Boltzmann himself, and later by Nernst.

Here, it is first discussed why nearly integrable systems can be expected to present the FPU phenomenon. Then the latter is illustrated. Finally, some hints are given for the corresponding thermodynamics.

## Nearly Integrable versus Hyperbolic Systems, and the Question of the Rates of Thermalization

As mentioned above, it is usually assumed that the problem of providing a dynamical foundation to classical statistical mechanics is reduced to the mathematical problem of ascertaining whether the Hamiltonian systems of physical interest are ergodic or not. However, there remains open a subtler problem. Indeed, the notion of ergodicity involves the limit of an infinite time (time averages should converge to ensemble averages as $t \to \infty$), while intermediate times might be relevant. In this connection it is convenient to distinguish between two classes of dynamical systems, namely the hyperbolic and the nearly integrable ones.

The first class, in a sense the prototype of chaotic systems, should include the systems of hard spheres (extensively studied after the classical works of Sinai), or more generally the systems of mass points with mutual repulsive interactions. For such systems it can be expected that the time averages of the relevant dynamical quantities in an extremely short time converge to the corresponding ensemble averages, so that the classical equilibrium ensembles could be safely used.

A completely different situation occurs for the dynamical systems such as the FPU systems, which are nearly integrable, that is, are perturbations of

systems having a number of integrals of motion equal to the number of degrees of freedom. Indeed, in such a case ergodicity means that the addition of an interaction, no matter how small, makes an integrable system lose all of its integrals of motion, apart from the Hamiltonian itself. And, in fact, this quite remarkable property was already proved to be generic by Poincaré, through a set of considerations which had a fundamental impact on the theory of dynamical systems itself. In view of its importance for the foundations of statistical mechanics, the proof given by Poincaré was reconsidered by Fermi, who added a subtle contribution concerning the role of single invariant surfaces. It is just to such a paper that Ulam makes reference in his comment to the FPU work mentioned above, when he says: "Fermi's earlier interest in the ergodic theory is one motive" for the FPU work.

The point is that the picture which looks at the ergodicity induced on an integrable system by the addition of a perturbation, no matter how small, somehow lacks continuity. One might expect that, in situations in which the nonlinear interaction which destroys the integrals of motion is very small (i.e., at low temperatures), the underlying integrable structure should somehow be still appreciable, in some continuous way. In fact, continuity should be recovered by making a question of times, namely by considering the rates of thermalization (to use the very FPU phrase), or equivalently the relaxation times, namely the times needed for the time averages of the relevant dynamical quantities to converge to the corresponding ensemble averages. By continuity, one clearly expects that the relaxation times diverge as the perturbation tends to zero. But more complicated situations might occur, as, for example, the existence of two (or more) relevant timescales. The point of view that timescales of different orders of magnitude might occur in dynamical systems (with the exhibition of an interesting example) and that this might be relevant for statistical mechanics, was discussed by Poincaré himself in the year 1906. Indeed, he denotes as "first-order very large time" a time which is sufficient for a system to reach a "provisional equilibrium," whereas he denotes as "second-order very large time" a time which is necessary for the system to reach its "definitive equilibrium."

## The FPU Phenomenon: Historical and Conceptual Developments

We now illustrate the FPU phenomenon, following essentially its historical development. We will make reference to Figures 1–8, which are the results of numerical integrations of the FPU dynamical system. If $x_1, \ldots, x_N$ denote the positions of the particles (of unitary mass), or more precisely the displacements from their equilibrium positions, and $p_i$ the corresponding momenta, the Hamiltonian is

$$H = \sum_{i=1}^{N} \frac{p_i^2}{2} + \sum_{i=1}^{N+1} V(r_i)$$

where $r_i = x_i - x_{i-1}$ and one has taken a potential $V(r) = r^2/2 + \alpha r^3/3 + \beta r^4/4$ depending on two positive parameters $\alpha$ and $\beta$. Boundary conditions with fixed ends, namely $x_0 = x_{N+1} = 0$, are considered. We recall that the angular frequencies

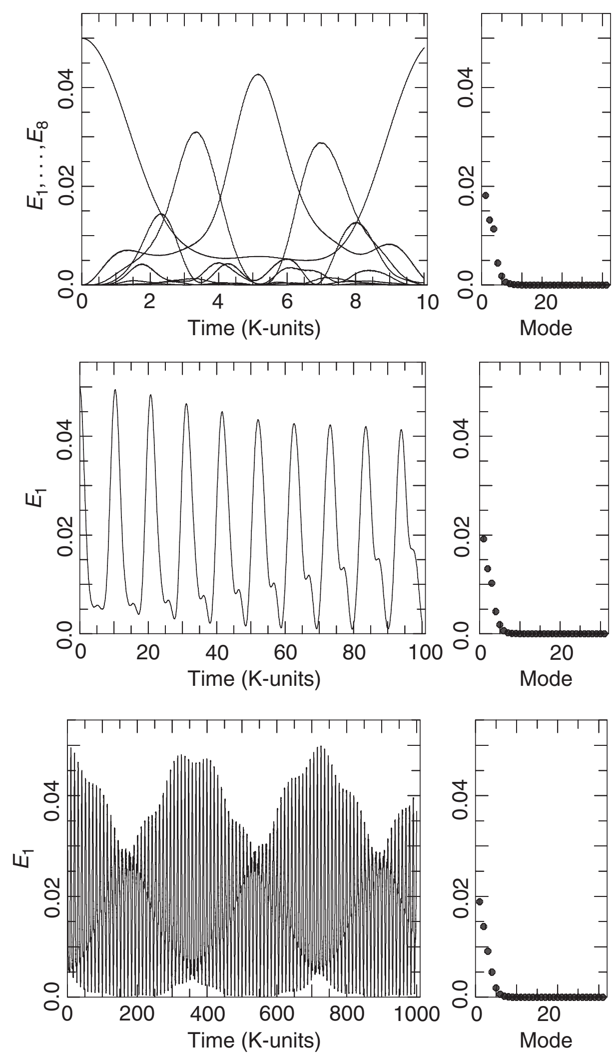

**Figure 1** The FPU paradox: normal-mode energies $E_j$ versus time (left) and energy spectrum, namely time average of $E_j$ versus $j$ (right) for three different timescales. The energy, initially given to the lowest-frequency mode, does not flow to the high-frequency modes within the accessible observation time. Here, $N = 32$ and $E = 0.05$.

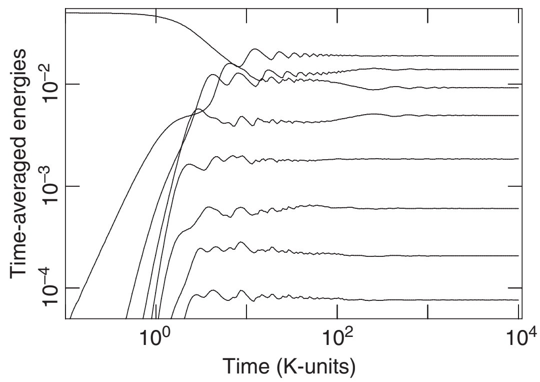

**Figure 2** The FPU paradox: time averages of the energies of the modes 1, 2, …, 8 (from top to bottom) versus time for the same run as **Figure 1**. The spectrum has reached an apparent equilibrium, different from that of equipartition predicted by classical equilibrium statistical mechanics. An exponential decay of the tail is clearly exhibited.

of the corresponding normal modes are $\omega_j = 2\sin[j\pi/2(N+1)]$, with $j=1,\ldots,N$; it is thus convenient to take as time unit the value $\pi$, which is essentially, for any $N$, the period of the fastest normal mode.

The original FPU result is illustrated in Figures 1 and 2. Here $N=32, \alpha=\beta=1/4$, and the total energy is $E=0.05$; the energy was given initially to the first normal mode (with vanishing potential energy). Three timescales (increasing from top to bottom) are considered, the top one corresponding to the timescale of the original FPU paper. In the boxes on the left the energies $E_j(t)$ of modes $j$ are reported versus time ($j=1,\ldots,8$ at top, $j=1$ at center and bottom). In the boxes on the right we report the corresponding spectra, namely the time average (up to the respective final times) of the energy of mode $j$ versus $j$, for $1 \le j \le N$. In Figure 2 we report, for the same run of Figure 1, the time averages of the energies of the various modes versus time; this figure corresponds to the last one of the original FPU work. The facts to be noticed in connection with these two figures are the following: (1) the spectrum (namely the distribution of energy among the modes, in time average) appears to have relaxed very quickly to some form, which remains essentially unchanged up to the maximum observed time; (2) there is no global equipartition, but only a partial one, because the energy remains confined within a group of low-frequency modes, which form a small packet of a certain definite width; and (3) the time evolutions of the mode energies appear to be of quasiperiodic type, since longer and longer quasiperiods can be observed as the total time increases.

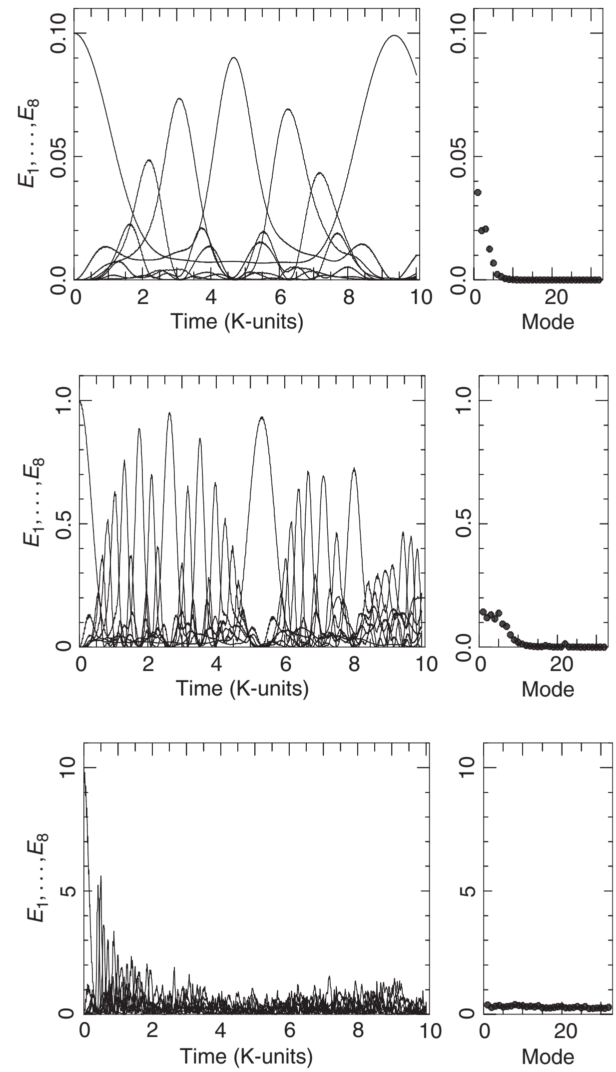

**Figure 3** The Izrailev–Chirikov contribution: for a fixed observation time, equipartition is attained if the initial energy $E$ is high enough. Here, from top to bottom, $E=0.1, 1, 10$.

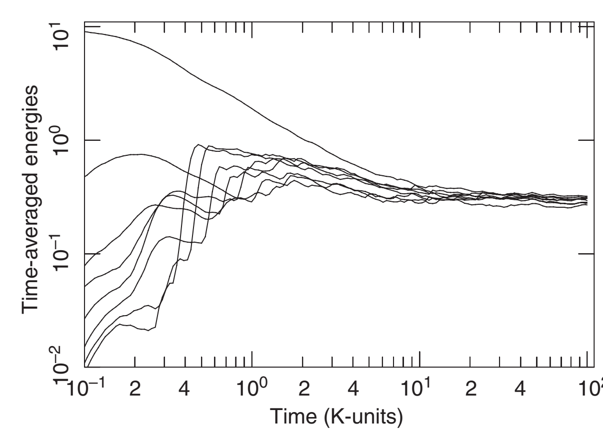

**Figure 4** The Izrailev–Chirikov contribution: time averages of the mode energies versus time for the same run as at bottom of **Figure 3**.

After the works of Zabusky and Kruskal, by which the FPU system was somehow assimilated to an integrable system, the bridge toward ergodicity was made by Izrailev and Chirikov (1966), through the idea that there should exist a stochasticity threshold. Making reference to KAM theory, which had just been formulated in the framework of perturbation theory for nearly integrable systems, their main remark was as follows. It is known that KAM theory, which essentially guarantees a behavior similar to that of an integrable system, applies only if the perturbation is smaller than a certain threshold; on the other hand, in the FPU model the natural perturbation parameter is the energy $E$ of the system. Thus, the FPU phenomenon can be expected to disappear above a certain threshold energy $E_c$. This is indeed the case, as illustrated in **Figures 3 and 4**. The parameters $\alpha, \beta$ and the class of initial data are as in **Figure 1**. In **Figure 3** the total time is kept fixed (at 10 000 units), whereas the energy $E$ is increased in passing from top to bottom, actually from $E = 0.1$ to $E = 1$ and $E = 10$. One sees that at $E = 10$ equipartition is attained within the given observation time; correspondingly, the motion of the modes visually appears to be nonregular. The approach to equipartition at $E = 10$ is clearly exhibited in **Figure 4**, where the time averages of the energies are reported versus time.

There naturally arose the problem of the dependence of the threshold $E_c$ on the number $N$ of degrees of freedom (and also on the class of initial data). Certain semianalytical considerations of Izrailev and Chirikov were generally interpreted as suggesting that the threshold should vanish in the thermodynamic limit for initial excitations of high-frequency modes. Recently, Shepelyanski completed the analysis by showing that the threshold should vanish also for initial excitations of the low-frequency modes, as in the original FPU work (see, however, the subsequent paper by Ponno mentioned below). If this were true, the FPU phenomenon would disappear in the thermodynamic limit. In particular, the equipartition principle would be dynamically justified at all temperatures.

The opposite conjecture was advanced by Bocchieri *et al.* (1970). This was based on numerical calculations, which indicated that the energy threshold should be proportional to $N$, namely that the FPU phenomenon persists in the thermodynamic limit provided the specific energy $\epsilon = E/N$ is below a critical value $\epsilon_c$, which should be definitely nonvanishing. Actually, the computations were performed on a slightly different model, in which nearby particles were interacting through a more physical Lennard-Jones potential. By taking concrete values having a physical significance, namely the values commonly assumed for argon, for the threshold of the specific energy they found the value $\epsilon_c \simeq 0.04 V_0$, where $V_0$ is the depth of the Lennard-Jones potential well. This corresponds to a critical temperature of the order of a few kelvin. The relevance of such a conjecture (persistence of the FPU phenomenon in the thermodynamic limit) was soon strongly emphasized by Cercignani, Galgani, and Scotti, who also tried to establish a connection between the FPU spectrum and Planck's distribution.

Up to this point, the discussion was concerned with the alternative whether the FPU system is ergodic or not, and thus reference was made to properties holding in the limit $t \to \infty$. Correspondingly, one was making reference to KAM theory, namely to the possible existence of surfaces ($N$-dimensional tori) which should be dynamically invariant (for all times). The first paper in which attention was drawn to the problem of estimating the relaxation times to equilibrium was by Fucito *et al.* (1982). The model considered was actually a different one (the so-called $\phi^4$ model), but the results can also be extended to the FPU model. Analytical and numerical indications were given for the existence of two timescales. In a short time the system was found to relax to a state characterized by an FPU-like spectrum, with a plateau at the low frequencies, followed by an exponential tail. This, however, appeared as being a sort of metastable state. In their words: "The nonequilibrium spectrum may persist for extremely long times, and may be mistaken for a stationary state if the observation time is not sufficiently long." Indeed, on a second much larger timescale the slope of the exponential tail was found to increase logarithmically with time, with a rate which decreases to zero with the energy. This is an indication that the time for equipartition should increase as an exponential with the inverse of the energy.

This is indeed the picture that the present authors consider to be essentially correct, being supported by very recent numerical computations, and by analytical considerations. Curiously enough, however, such a picture was not fully appreciated until quite recently. Possibly, the reason is that the scientific community had to wait until becoming acquainted with two relevant aspects of the theory of dynamical systems, namely Nekhoroshev theory and the relations between KdV equation and resonant normal-form theory.

The first step was the passage from KAM theory to Nekhoroshev theory. Let us recall that, whereas in KAM theory one looks for surfaces which are invariant (for all times), in Nekhoroshev theory one

looks instead for a kind of weak stability involving finite times, albeit "extremely long" ones, as they are found to increase as stretched exponentials with the inverse of the perturbative parameter. Thus, one meets with situations in which one can have instability over infinite times, while having a kind of practical stability up to exponentially long times. Notice that Nekhoroshev's theory was formulated only in the year 1974, and that it started to be known in the West only in the early 1980s, just because of its interest for the FPU problem. Another interesting point is that just in those years one started to become acquainted with a related historical fact. Indeed, the idea that equipartition might require extremely long times, so that one would be confronted with situations of a practical lack of equipartition, has in fact a long tradition in statistical mechanics, going back to Boltzmann and Jeans, and later (in connection with sound dispersion in gases of polyatomic molecules) to Landau and Teller.

In this way the idea of the existence of extremely long relaxation times to equipartition came to be accepted. The ingredient that was still lacking is the idea of a quick relaxation to a metastable state. The importance of this should not be overlooked. Indeed, without it one cannot at all have a thermodynamics different from the standard equilibrium one corresponding to equipartition. This was repeatedly emphasized, against Jeans, by Poincaré on general grounds and by Nernst on empirical grounds. The full appreciation of this latter ingredient was obtained quite recently (although it had been clearly stated by Fucito *et al.* (1982)). A first hint in this direction came from the realization (see **Figure 5**) of a deep analogy between the FPU phenomenon and the phenomenology of glasses. Then there came a strong numerical indication by Berchialla, Galgani, and Giorgilli. Finally, from the analytical point of view, there was a suitable revisitation (by Ponno) of the traditional connection between the FPU system and the KdV equation with its solitons. The relevant points are the following: (1) the KdV equation describes well the solutions of the FPU problem (for initial data of FPU type) only on a "short" timescale, which increases as a power of $1/\epsilon$, and so describes only a first process of quick relaxation; (2) the corresponding spectrum has a very definite analytical form, the energy being spread up to a maximal frequency $\bar{\omega}(\epsilon) \simeq \epsilon^{1/4}$ and then decaying exponentially; and (3) the relevant formulas contain the energy only through the specific energy $\epsilon$, and thus can be expected to hold also in the thermodynamic limit. It should be mentioned, however, that all the results of an

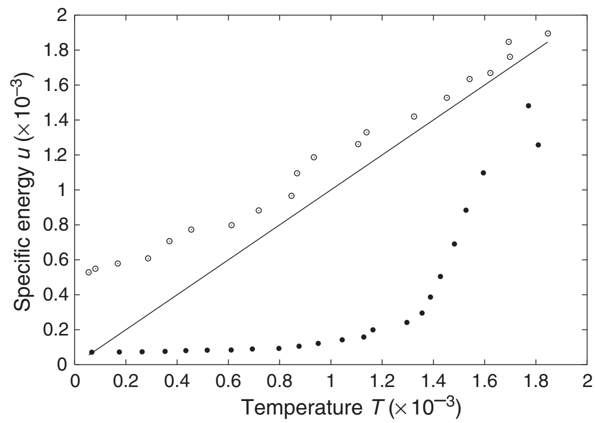

**Figure 5** Analogy with glasses: the specific energy $u$ of an FPU system is plotted versus temperature $T$ for a cooling process (upper curve) and a heating process (lower curve). The FPU system is kept in contact with a heat reservoir, whose temperature is changed at a given rate. At low temperatures the system does not have time to reach the equilibrium curve $u = T$ (with $k_B = 1$).

analytic type mentioned above have a purely formal character, because up to now none of them was proved, in the thermodynamic limit, in the sense of rigorous perturbation theory. This requires a suitable readaptation of the known techniques, which is currently being obtained both in connection with Nekhoroshev's theorem (in order to explain the extreme slowness of a possible final approach to equilibrium) and in connection with the normal-form theory for partial differential equations (in order to explain the fast relaxation to the metaequilibrium state).

In conclusion, for the case of initial conditions of the FPU type (excitation of a few low-frequency modes) the situation seems to be as follows. The first phenomenon that occurs in a "short" time (of the order of $(1/\epsilon)^{3/4}$ is a quick relaxation to the formation of what can be called a "natural packet" of low-frequency modes extending up to a certain maximal frequency $\bar{\omega} \simeq \epsilon^{1/4}$. This is a phenomenon which has nothing to do with any diffusion in phase space. In fact, it shows up also for an integrable system such as a Toda lattice (as will be illustrated below), and should be described by a suitable resonant normal form related to the KdV equation. One has then to take into account the fact that the domain of the frequencies in the FPU model is bounded ($\omega < 2$ in the chosen units). Now, as the function $\bar{\omega}(\epsilon)$ is monotonic, this fact leads to the existence of a critical value $\epsilon_c$ of the specific energy $\epsilon$, defined by $\bar{\omega}(\epsilon_c) = 2$. Indeed, for $\epsilon > \epsilon_c$ the quick relaxation process leads altogether to equipartition. Below the threshold, instead, the same quick process leads to the formation of an FPU-like spectrum,

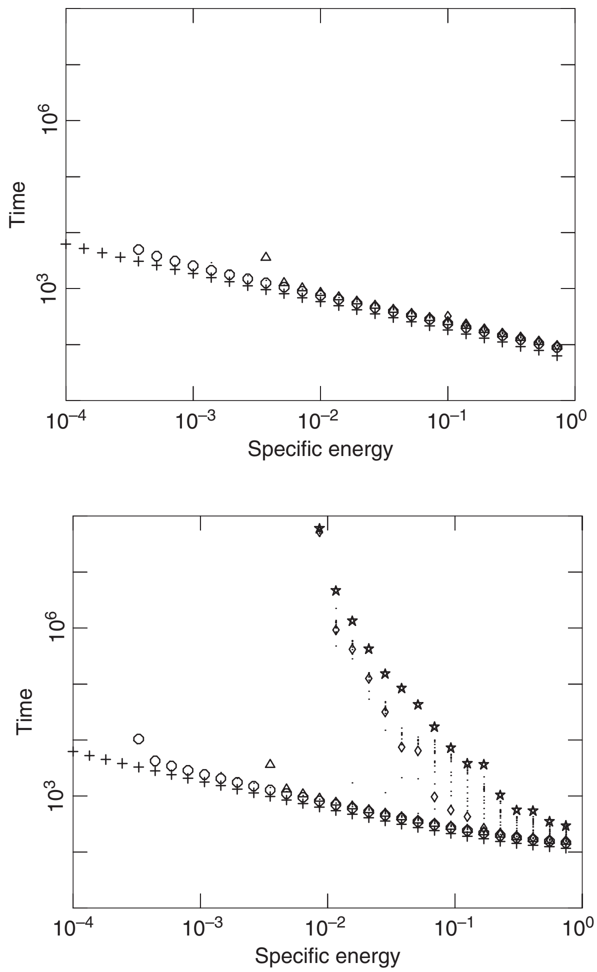

**Figure 6** Time needed to form a packet versus specific energy for the FPU model (bottom) and the corresponding Toda model (top). Different symbols refer to packets of different width. The existence of two timescales below a critical specific energy in the FPU model is exhibited.

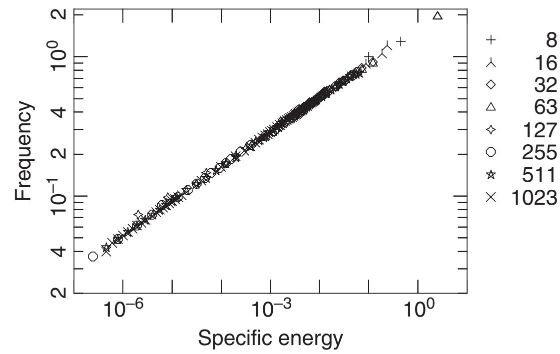

**Figure 7** Width of the natural packet versus specific energy, for *N* ranging from 8 to 1023. Reproduced from Berchialla L, Galgani L, and Giorgilli A (2004) Localization of energy in FPU chains, *Discr. Cont. Dyn. Systems B* 11: 855–866, with permission from American Institute of Mathematical Sciences.

involving only modes of sufficiently low frequency. This should, however, be a metastable state (which might be mistaken for a stationary one), which should be followed, on a second timescale, by a relaxation to the final equilibrium, through a sort of Arnol'd diffusion requiring extremely long Nekhoroshev-like times. This is actually the way in which the old idea of a threshold, originally conceived in terms of KAM tori, is now recovered even for ergodic systems, in terms of timescales.

The existence of a process of quick relaxation, and of a threshold in the above-mentioned sense, is illustrated in Figures 6 and 7. In Figure 6 the lower part refers to the FPU model, while the upper one refers to a corresponding Toda model. The latter is in a sense the prototype of an integrable nonlinear system; with respect to the FPU case, the difference is that the potential $V(r)$ is now exponential. The parameters of the exponential were chosen so that the two models coincide up to cubic terms in the potential. With the energy given to the lowest-frequency mode, the figure shows the time needed in order that energy spreads up to a mode $\bar{k}$, for several values of $\bar{k}$, as a function of $\epsilon$. It is seen that in the Toda model (top) there is formed a packet extending up to rather well-defined width, and that this occurs within a relaxation time increasing as a power of $1/\epsilon$. An analogous phenomenon occurs for the FPU model (bottom). The only difference is that, below a critical specific energy $\epsilon_c \simeq 0.1$, there exists a subsequent relaxation time to equipartition, which involves a time growing faster than any inverse power of $\epsilon$. Such a second phenomenon is due to the nonintegrable character of the FPU model. In Figure 7 the width of the natural packet for the FPU model is exhibited, by reporting the frequency $\bar{\omega}$ of its highest mode as a function of $\epsilon$. As one sees, the numerical results clearly indicate the existence of a relation $\bar{\omega} \simeq \epsilon^{1/4}$, which holds for a number of degrees of freedom $N$ ranging from 8 to 1023. This is actually the law which is predicted by resonant normal-form theory.

## Boltzmann and Nernst Revisited

All the results illustrated above refer to initial data of FPU type, namely with an excitation of a few low-frequency modes. However, from the point of view of statistical mechanics, such initial data are exceptional, and one should rather consider initial data extracted from the Gibbs distribution at a certain temperature. One can then couple the FPU system to a heat bath at a slightly different temperature, and look at the spectrum of the FPU system after a certain time. The result, for the case of a heat bath at a higher temperature, is shown in

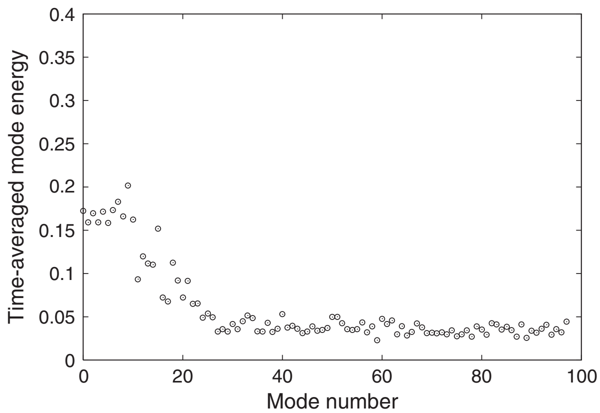

**Figure 8** A case of an FPU system initially at equilibrium and thus in equipartition. Spectrum of the FPU system after it was kept in contact with a heat reservoir at a higher temperature.

Figure 8. Clearly, here one has a situation similar to that occurring for initial data of FPU type, because only a packet of low-frequency modes exhibits a reaction, each of its modes actually adapting itself to the temperature of the bath, whereas the high-frequency modes do not react at all, that is, remain essentially frozen.

This capability of reacting to external disturbances (which seems to pertain only to a fraction of the mechanical energy initially inserted into the system) can be characterized in a quantitative way through an estimate of the fluctuations of the total energy of the FPU system. This is indeed the sense of the fluctuation–dissipation theorem, the precursor of which is perhaps the contribution of Einstein to the first Solvay conference (1911). Through such a method, the specific heat of the FPU system is estimated (apart from a numerical factor) by the time average of $[E(t) - E(0)]^2$, where $E(t)$ is the energy, at time $t$, of the FPU system in dynamical contact with a heat bath (at the same temperature from which the initial data are extracted). Usually, in the spirit of ergodic theory, one looks at the infinite-time limit of such a quantity. But in the spirit of the metastable picture described above, one can check whether the time average presents a previous stabilization to some value smaller than the one predicted at equilibrium. Such a result, which is in qualitative agreement with the third principle, has indeed been obtained (by Carati and Galgani) recently.

In conclusion, in situations of metaequilibrium such as those existing in the FPU model at low temperatures, a thermodynamics can still be formulated. Indeed, by virtue of the quick relaxation process described above, the time averages of the relevant quantities are found to stabilize in rather short times. In this way, one overcomes the critique of Poincaré to Jeans, namely that one cannot have a thermodynamics at all if reference is made only to the existence of extremely long relaxation times to the final equilibrium. A relaxation to a “provisional equilibrium” within a “first-order very large time” (to quote Poincaré) is required . The difference with respect to the standard equilibrium thermodynamics relies now in the mechanical interpretation of the first principle. Indeed, the internal thermodynamic energy is identified not with the whole mechanical energy, but just with that fraction of it which is capable of reacting in short times to the external perturbations.

This is the way in which the old idea of Boltzmann (and Jeans) might perhaps be presently implemented. For what concerns the fraction of the mechanical energy which is not included in the thermodynamic internal energy, as not being able to react in relatively short times, this should somehow play the role of a zero-point energy. This was suggested in the year 1971 by C Cercignani. But in fact, such a concept was put forward by Nernst himself in an extremely speculative work in 1916, where he also advanced the concept that, for a system of oscillators of a given frequency, there should exist both dynamically ordered (*geordnete*) and dynamically chaotic (*ungeordnete*) motions, the latter being prevalent above a certain energy threshold. According to him, this fact should be relevant for a dynamical understanding of the third principle and of Planck’s law.

It is well known that the modern theory of dynamical systems has led to familiarity with the (sometimes abused) notions of order and chaos and of a transition between them. One might say that the FPU work just forced the scientific community to take into account such notions in connection with the principle of equipartition of energy. It is really fascinating to see that the same notions, with the same terminology, had already been introduced much earlier on purely thermodynamic grounds, in connection with the relations between classical and quantum mechanics.

# Dynamical Systems in Mathematical Physics: An Illustration from Water Waves

**O Goubet**, Université de Picardie Jules Verne, Amiens, France

## Introduction

The purpose of this article is to describe some basic problems related to the interplay between dynamical systems and mathematical physics. Since it is impossible to be exhaustive in these topics, the focus here is on water-wave models. These mathematical models are described by partial differential equations that can be understood as dynamical systems in a suitable infinite-dimensional phase space.

We will not address the original equations for two-dimensional (2D) surface water waves, even if we know that dynamical-system methods can help to exhibit some solitary waves for the equations. The reader is referred to relevant articles in this encyclopedia for details. Another approach is to seek these 2D surface water waves as saddle points for some Hamiltonians, which too is discussed elsewhere in this work.

This article presents these arguments on some asymptotical models for the propagation of surface water waves.

## Asymptotical Models in Hydrodynamics

To begin with, consider an irrotational fluid in a canal that is governed by the Euler equations and that is subject to gravitational forces. For a canal of finite depth, Boussinesq (1877) and Korteweg–de Vries (KdV) (1890) obtained the following model for unidirectional long waves:

$$u_t + u_x + u_{xxx} + uu_x = 0 \qquad [1]$$

Sometimes we drop the $u_x$ term on the left-hand side of [1], thanks to a suitable change of coordinates. Alternatively, we can also deal with the so-called generalized KdV equation, which reads

$$u_t + u_{xxx} + u^k u_x = 0 \qquad [2]$$

where $k$ is a positive integer. There are also other models designed to represent long waves in shallow water. Let us introduce the regularized long-wave equation (also referred to as the Benjamin–Bona–Mahony equation) that reads

$$u_t - u_{txx} + u_x + uu_x = 0 \qquad [3]$$

or the Camassa–Holm equation

$$u_t - u_{txx} + 3uu_x = 2u_x u_{xx} + uu_{xxx} \qquad [4]$$

For deep water, a well-known model was introduced by Zakharov (1968)

$$\mathrm{i}u_t + u_{xx} + \varepsilon|u|^2 u = 0 \qquad [5]$$

which describes the slow modulations of wave packets. Here the unknown $u(x, t)$ takes values in $\mathbb{C}$, and this nonlinear Schrödinger equation is in fact a system. In these equations, $\varepsilon$ is either 1 or –1; throughout this article, we shall refer to the former case as the focusing case and to the latter

as the defocusing case. We may also substitute $|u|^{2p}u$ in the nonlinear term in [5] to obtain alternate models.

The variable $t$ represents the time and the space variable $x$ belongs either to $\mathbb{R}$ or to a finite interval when we are dealing with periodic flows.

The above models are intended to describe the propagation of unidirectional waves. For two-way waves, see Bona *et al.* (2002).

Actually, these equations feature particular solutions, the so-called traveling waves. Let us recall, for instance, that for generalized KdV equation [2] these solutions are

$$u(t,x) = Q_c(x - ct) \qquad [6]$$

$$Q_c(x) = c^{1/p}Q(\sqrt{c}x) \qquad [7]$$

$$Q(x) = (3\,\mathrm{ch}^{-2}(px))^{1/p} \qquad [8]$$

These so-called solitons (**Figure 1**) move to the right without changing their shape; $c$ is the speed of propagation. In real life, this phenomenon was observed by Russel (1834). Riding his horse, he was able to follow for miles the propagation of such a wave on the canal from Edinburgh to Glasgow. On the other hand, Camassa–Holm equations are designed to describe the propagation of peaked solitons as shown in **Figure 2**.

Focusing nonlinear Schrödinger equations also feature solitary waves that read $u_\omega(t,x) = \exp(\mathrm{i}\omega t)Q(x)$, where $Q$ is solution to

$$Q_{xx} - \omega Q + Q^{2p+1} = 0 \qquad [9]$$

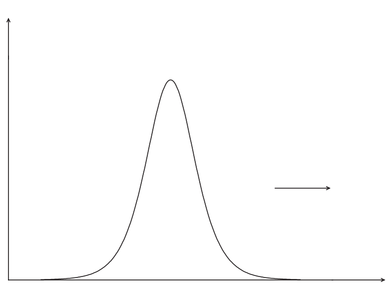

**Figure 1** A soliton.

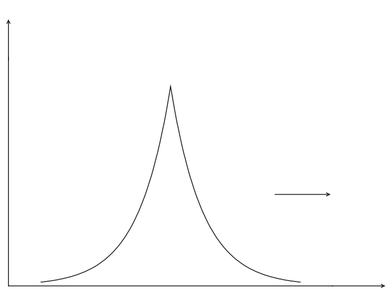

**Figure 2** Peaked soliton.

There are numerous examples of equations or systems of equations that model 2D surface water waves. Among all these models, a first issue is to identify the relevant models insofar as the dynamical properties are concerned. Indeed, we address here the question of stability of solitary waves (up to the symmetries of the equation). For instance, the orbital stability for cubic Schrödinger reads: for any $\varepsilon > 0$, there exists a neighborhood $\Omega$ of $u_\omega(x,0)$ such that any trajectory starting from $\Omega$ satisfies

$$\sup_t \inf_\theta \inf_y ||u(t) - \exp(\mathrm{i}\theta)u_\omega(t, . - y)||_{H^1} \le \varepsilon \qquad [10]$$

Another issue consists in the interaction of $N$ solitons. Schneider and Wayne (2000) have addressed the issue of the validity of water-wave models when this interaction is concerned.

Assume now that the validity of these models is granted. To consider [1] or [5] as a dynamical system, the next issue is then to consider the initial-value problem.

## The Initial-Value Problem

Let us supplement these equations with initial data $u_0$ in some Sobolev space. We shall consider either

$$H^s(\mathbb{R}) = \left\{ u; \int_{\mathbb{R}} (1 + |\xi|^2)^s |\hat{u}(\xi)|^2 \,\mathrm{d}\xi < +\infty \right\} \qquad [11]$$

in the case where $x$ belongs to the whole line, or the corresponding Sobolev space with periodic boundary conditions. It should be examined whether these equations provide a continuous flow $S(t): u_0 \to u(t)$ in these functional spaces (at least locally in time). We would like to point out that for each Sobolev space under consideration, we may have a different flow. This fact is at the heart of infinite-dimensional dynamical systems.

The initial-value problem was a challenge for decades for low norms, that is for small $s$. The last breakthrough was performed by Bourgain (1993). Let us present the method for KdV equation. Consider $U(t)u_0$ the solution of the Airy equation

$$u_t + u_{xxx} = 0, \quad u(0) = u_0 \qquad [12]$$

Without going into further details, the idea is to perform a fixed-point argument to the Duhamel's form of the equation,

$$u(t) = U(t)u_0 - \frac{1}{2}\int_0^t U(t-s)\partial_x(u^2(s))\mathrm{d}s \qquad [13]$$

in a suitable mixed-spacetime Banach space whose norm reads $\|U(-t)u(t,x)\|_{H_t^b H_x^\rho}$. This relies on fine properties in harmonic analysis. Thanks to this method, we know that the Schrödinger equation [5] and the KdV equation [1] are well-posed in, respectively, $H^s(\mathbb{R}), s \geq 0$ and $H^s(\mathbb{R}), s > -3/4$, locally in time. For the periodic case, the results are slightly different. We would like to point out that both KdV and nonlinear Schrödinger equations provide semigroups $S(t)$ that do not feature smoothing effect. A trajectory that starts from $H^s$ remains in $H^s$; indeed, we can also solve these partial differential equations backward in time.

The next issue is to determine if these flows are defined for all times. Loosely speaking, the following alternative holds true: either the local flow in $H^s$ extends to a global one, or some blow-up phenomenon occurs, that is, $||S(t)u_0||_{H^s}$ collapses in finite time.

To this end, let us observe that, for instance, the mass $\int_{\mathbb{R}} |u(x)|^2\, dx$ is conserved for both KdV and nonlinear Schrödinger flows. Therefore, one can prove that the solutions in $L^2$ are global in time. It is worthwhile to observe that the Bourgain method also provides some global existence results below the energy norm.

Consider now the flow of the solutions in $H^1$. The second invariant for nonlinear Schrödinger equations reads

$$\int_{\mathbb{R}} |u_x(x)|^2 \mathrm{d}x - \frac{\varepsilon}{p+1} |u(x)|^{2p+2} \mathrm{d}x \qquad [14]$$

Therefore, the local solutions in $H^1$ extend to global ones in the defocusing case ($\varepsilon = -1$). In the focusing case, the situation is more contrasted. The solution is global if the nonlinearity is less than an $H^1$-critical value ($p = 2$ for Schrödinger, and $k = 4$ for generalized KdV equation). This critical value depends on some Sobolev embeddings as

$$\int_{\mathbb{R}} |u(x)|^{2p+2} \mathrm{d}x \leq C_p \|u\|_{L^2}^{p+1} \|u_x\|_{L^2}^{p} \qquad [15]$$

Therefore, since the mass is constant, the second invariant controls the $H^1$ norm of the solution if $p < 2$. Note that the critical power of the nonlinearity depends also on the dimension of the space; it is the cubic Schrödinger that is critical in $H^1(\mathbb{R}^2)$. It is well known that, for some initial data, blow-up phenomena can occur for 2D cubic Schrödinger equations. Moreover, the behavior of blow-up solutions is more or less understood. This analysis was performed using the conformal invariance of the equation. For quintic Schrödinger equation, which is critical in 1D, this conformal invariance states that if $u(t,x)$ is solution, then

$$v(t,x) = |t|^{-1/2} \exp\left(\frac{\mathrm{i}x^2}{4t}\right) \bar{u}\left(\frac{1}{t}, \frac{x}{t}\right) \qquad [16]$$

is also solution.

On the other hand, for the generalized KdV equation, there is no conformal invariance and the blow-up issue had been open for years. There was some numerical evidence that blow-up can occur for $k = 4$. Recently, Martel and Merle (2002) have given a complete description of the blow-up profile for this equation. Their methods are quite complex and rely on an ejection of mass at infinity in a suitable coordinate system.

In the discussion so far we have presented some quantities that are invariant by the flow of the solutions. This is related to the Hamiltonian structure of the dynamical systems under consideration.

## Hamiltonian Systems in Hydrodynamics

The study of Hamiltonian systems has developed beyond celestial mechanics (the famous $n$-body problems) to other fields in mathematical physics. We focus here on dynamical systems that read

$$u_t = J \frac{\partial}{\partial u} H(u) \qquad [17]$$

where $H$ is the Hamiltonian and $J$ some skew-symmetric operator. For instance, [1] is a Hamiltonian system with $J = \partial_x$ (i.e., an unbounded skew-symmetric operator) and

$$H(u) = \frac{1}{2} \int (u^2 - u_x^2) \mathrm{d}x + \frac{1}{6} \int u^3 \mathrm{d}x \qquad [18]$$

There is a subclass of Hamiltonian systems that are integrable by inverse-scattering methods. For instance, [1] belongs to this class. Indeed, these methods give a complete description of the asymptotics when $t \to \pm\infty$. It is well known (Deift and Zhou 1993) that, asymptotically, any solution to KdV equation consists of a wave train moving to the right in the physical space up to a dispersive part moving to the left.

On the other hand, a generic Hamiltonian system is not integrable. The study of the asymptotics and of the dynamical properties of such a system deserves another analysis. We say that a system features asymptotic completeness if there exist $u_+$

and $u_-$ such that the solution $u(t)$ of [17] supplemented with initial data $u_0$ satisfies

$$\|u(t) - U(t)u_+\| \to 0 \quad [19]$$

$$\|u(t) - U(t)u_-\| \to 0 \quad [20]$$

when, respectively, $t \to +\infty$ or $t \to -\infty$. Here $U(t)u_0$ is the solution of the free equation, that is, the associated linear equation, supplemented with initial data $u_0$; for instance, the Airy equation is the free equation related to the KdV equation. The operators $u_- \to u_0 \to u_+$ are called wave operators. This is related to the Bohr's transition in quantum mechanics. Loosely speaking, we are able to prove these scattering properties for high powers in the nonlinearity for subcritical defocusing Schrödinger equations.

The asymptotics of trajectories can be more complicated. Let us recall that the stability of traveling waves is also an important issue in understanding the dynamical properties of these models. For instance, let us point out that Martel and Merle proved the asymptotic stability of the sum of $N$ solitons for KdV in the subcritical case.

Beyond these asymptotics we are interested in the case where the permanent regime is chaotic (or turbulent). A scenario is that there exist quasiperiodic solutions of arbitrarily order $N$ for the system under consideration. The next challenge about these Hamiltonian systems is to apply the Kolmogorov–Arnol'd–Moser theory to exhibit this type of solutions to systems like [17]. Here we restrict our discussion to the case of bounded domains, with either periodic or homogeneous Dirichlet conditions. Then, let us introduce the following definition: a solution is quasiperiodic if there exist a finite number $N$ of frequencies $\omega_k$ such that

$$u(t, x) = \sum_{l=1}^{N} u_l(x) \exp(\mathrm{i}\omega_k t) \quad [21]$$

This extends the case of periodic solutions ($N = 1$), which are isomorphic to the torus. To prove the existence of such structures, one idea is then to imbed $N$-dimensional invariant tori into the phase space of solutions. One may approximate the infinite-dimensional Hamiltonian by a sequence of finite ones and consider the convergence of iterated symplectic transformations, or one solves directly some nonlinear functional equation. Actually, the difficulty is that resonances can occur. Resonances occur when there are some linear combinations of the frequencies that vanish (or that are arbitrarily close to 0). This introduces a small divisor problem in a phase space that has infinite dimension. To overcome these difficulties, a Nash–Moser scheme can be implemented (Craig 1996). There are numerous such open problems. For instance, let us observe that known results are essentially only for the case where the dimension of the ambient space is 1. On the other hand, quasiperiodic solutions correspond to $N$-dimensional invariant tori for the flow of solutions; one may seek for Lagrangian invariant tori that correspond to the case where $N = +\infty$. Current research is directed towards extending this analysis.

Another issue is to seek invariant measures for these Hamiltonian dynamical systems, as in statistical mechanics. Bourgain was successful in performing this analysis for some nonlinear Schrödinger equations either in the case of periodic boundary conditions or in the whole space. This result is an important step in the ergodic analysis of our Hamiltonian dynamical systems. This could explain the Poincaré recurrence phenomena observed numerically for these types of equations: some particular solutions seem to come back to their initial state after a transient time. This point will not be developed here.

All these results are properties of conservative dynamical systems. We now address the case when some dissipation takes place.

## Dissipative Water-Wave Models

To model the effect of viscosity on 2D surface water waves, we go back to a flow governed by the Navier–Stokes equations and we proceed to obtain damped equations (Ott and Sudan 1970, Kakutani and Matsuuchi 1975). In fact, the damping in KdV equations can be either a diffusion term that leads to study the equation

$$u_t + u_{xxx} + uu_x = \nu u_{xx} \quad [22]$$

where $\nu$ is a positive number analogous to the viscosity, or a zero-order term $-\nu u$ on the right-hand side of [22]. In the first case, we obtain a KdV–Burgers equation that has some smoothing effect in time. In the second case, we have a zero-order dissipation term. A nonlocal term would be $\nu\mathcal{F}^{-1}(|\xi|^{2\beta}\hat{u}(\xi))$ for $\beta \in [0, 1]$, where $\mathcal{F}(u) = \hat{u}$ denotes the Fourier transform of $u$.

A first issue concerning damped water-wave equations is to estimate the decay rate of the solutions towards the equilibrium (no decay) when $t \to +\infty$. For [22] the ultimate result is that, for initial data $u_0 \in L^1(\mathbb{R}) \cap L^2(\mathbb{R})$, the $L^2$ norm of the solution decays like $t^{-1/4}$ (Amick *et al.* 1989). Energy methods have been developed to handle these problems, as the Shonbeck's splitting method.

The center manifold theory is another approach that is employed in dynamical systems. The aim is to prove the existence of a finite-dimensional manifold that is invariant (in a neighborhood of the origin) by the flow of the solutions and that attracts the other trajectories with high speed. Therefore, this manifold, and the trajectories therein, monitor the decay rate of the solutions towards the origin. The construction of such a manifold relies on splitting properties of the spectrum of the associated linearized operator (Gallay and Wayne 2002). Using a suitable change of variables (that moves the continuous spectrum away from the origin), Gallay and Wayne were able to construct such a manifold in an infinite-dimensional phase space.

Another issue is the understanding of the dynamics for damped–forced water-wave equations as

$$u_t + uu_x + u_{xxx} + \nu u = f(x) \qquad [23]$$

The dynamical system approach is the attractor theory (Temam 1997). Equations such as [23] provide dissipative semigroups $S(t)$ in some energy spaces. The theory has developed for years and we know that these dynamical systems feature global attractors. A global attractor is a compact subset in the energy space under consideration which is invariant by the flow of the solutions and that attracts all the trajectories when $t \to +\infty$. Moreover, if we deal with periodic boundary conditions, this global attractor has finite fractal (or Hausdorff) dimension. This dimension depends on the data concerning $\nu$ and $f$.

Actually, eqn [23] provides semigroups either in $L^2(\mathbb{R}), H^1(\mathbb{R})$, or in $H^2(\mathbb{R})$. These three dynamical systems feature global attractors $\mathcal{A}_0, \mathcal{A}_1, \mathcal{A}_2$. From the viewpoint of physics, the attractors describe the permanent regime of the flow. One may wonder if this permanent regime depends on the space chosen for the mathematical study. Eventually, the last result for this issue establish that $\mathcal{A}_0 = \mathcal{A}_1 = \mathcal{A}_2$. This property is equivalent to prove the asymptotical smoothing effect for the associated semigroup: even if $S(t)$ is not a smoothing operator for finite $t$, then all solutions converge to a smooth set when $t$ goes to the infinity.

All these results are for subcritical nonlinearities. As already noted, dissipation provides smoothing at infinity. Nevertheless, damping does not prevent blow-up. Let us illuminate this by the following result due to Tsutsumi (1984). The damped Schrödinger equation

$$\mathrm{i}u_t + \mathrm{i}\nu u + u_{xx} + |u|^{2p}u = 0 \qquad [24]$$

features blow-up solutions in $H^1(\mathbb{R})$ for $p > 2$, even if all solutions are damped in $L^2(\mathbb{R})$ with exponential speed.

This completes the discussion of damped–forced water-wave equations. We now consider equations that are forced with a random forcing term.

## Stochastic Water-Wave Models

During the modeling process that led to KdV or Schrödinger equations from Euler equation, we have neglected some low-order terms. We now model these terms by a noise and we are led to a new randomly forced dynamical system that reads

$$u_t + u_x + u_{xxx} + uu_x = \gamma\dot{\xi} \qquad [25]$$

Here one may assume that $\xi(x, t)$ is a Gaussian process with correlations

$$\mathbb{E}(\dot{\xi}(x,t)\dot{\xi}(y,s)) = \delta_{x-y}\delta_{t-s} \qquad [26]$$

that is, a spacetime white noise. The parameter $\gamma$ is the amplitude of the process. Unfortunately, due to the lack of smoothing effect of KdV or Schrödinger equations, it is more convenient to work with a noise that is correlated in space, satisfying

$$\mathbb{E}(\dot{\xi}(x,t)\dot{\xi}(y,s)) = c(x-y)\delta_{t-s} \qquad [27]$$

here $c(x - y)$ is some smooth ansatz for $\delta_{x-y}$, defined from some Hilbert–Schmidt kernel $K$ as

$$c(x-y) = \int_{\mathbb{R}} K(x,z)K(y,z)\,\mathrm{d}z$$

We also consider random perturbation of focusing Schrödinger equation, which reads either

$$u_t + \mathrm{i}u_{xx} + \mathrm{i}|u|^{2p}u = u\dot{\xi} \qquad [28]$$

(which represents a multiplicative noise) or

$$u_t + \mathrm{i}u_{xx} + \mathrm{i}|u|^{2p}u = \mathrm{i}\gamma\dot{\xi} \qquad [29]$$

(which is an additive noise). In the former case, the noise acts as a potential, while in the latter case it represents a forcing term. These equations also model the propagation of waves in an inhomogeneous medium.

Research is in progress to study these stochastic dynamical systems. To begin with, the theory of the

initial-value problem has to be established in this new context (see, e.g., de Bouard and Debussche (2003)).

One challenge is to understand the effect of noise on dynamical properties of the particular solutions described above, for instance, the solitary waves for Schrödinger equation, either in the subcritical case $p < 2$ or in the critical case $p = 2$ and beyond.

Results obtained both theoretically and numerically on the influence of the noise on blow-up phenomena (random process) for generalized Schrödinger equations are likely almost-sure results.

On the one hand, if the noise is additive and the power supercritical, $p > 1$, there is some numerical evidence that a spacetime white noise can delay or even prevent the blow-up. However, if the noise is not so irregular (as for the correlated in space noise described above) it seems that any solution blows up in finite time.

de Bouard and Debussche have proved that for either an additive or a multiplicative noise, any smooth and localized (in space) initial data give rise to a trajectory that collapses in arbitrarily small time with a positive probability. This contrasts with the deterministic case, where only particular initial data could lead to blow-up trajectories. Actually, the noise enforces that any trajectory must pass through this blow-up region, with a positive probability.

## Effective Field Theories

**G Ecker**, Universität Wien, Vienna, Austria

### Introduction

Effective field theories (EFTs) are the counterpart of the "theory of everything." They are the field theoretical implementation of the quantum ladder: heavy degrees of freedom need not be included among the quantum fields of an EFT for a description of low-energy phenomena. For example, we do not need quantum gravity to understand the hydrogen atom nor does chemistry depend upon the structure of the electromagnetic interaction of quarks.

EFTs are approximations by their very nature. Once the relevant degrees of freedom for the problem at hand have been established, the corresponding EFT is usually treated perturbatively. It does not make much sense to search for an exact solution of the Fermi theory of weak interactions. In the same spirit, convergence of the perturbative expansion in the mathematical sense is not an issue. The asymptotic nature of the expansion becomes apparent once the accuracy is reached where effects of the underlying "fundamental" theory cannot be neglected any longer. The range of applicability of the perturbative expansion depends on the separation of energy scales that define the EFT.

EFTs pervade much of modern physics. The effective nature of the description is evident in atomic and condensed matter physics. The present article will be restricted to particle physics, where EFTs have become important tools during the last 25 years.

### Classification of EFTs

A first classification of EFTs is based on the structure of the transition from the "fundamental" (energies $> \Lambda$) to the "effective" level (energies $< \Lambda$).

1. *Complete decoupling* The fundamental theory contains heavy and light degrees of freedom. Under very general conditions (decoupling theorem, Appelquist and Carazzone 1975) the effective Lagrangian for energies $\ll \Lambda$, depending only on light fields, takes the form

$$\mathcal{L}_{\text{eff}} = \mathcal{L}_{d\leq 4} + \sum_{d>4} \frac{1}{\Lambda^{d-4}} \sum_{i_d} g_{i_d} O_{i_d} \qquad [1]$$

The heavy fields with masses $> \Lambda$ have been "integrated out" completely. $\mathcal{L}_{d\leq 4}$ contains the potentially renormalizable terms with operator dimension $d \leq 4$ (in natural mass units where Bose and Fermi fields have $d = 1$ and 3/2, respectively), the $g_{i_d}$ are coupling constants and the $O_{i_d}$ are monomials in the light fields with operator dimension $d$. In a slightly misleading notation, $\mathcal{L}_{d\leq 4}$ consists of relevant and marginal operators, whereas the $O_{i_d}$ $(d > 4)$ are denoted irrelevant operators. The scale $\Lambda$ can be the mass of a heavy field (e.g., $M_W$ in the Fermi theory of weak interactions) or it reflects the short-distance structure in a more indirect way.

2. *Partial decoupling* In contrast to the previous case, the heavy fields do not disappear completely from the EFT but only their high-momentum modes are integrated out. The main area of application is the physics of heavy quarks. The procedure involves one or several field redefinitions introducing a frame dependence. Lorentz invariance is not manifest but implies relations between coupling constants of the EFT (reparametrization invariance).

3. *Spontaneous symmetry breaking* The transition from the fundamental to the effective level occurs via a phase transition due to spontaneous symmetry breaking generating (pseudo-)Goldstone bosons. A spontaneously broken symmetry relates processes with different numbers of Goldstone bosons. Therefore, the distinction between renormalizable ($d \leq 4$) and nonrenormalizable ($d > 4$) parts in the effective Lagrangian [1] becomes meaningless. The effective Lagrangian of type 3 is generically nonrenormalizable. Nevertheless, such Lagrangians define perfectly consistent quantum field theories at sufficiently low energies. Instead of the operator dimension as in [1], the number of derivatives of the fields and the number of symmetry-breaking

insertions distinguish successive terms in the Lagrangian. The general structure of effective Lagrangians with spontaneously broken symmetries is largely independent of the specific physical realization (universality). There are many examples in condensed matter physics, but the two main applications in particle physics are electroweak symmetry breaking and chiral perturbation theory (both discussed later) with the spontaneously broken global chiral symmetry of quantum chromodynamics QCD.

Another classification of EFTs is related to the status of their coupling constants.

A. *Coupling constants can be determined by matching the EFT with the underlying theory at short distances*. The underlying theory is known and Green functions can be calculated perturbatively at energies $\sim\Lambda$ both in the fundamental and in the effective theory. Identifying a minimal set of Green functions fixes the coupling constants $g_{i_d}$ in eqn [1] at the scale $\Lambda$. Renormalization group equations can then be used to run the couplings down to lower scales. The nonrenormalizable terms in the Lagrangian [1] can be fully included in the perturbative analysis.
B. *Coupling constants are constrained by symmetries only*.
   - The underlying theory and therefore also the EFT coupling constants are unknown. This is the case of the standard model (SM) (see the next section). A perturbative analysis beyond leading order only makes sense for the known renormalizable part $\mathcal{L}_{d\leq 4}$. The nonrenormalizable terms suppressed by powers of $\Lambda$ are considered at tree level only. The associated coupling constants $g_{i_d}$ serve as bookmarks for new physics. Usually, but not always (cf., e.g., the subsection "Noncommutative spacetime"), the symmetries of $\mathcal{L}_{d\leq 4}$ are assumed to constrain the couplings.
   - The matching cannot be performed in perturbation theory even though the underlying theory is known. This is the generic situation for EFTs of type 3 involving spontaneous symmetry breaking. The prime example is chiral perturbation theory as the EFT of QCD at low energies.

## The SM as an EFT

With the possible exception of the scalar sector to be discussed in the subsection "Electroweak symmetry breaking" the SM is very likely the renormalizable part of an EFT of type 1B. Except for nonzero neutrino masses, the SM Lagrangian $\mathcal{L}_{d\leq 4}$ in [1] accounts for physics up to energies of roughly the Fermi scale $G_F^{-1/2} \simeq 300\,\text{GeV}$.

Since the SM works exceedingly well up to the Fermi scale where the electroweak gauge symmetry is spontaneously broken it is natural to assume that the operators $O_{i_d}$ with $d > 4$, made up from fields representing the known degrees of freedom and including a single Higgs doublet in the SM proper, should be gauge invariant with respect to the full SM gauge group $SU(3)_c \times SU(2)_L \times U(1)_Y$. An almost obvious constraint is Lorentz invariance that will be lifted in the next subsection, however.

These requirements limit the Lagrangian with operator dimension $d = 5$ to a single term (except for generation multiplicity), consisting only of a left-handed lepton doublet $L_L$ and the Higgs doublet $\Phi$:

$$O_{d=5} = \epsilon_{ij}\epsilon_{kl} L_{iL}^{\top} C^{-1} L_{kL} \Phi_j \Phi_l + \text{h.c.} \qquad [2]$$

This term violates lepton number and generates nonzero Majorana neutrino masses. For a neutrino mass of 1 eV, the scale $\Lambda$ would have to be of the order of $10^{13}$ GeV if the associated coupling constant in the EFT Lagrangian [1] is of order 1.

In contrast to the simplicity for $d = 5$, the list of gauge-invariant operators with $d = 6$ is enormous. Among them are operators violating baryon or lepton number that must be associated with a scale much larger than 1 TeV. To explore the territory close to present energies, it therefore makes sense to impose baryon and lepton number conservation on the operators with $d = 6$. Those operators have all been classified (Buchmüller and Wyler 1986) and the number of independent terms is of the order of 80. They can be grouped in three classes.

The first class consists of gauge and Higgs fields only. The corresponding EFT Lagrangian has been used to parametrize new physics in the gauge sector constrained by precision data from LEP. The second class consists of operators bilinear in fermion fields, with additional gauge and Higgs fields to generate $d = 6$. Finally, there are four-fermion operators without other fields or derivatives. Some of the operators in the last two groups are also constrained by precision experiments, with a certain hierarchy of limits. For lepton and/or quark flavor conserving terms, the best limits on $\Lambda$ are in the few TeV range, whereas the absence of neutral flavor changing processes yields lower bounds on $\Lambda$ that are several orders of magnitude larger. If there is new physics in the TeV range flavor changing neutral transitions must be strongly suppressed, a powerful constraint on model building.

It is amazing that the most general renormalizable Lagrangian with the given particle content accounts

for almost all experimental results in such an impressive manner. Finally, we recall that many of the operators of dimension 6 are also generated in the SM via radiative corrections. A necessary condition for detecting evidence for new physics is therefore that the theoretical accuracy of radiative corrections matches or surpasses the experimental precision.

### Noncommutative Spacetime

Noncommutative geometry arises in some string theories and may be expected on general grounds when incorporating gravity into a quantum field theory framework. The natural scale of noncommutative geometry would be the Planck scale in this case without observable consequences at presently accessible energies. However, as in theories with large extra dimensions the characteristic scale $\Lambda_{NC}$ could be significantly smaller. In parallel to theoretical developments to define consistent noncommutative quantum field theories (short for quantum field theories on noncommutative spacetime), a number of phenomenological investigations have been performed to put lower bounds on $\Lambda_{NC}$.

Noncommutative geometry is a deformation of ordinary spacetime where the coordinates, represented by Hermitian operators $\hat{x}_\mu$, do not commute:

$$\left[\hat{x}_\mu, \hat{x}_\nu\right] = \mathrm{i}\theta_{\mu\nu} \qquad [3]$$

The antisymmetric real tensor $\theta_{\mu\nu}$ has dimensions length$^2$ and it can be interpreted as parametrizing the resolution with which spacetime can be probed. In practically all applications, $\theta_{\mu\nu}$ has been assumed to be a constant tensor and we may associate an energy scale $\Lambda_{NC}$ with its nonzero entries:

$$\Lambda_{NC}^{-2} \sim \theta_{\mu\nu} \qquad [4]$$

There is to date no unique form for the noncommutative extension of the SM. Nevertheless, possible observable effects of noncommutative geometry have been investigated. Not unexpected from an EFT point of view, for energies $\ll \Lambda_{NC}$, noncommutative field theories are equivalent to ordinary quantum field theories in the presence of nonstandard terms containing $\theta_{\mu\nu}$ (Seiberg–Witten map). Practically all applications have concentrated on effects linear in $\theta_{\mu\nu}$.

Kinetic terms in the Lagrangian are in general unaffected by the noncommutative structure. New effects arise therefore mainly from renormalizable $d = 4$ interactions terms. For example, the Yukawa coupling $g_Y \bar{\psi}\psi\phi$ generates the following interaction linear in $\theta_{\mu\nu}$:

$$\mathcal{L}_Y^{NC} = g_Y \theta_{\mu\nu}\left(\partial^\mu\bar{\psi}\partial^\nu\psi\phi + \partial^\mu\bar{\psi}\psi\partial^\nu\phi + \bar{\psi}\partial^\mu\psi\partial^\nu\phi\right) \qquad [5]$$

These interaction terms have operator dimension 6 and they are suppressed by $\theta_{\mu\nu} \sim \Lambda_{NC}^{-2}$. The major difference to the previous discussion on physics beyond the SM is that there is an intrinsic violation of Lorentz invariance due to the constant tensor $\theta_{\mu\nu}$. In contrast to the previous analysis, the terms with dimension $d > 4$ do not respect the symmetries of the SM.

If $\theta_{\mu\nu}$ is indeed constant over macroscopic distances, many tests of Lorentz invariance can be used to put lower bounds on $\Lambda_{NC}$. Among the exotic effects investigated are modified dispersion relations for particles, decay of high-energy photons, charged particles producing Cerenkov radiation in vacuum, birefringence of radiation, a variable speed of light, etc. A generic signal of noncommutativity is the violation of angular momentum conservation that can be searched for at the Large Hadron Collider (LHC) and at the next linear collider.

Lacking a unique noncommutative extension of the SM, unambiguous lower bounds on $\Lambda_{NC}$ are difficult to establish. However, the range $\Lambda_{NC} \lesssim 10\,\mathrm{TeV}$ is almost certainly excluded. An estimate of the induced electric dipole moment of the electron (noncommutative field theories violate CP in general to first order in $\theta_{\mu\nu}$) yields $\Lambda_{NC} \gtrsim 100\,\mathrm{TeV}$. On the other hand, if the SM were CP invariant, noncommutative geometry would be able to account for the observed CP violation in $K^0 - \overline{K^0}$ mixing for $\Lambda_{NC} \sim 2\,\mathrm{TeV}$.

### Electroweak Symmetry Breaking

In the SM, electroweak symmetry breaking is realized in the simplest possible way through renormalizable interactions of a scalar Higgs doublet with gauge bosons and fermions, a gauged version of the linear $\sigma$ model.

The EFT version of electroweak symmetry breaking (EWEFT) uses only the experimentally established degrees of freedom in the SM (fermions and gauge bosons). Spontaneous gauge symmetry breaking is realized nonlinearly, without introducing additional scalar degrees of freedom. It is a low-energy expansion where energies and masses are assumed to be small compared to the symmetry-breaking scale. From both perturbative and nonperturbative arguments we know that this scale cannot be much bigger than 1 TeV. The Higgs model can be viewed as a specific example of an EWEFT as long as the Higgs boson is not too light (heavy-Higgs scenario).

The lowest-order effective Lagrangian takes the following form:

$$\mathcal{L}_{EWSB}^{(2)} = \mathcal{L}_B + \mathcal{L}_F \qquad [6]$$

where $\mathcal{L}_F$ contains the gauge-invariant kinetic terms for quarks and leptons including mass terms. In addition to the kinetic terms for the gauge bosons $\boldsymbol{W}_\mu, B_\mu$, the bosonic Lagrangian $\mathcal{L}_B$ contains the characteristic lowest-order term for the would-be-Goldstone bosons:

$$\mathcal{L}_B = \mathcal{L}_{\text{gauge}}^{\text{kin}} + \frac{v^2}{4}\langle D_\mu U^\dagger D^\mu U\rangle \qquad [7]$$

with the gauge-covariant derivative

$$\begin{aligned} D_\mu U &= \partial_\mu U - \mathrm{i}gW_\mu U + \mathrm{i}g' U\hat{B}_\mu \\ W_\mu &= \frac{\vec{\tau}}{2}\boldsymbol{W}_\mu, \qquad \hat{B}_\mu = \frac{\tau_3}{2}B_\mu \end{aligned} \qquad [8]$$

where $\langle\ldots\rangle$ denotes a (two-dimensional) trace. The matrix field $U(\phi)$ carries the nonlinear representation of the spontaneously broken gauge group and takes the value $U = \mathbb{1}$ in the unitary gauge. The Lagrangian [6] is invariant under local $SU(2)_L \times U(1)_Y$ transformations:

$$\begin{aligned} W_\mu &\to g_L W_\mu g_L^\dagger + \frac{\mathrm{i}}{g} g_L \partial_\mu g_L^\dagger \\ \hat{B}_\mu &\to \hat{B}_\mu + \frac{\mathrm{i}}{g'} g_R \partial_\mu g_R^\dagger \\ f_L &\to g_L f_L, \quad f_R \to g_R f_R, \quad U \to g_L U g_R^\dagger \end{aligned} \qquad [9]$$

with

$$\begin{aligned} g_L(x) &= \exp(\mathrm{i}\vec{\alpha}_L(x)\vec{\tau}/2) \\ g_R(x) &= \exp(\mathrm{i}\alpha_Y(x)\tau_3/2) \end{aligned}$$

and $f_{L(R)}$ are quark and lepton fields grouped in doublets.

As is manifest in the unitary gauge $U = \mathbb{1}$, the lowest-order Lagrangian of the EWEFT just implements the tree-level masses of gauge bosons ($M_W = M_Z \cos\theta_W = vg/2$, $\tan\theta_W = g'/g$) and fermions but does not carry any further information about the underlying mechanism of spontaneous gauge symmetry breaking. This information is first encoded in the couplings $a_i$ of the next-to-leading-order Lagrangian

$$\mathcal{L}_{\text{EWSB}}^{(4)} = \sum_{i=0}^{14} a_i O_i \qquad [10]$$

with monomials $O_i$ of $O(p^4)$ in the low-energy expansion. The Lagrangian [10] is the most general CP and $SU(2)_L \times U(1)_Y$ invariant Lagrangian of $O(p^4)$.

Instead of listing the full Lagrangian, we display three typical examples:

$$\begin{aligned} O_0 &= \frac{v^2}{4}\langle TV_\mu\rangle^2 \\ O_3 &= -g\langle W_{\mu\nu}[V^\mu, V^\nu]\rangle \\ O_5 &= \langle V_\mu V^\mu\rangle^2 \end{aligned} \qquad [11]$$

where

$$\begin{aligned} T &= U\tau_3 U^\dagger, \qquad V_\mu = D_\mu U U^\dagger \\ W_{\mu\nu} &= \frac{\mathrm{i}}{g}[\partial_\mu - \mathrm{i}gW_\mu, \partial_\nu - \mathrm{i}gW_\nu] \end{aligned} \qquad [12]$$

In the unitary gauge, the monomials $O_i$ reduce to polynomials in the gauge fields. The three examples in eqn [11] start with quadratic, cubic, and quartic terms in the gauge fields, respectively. The strongest constraints exist for the coefficients of quadratic contributions from the Large Electron–Positron collider LEP1, less restrictive ones for the cubic self-couplings from LEP2, and none so far for the quartic ones.

## Heavy-Quark Physics

EFTs in this section are derived from the SM and they are of type 2A in the classification introduced previously. In a first step, one integrates out $W$, $Z$, and top quark. Evolving down from $M_W$ to $m_b$, large logarithms $\alpha_s(m_b)\ln(M_W^2/m_b^2)$ are resummed into the Wilson coefficients. At the scale of the $b$-quark, QCD is still perturbative, so that at least a part of the amplitudes is calculable in perturbation theory. To separate the calculable part from the rest, the EFTs below perform an expansion in $1/m_Q$, where $m_Q$ is the mass of the heavy quark.

Heavy-quark EFTs offer several important advantages.

1. Approximate symmetries that are hidden in full QCD appear in the expansion in $1/m_Q$.
2. Explicit calculations simplify in general, for example, the summing of large logarithms via renormalization group equations.
3. The systematic separation of hard and soft effects for certain matrix elements (factorization) can be achieved much more easily.

### Heavy-Quark Effective Theory

Heavy-quark effective theory (HQET) is reminiscent of the Foldy–Wouthuysen transformation (nonrelativistic expansion of the Dirac equation). It is a systematic expansion in $1/m_Q$, when $m_Q \gg \Lambda_{QCD}$, the scale parameter of QCD. It can be applied to processes where the heavy quark remains essentially on shell: its velocity $v$ changes only by small amounts $\sim\Lambda_{QCD}/m_Q$. In the hadron rest frame, the heavy quark is almost at rest and acts as a quasistatic source of gluons.

More quantitatively, one writes the heavy-quark momentum as $p^\mu = m_Q v^\mu + k^\mu$, where $v$ is the hadron 4-velocity ($v^2 = 1$) and $k$ is a residual

momentum of $O(\Lambda_{QCD})$. The heavy quark field $Q(x)$ is then decomposed with the help of energy projectors $P_v^{\pm} = (1 \pm \not{v})/2$ and employing a field redefinition:

$$\begin{aligned} Q(x) &= e^{-im_Q v \cdot x}(h_v(x) + H_v(x)) \\ h_v(x) &= e^{im_Q v \cdot x} P_v^+ Q(x) \\ H_v(x) &= e^{im_Q v \cdot x} P_v^- Q(x) \end{aligned} \qquad [13]$$

In the hadron rest frame, $h_v(x)$ and $H_v(x)$ correspond to the upper and lower components of $Q(x)$, respectively. With this redefinition, the heavy-quark Lagrangian is expressed in terms of a massless field $h_v$ and a "heavy" field $H_v$:

$$\begin{aligned} \mathcal{L}_Q &= \bar{Q}(i\not{D} - m_Q)Q \\ &= \overline{h_v}\, iv \cdot D\, h_v - \overline{H_v}(iv \cdot D + 2m_Q)H_v \\ &\quad + \text{mixed terms} \end{aligned} \qquad [14]$$

At the semiclassical level, the field $H_v$ can be eliminated by using the QCD field equation $(i\not{D} - m_Q)Q = 0$ yielding the nonlocal expression

$$\mathcal{L}_Q = \overline{h_v} iv \cdot D h_v + \overline{h_v}\, i\not{D}_\perp \frac{1}{iv \cdot D + 2m_Q - i\epsilon} i\not{D}_\perp h_v \qquad [15]$$

with $D_\perp^\mu = (g^{\mu\nu} - v^\mu v^\nu)D_\nu$. The field redefinition in [13] ensures that, in the heavy-hadron rest frame, derivatives of $h_v$ give rise to small momenta of $O(\Lambda_{QCD})$ only. The Lagrangian [15] is the starting point for a systematic expansion in $m_Q$.

To leading order in $1/m_Q (Q = b, c)$, the Lagrangian

$$\mathcal{L}_{b,c} = \overline{b_v}\, iv \cdot D\, b_v + \overline{c_v} iv \cdot D c_v \qquad [16]$$

exhibits two important approximate symmetries of HQET: the flavor symmetry $SU(2)_F$ relating heavy quarks moving with the same velocity and the heavy-quark spin symmetry generating an overall SU(4) spin-flavor symmetry. The flavor symmetry is obvious and the spin symmetry is due to the absence of Dirac matrices in [16]: both spin degrees of freedom couple to gluons in the same way. The simplest spin-symmetry doublet consists of a pseudoscalar meson $H$ and the associated vector meson $H^*$. Denoting the doublet by $\mathcal{H}$, the matrix elements of the heavy-to-heavy transition current are determined to leading order in $1/m_Q$ by a single form factor, up to Clebsch–Gordan coefficients:

$$\langle \mathcal{H}(v') | \overline{h_{v'}} \Gamma h_v | \mathcal{H}(v) \rangle \sim \xi(v \cdot v') \qquad [17]$$

$\Gamma$ is an arbitrary combination of Dirac matrices and the form factor $\xi$ is the so-called Isgur–Wise function. Moreover, since $\overline{h_v}\gamma^\mu h_v$ is the Noether current of heavy-flavor symmetry, the Isgur–Wise function is fixed in the no-recoil limit $v' = v$ to be $\xi(v \cdot v' = 1) = 1$. The semileptonic decays $B \to Dl\nu_l$ and $B \to D^* l\nu_l$ are therefore governed by a single normalized form factor to leading order in $1/m_Q$, with important consequences for the determination of the Cabibbo–Kobayashi–Maskawa (CKM) matrix element $V_{cb}$.

The HQET Lagrangian is superficially frame dependent. Since the SM is Lorentz invariant, the HQET Lagrangian must be independent of the choice of the frame vector $v$. Therefore, a shift in $v$ accompanied by corresponding shifts of the fields $h_v$ and of the covariant derivatives must leave the Lagrangian invariant. This reparametrization invariance is unaffected by renormalization and it relates coefficients with different powers in $1/m_Q$.

### Soft-Collinear Effective Theory

HQET is not applicable in heavy-quark decays where some of the light particles in the final state have momenta of $O(m_Q)$, for example, for inclusive decays like $B \to X_s\gamma$ or exclusive ones like $B \to \pi\pi$. In recent years, a systematic heavy-quark expansion for heavy-to-light decays has been set up in the form of soft-collinear effective theory (SCET).

SCET is more complicated than HQET because now the low-energy theory involves more than one scale. In the SCET Lagrangian, a light quark or gluon field is represented by several effective fields. In addition to the soft fields $h_v$ in [15], the so-called collinear fields enter that have large energy and carry large momentum in the direction of the light hadrons in the final state.

In addition to the frame vector $v$ of HQET ($v = (1, 0, 0, 0)$ in the heavy-hadron rest frame), SCET introduces a lightlike reference vector $n$ in the direction of the jet of energetic light particles (for inclusive decays), for example, $n = (1, 0, 0, 1)$. All momenta $p$ are decomposed in terms of light-cone coordinates $(p_+, p_-, p_\perp)$ with

$$p^\mu = \frac{n \cdot p}{2}\bar{n}^\mu + \frac{\bar{n} \cdot p}{2} n^\mu + p_\perp^\mu = p_+^\mu + p_-^\mu + p_\perp^\mu \qquad [18]$$

where $\bar{n} = 2v - n = (1, 0, 0, -1)$. For large energies, the three light-cone components are widely separated, with $p_- = O(m_Q)$ being large while $p_\perp$ and $p_+$ are small. Introducing a small parameter $\lambda \sim p_\perp/p_-$, the light-cone components of (hard-)collinear particles scale like $(p_+, p_-, p_\perp) = m_Q(\lambda^2, 1, \lambda)$. Thus, there are three different scales in the problem compared to only two in HQET. For exclusive decays, the situation is even more involved.

The SCET Lagrangian is obtained from the full theory by an expansion in powers of $\lambda$. In addition to the heavy quark field $h_v$, one introduces soft as well as collinear quark and gluon fields by field

redefinitions so that the various fields have momentum components that scale appropriately with $\lambda$.

Similar to HQET, the leading-order Lagrangian of SCET exhibits again approximate symmetries that can lead to a reduction of form factors describing heavy-to-light decays. As in HQET, reparametrization invariance implements Lorentz invariance and results in stringent constraints on subleading corrections in SCET.

An important result of SCET is the proof of factorization theorems to all orders in $\alpha_s$. For inclusive decays, the differential rate is of the form

$$\mathrm{d}\Gamma \sim HJ \times S \qquad [19]$$

where $H$ contains the hard corrections. The so-called jet function $J$ sensitive to the collinear region is convoluted with the shape function $S$ representing the soft contributions. At leading order, the shape function drops out in the ratio of weighted decay spectra for $B \to X_u l \nu_l$ and $B \to X_s \gamma$ allowing for a determination of the CKM matrix element $V_{ub}$. Factorization theorems have become available for an increasing number of processes, most recently also for exclusive decays of $B$ into two light mesons.

#### Nonrelativistic QCD

In HQET the kinetic energy of the heavy quark appears as a small correction of $O(\Lambda^2_{\mathrm{QCD}}/m_Q)$. For systems with more than one heavy quark, the kinetic energy cannot be treated as a perturbation in general. For instance, the virial theorem implies that the kinetic energy in quarkonia $\bar{Q}Q$ is of the same order as the binding energy of the bound state.

NRQCD, the EFT for heavy quarkonia, is an extension of HQET. The Lagrangian for NRQCD coincides with HQET in the bilinear sector of the heavy-quark fields but it also includes quartic interactions between quarks and antiquarks. The relevant expansion parameter in this case is the relative velocity between $Q$ and $\bar{Q}$. In contrast to HQET, there are at least three widely separate scales in heavy quarkonia: in addition to $m_Q$, the relative momentum of the bound quarks $p \sim m_Q v$ with $v \ll 1$ and the typical kinetic energy $E \sim m_Q v^2$. The main challenges are to derive the quark–antiquark potential directly from QCD and to describe quarkonium production and decay at collider experiments. In the abelian case, the corresponding EFT for quantum electrodynamics (QED) is called NRQED that has been used to study electromagnetically bound systems like the hydrogen atom, positronium, muonium, etc.

In NRQCD only the hard degrees of freedom with momenta $\sim m_Q$ are integrated out. Therefore, NRQCD is not enough for a systematic computation of heavy-quarkonium properties. Because the nonrelativistic fluctuations of order $m_Q v$ and $m_Q v^2$ have not been separated, the power counting in NRQCD is ambiguous in higher orders.

To overcome those deficiencies, two approaches have been put forward: potential NRQCD (pNRQCD) and velocity NRQCD (vNRQCD). In pNRQCD, a two-step procedure is employed for integrating out quark and gluon degrees of freedom:

$$\begin{array}{cc} \mathrm{QCD} & \Lambda > m_Q \\ \Downarrow & \\ \mathrm{NRQCD} & m_Q > \Lambda > m_Q v \\ \Downarrow & \\ \mathrm{pNRQCD} & m_Q v > \Lambda > m_Q v^2 \end{array}$$

The resulting EFT derives its name from the fact that the four-quark interactions generated in the matching procedure are the potentials that can be used in Schrödinger perturbation theory. It is claimed that pNRQCD can also be used in the nonperturbative domain where $\alpha_s(m_Q v^2)$ is of order 1 or larger. The advantage would be that also charmonium becomes accessible to a systematic EFT analysis.

The alternative approach of vNRQCD is only applicable in the fully perturbative regime when $m_Q \gg m_Q v \gg m_Q v^2 \gg \Lambda_{\mathrm{QCD}}$ is valid. It separates the different degrees of freedom in a single step leaving only ultrasoft energies and momenta of $O(m_Q v^2)$ as continuous variables. The separation of larger scales proceeds in a similar fashion as in HQET via field redefinitions. A systematic nonrelativistic power counting in the velocity $v$ is implemented.

### The Standard Model at Low Energies

At energies below 1 GeV, hadrons – rather than quarks and gluons – are the relevant degrees of freedom. Although the strong interactions are highly nonperturbative in the confinement region, Green functions and amplitudes are amenable to a systematic low-energy expansion. The key observation is that the QCD Lagrangian with $N_f = 2$ or 3 light quarks,

$$\begin{aligned} \mathcal{L}_{\mathrm{QCD}} &= \bar{q}\big(\mathrm{i}\not{D} - \mathcal{M}_q\big)q - \tfrac{1}{4}G^{\alpha}_{\mu\nu}G^{\alpha\mu\nu} + \mathcal{L}_{\text{heavy quarks}} \\ &= \overline{q_{\mathrm{L}}}\mathrm{i}\not{D}q_{\mathrm{L}} + \overline{q_{\mathrm{R}}}\mathrm{i}\not{D}q_{\mathrm{R}} - \overline{q_{\mathrm{L}}}\mathcal{M}_q q_{\mathrm{R}} \\ &\quad - \overline{q_{\mathrm{R}}}\mathcal{M}_q q_{\mathrm{L}} + \cdots \\ q_{\mathrm{R,L}} &= \tfrac{1}{2}(1 \pm \gamma_5)q, \quad q^{\top} = (ud[s]) \end{aligned} \qquad [20]$$

exhibits a global symmetry

$$\underbrace{\mathrm{SU}(N_f)_{\mathrm{L}} \times \mathrm{SU}(N_f)_{\mathrm{R}}}_{\text{chiral group } G} \times \mathrm{U}(1)_{\mathrm{V}} \times \mathrm{U}(1)_{\mathrm{A}} \qquad [21]$$

in the limit of $N_f$ massless quarks ($\mathcal{M}_q = 0$). At the hadronic level, the quark number symmetry $U(1)_V$ is realized as baryon number. The axial $U(1)_A$ is not a symmetry at the quantum level due to the abelian anomaly.

Although not yet derived from first principles, there are compelling theoretical and phenomenological arguments that the ground state of QCD is not even approximately chirally symmetric. All evidence, such as the existence of relatively light pseudoscalar mesons, points to spontaneous chiral symmetry breaking $G \to SU(N_f)_V$, where $SU(N_f)_V$ is the diagonal subgroup of $G$. The resulting $N_f^2 - 1$ (pseudo-)Goldstone bosons interact weakly at low energies. In fact, Goldstone's theorem ensures that purely mesonic or single-baryon amplitudes vanish in the chiral limit ($\mathcal{M}_q = 0$) when the momenta of all pseudoscalar mesons tend to zero. This is the basis for a systematic low-energy expansion of Green functions and amplitudes. The corresponding EFT (type 3B in our classification) is called chiral perturbation theory (CHPT) (Weinberg 1979, Gasser and Leutwyler 1984, 1985).

Although the construction of effective Lagrangians with nonlinearly realized chiral symmetry is well understood, there are some subtleties involved. First of all, there may be terms in a chiral-invariant action that cannot be written as the four-dimensional integral of an invariant Lagrangian. The chiral anomaly for $SU(3) \times SU(3)$ bears witness of this fact and gives rise to the Wess–Zumino–Witten action. A general theorem to account for such exceptional cases is due to D'Hoker and Weinberg (1994). Consider the most general action for Goldstone fields with symmetry group $G$, spontaneously broken to a subgroup $H$. The only possible non-$G$-invariant terms in the Lagrangian that give rise to a $G$-invariant action are in one-to-one correspondence with the generators of the fifth cohomology group $\mathcal{H}^5(G/H; \mathbb{R})$ of the coset manifold $G/H$. For the relevant case of chiral $SU(N)$, the coset space $SU(N)_L \times SU(N)_R / SU(N)_V$ is itself an $SU(N)$ manifold. For $N \geq 3, \mathcal{H}^5(SU(N); \mathbb{R})$ has a single generator that corresponds precisely to the Wess–Zumino–Witten term.

At a still deeper level, one may ask whether chiral-invariant Lagrangians are sufficient (except for the anomaly) to describe the low-energy structure of Green functions as dictated by the chiral Ward identities of QCD. To be able to calculate such Green functions in general, the global chiral symmetry of QCD is extended to a local symmetry by the introduction of external gauge fields. The following invariance theorem (Leutwyler 1994) provides an answer to the above question. Except for the anomaly, the most general solution of the Ward identities for a spontaneously broken symmetry in Lorentz-invariant theories can be obtained from gauge-invariant Lagrangians to all orders in the low-energy expansion. The restriction to Lorentz invariance is crucial: the theorem does not hold in general in nonrelativistic effective theories.

### Chiral Perturbation Theory

The effective chiral Lagrangian of the SM in the meson sector is displayed in Table 1. The lowest-order Lagrangian for the purely strong interactions is given by

$$\mathcal{L}_{p^2} = \frac{F^2}{4}\langle D_\mu U D^\mu U^\dagger \rangle + \frac{F^2 B}{2}\langle (s + ip)U^\dagger + (s - ip)U \rangle \qquad [22]$$

with a covariant derivative $D = \partial_\mu U - i(v_\mu + a_\mu)U + iU(v_\mu - a_\mu)$. The first term has the familiar form [7] of the gauged nonlinear $\sigma$ model, with the matrix field $U(\phi)$ transforming as $U \to g_R U g_L^\dagger$ under chiral rotations. External fields $v_\mu, a_\mu, s, p$ are introduced for constructing the generating functional of Green functions of quark currents. To implement explicit chiral symmetry breaking, the scalar field $s$ is set equal to the quark mass matrix $\mathcal{M}_q$ at the end of the calculation.

The leading-order Lagrangian has two free parameters $F$, $B$ related to the pion decay constant and to the quark condensate, respectively:

$$F_\pi = F\left[1 + O(m_q)\right]$$
$$\langle 0|\bar{u}u|0\rangle = -F^2 B\left[1 + O(m_q)\right] \qquad [23]$$

The Lagrangian [22] gives rise to $M_\pi^2 = B(m_u + m_d)$ at lowest order. From detailed studies of pion–pion scattering (Colangelo *et al.* 2001), we know that the leading term accounts for at least 94% of the pion mass. This supports the standard counting of CHPT,

**Table 1** The effective chiral Lagrangian of the SM in the meson sector

| $\mathcal{L}_{\text{chiral order}}$ (# *of LECs*) | *Loop order* |
|---|---|
| $\mathcal{L}_{p^2}(2) + \mathcal{L}^{\Delta S=1}_{G_F p^2}(2) + \mathcal{L}^{em}_{e^2p^0}(1) + \mathcal{L}^{emweak}_{G_8 e^2 p^0}(1)$ | $L = 0$ |
| $+\mathcal{L}_{p^4}(10) + \mathcal{L}^{odd}_{p^6}(32) + \mathcal{L}^{\Delta S=1}_{G_8 p^4}(22) + \mathcal{L}^{\Delta S=1}_{G_{27} p^4}(28)$ | $L = 1$ |
| $+\mathcal{L}^{em}_{e^2p^2}(14) + \mathcal{L}^{emweak}_{G_8 e^2 p^2}(14) + \mathcal{L}^{leptons}_{e^2 p}(5)$ | |
| $+\mathcal{L}_{p^6}(90)$ | $L = 2$ |

The numbers in brackets refer to the number of independent couplings for $N_f = 3$.. The parameter-free Wess–Zumino–Witten action $S_{WZW}$ that cannot be written as the four-dimensional integral of an invariant Lagrangian must be added.

with quark masses booked as $O(p^2)$ like the two-derivative term in [22].

The effective chiral Lagrangian in Table 1 contains the following parts:

1. strong interactions: $\mathcal{L}_{p^2}, \mathcal{L}_{p^4}, \mathcal{L}_{p^6}^{\text{odd}}, \mathcal{L}_{p^6} + S_{\text{WZW}}$;
2. nonleptonic weak interactions to first order in the Fermi coupling constant $G_F$: $\mathcal{L}_{G_F p^2}^{\Delta S=1}$, $\mathcal{L}_{G_8 p^4}^{\Delta S=1}, \mathcal{L}_{G_{27} p^4}^{\Delta S=1}$;
3. radiative corrections for strong processes: $\mathcal{L}_{e^2 p^0}^{\text{em}}, \mathcal{L}_{e^2 p^2}^{\text{em}}$;
4. radiative corrections for nonleptonic weak decays: $\mathcal{L}_{G_8 e^2 p^0}^{\text{emweak}}, \mathcal{L}_{G_8 e^2 p^2}^{\text{emweak}}$; and
5. radiative corrections for semileptonic weak decays: $\mathcal{L}_{e^2 p}^{\text{leptons}}$.

Beyond the leading order, unitarity and analyticity require the inclusion of loop contributions. In the purely strong sector, calculations have been performed up to next-to-next-to-leading order. Figure 1 shows the corresponding skeleton diagrams of $O(p^6)$, with full lowest-order tree structures to be attached to propagators and vertices. The coupling constants of the various Lagrangians in Table 1 absorb the divergences from loop diagrams leading to finite renormalized Green functions with scale-dependent couplings, the so-called low-energy constants (LECs). As in all EFTs, the LECs parametrize the effect of "heavy" degrees of freedom that are not represented explicitly in the EFT Lagrangian. Determination of those LECs is a major task for CHPT. In addition to phenomenological information, further theoretical input is needed. Lattice gauge theory has already furnished values for some LECs. To bridge the gap between the low-energy domain of CHPT and the perturbative domain of QCD, large-$N_c$ motivated interpolations with meson resonance exchange have been used successfully to pin down some of the LECs.

Especially in cases where the knowledge of LECs is limited, renormalization group methods provide valuable information. As in renormalizable quantum field theories, the leading chiral logs $(\ln M^2/\mu^2)^L$ with a typical meson mass $M$, renormalization scale $\mu$ and loop order $L$ can in principle be determined from one-loop diagrams only. In contrast to the renormalizable situation, new derivative structures (and quark mass insertions) occur at each loop order preventing a straightforward resummation of chiral logs.

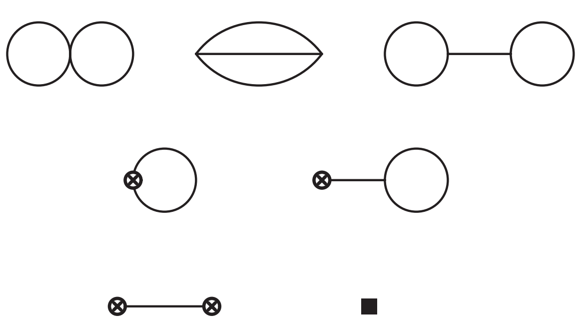

**Figure 1** Skeleton diagrams of $O(p^6)$.. Normal vertices are from $\mathcal{L}_{p^2}$, crossed circles and the full square denote vertices from $\mathcal{L}_{p^4}$ and $\mathcal{L}_{p^6}$, respectively.

Among the many applications of CHPT in the meson sector are the determination of quark mass ratios and the analysis of pion–pion scattering where the chiral amplitude of next-to-next-to-leading order has been combined with dispersion theory (Roy equations). Of increasing importance for precision physics (CKM matrix elements, $(g-2)_\mu, \ldots$) are isospin-violating corrections including radiative corrections, where CHPT provides the only reliable approach in the low-energy region. Such corrections are also essential for the analysis of hadronic atoms like pionium, a $\pi^+\pi^-$ bound state.

CHPT has also been applied extensively in the single-baryon sector. There are several differences to the purely mesonic case. For instance, the chiral expansion proceeds more slowly and the nucleon mass $m_N$ provides a new scale that does not vanish in the chiral limit. The formulation of heavy-baryon CHPT was modeled after HQET integrating out the nucleon modes of $O(m_N)$. To improve the convergence of the chiral expansion in some regions of phase space, a manifestly Lorentz-invariant formulation has been set up more recently (relativistic baryon CHPT). Many single-baryon processes have been calculated to fourth order in both approaches, for example, pion–nucleon scattering. With similar methods as in the mesonic sector, hadronic atoms like pionic or kaonic hydrogen have been investigated.

### Nuclear Physics

In contrast to the meson and single-baryon sectors, amplitudes with two or more nucleons do not vanish in the chiral limit when the momenta of Goldstone mesons tend to zero. Consequently, the power counting is different in the many-nucleon sector. Multinucleon processes are treated with different EFTs depending on whether all momenta are smaller or larger than the pion mass.

In the very low energy regime $|\vec{p}| \ll M_\pi$, pions or other mesons do not appear as dynamical degrees of freedom. The resulting EFT is called "pionless EFT" and it describes systems like the deuteron, where the typical nucleon momenta are $\sim\sqrt{m_N B_d} \simeq 45\,\text{MeV}$ ($B_d$ is the binding energy of the deuteron). The Lagrangian for the strong interactions between two nucleons has the form

$$\mathcal{L}_{NN} = C_0 \left(N^\top P_i N\right)^\dagger N^\top P_i N + \cdots \qquad [24]$$

where $P_i$ are spin–isospin projectors and higher-order terms contain derivatives of the nucleon fields. The existence of bound states implies that at least part of the EFT Lagrangian must be treated nonperturbatively. Pionless EFT is an extension of effective-range theory that has long been used in nuclear physics. It has been applied successfully especially to the deuteron but also to more complicated few-nucleon systems like the Nd and n$\alpha$ systems. For instance, precise results for Nd scattering have been obtained with parameters fully determined from NN scattering. Pionless EFT has also been applied to the so-called halo nuclei, where a tight cluster of nucleons (like $^4$He) is surrounded by one or more "halo" nucleons.

In the regime $|\vec{p}| > M_\pi$, the pion must be included as a dynamical degree of freedom. With some modifications in the power counting, the corresponding EFT is based on the approach of Weinberg (1990, 1991), who applied the usual rules of the meson and single-nucleon sectors to the nucleon–nucleon potential (instead of the scattering amplitude). The potential is then to be inserted into a Schrödinger equation to calculate physical observables. The systematic power counting leads to a natural hierarchy of nuclear forces, with only two-nucleon forces appearing up to next-to-leading order. Three- and four-nucleon forces arise at third and fourth order, respectively.

Significant progress has been achieved in the phenomenology of few-nucleon systems. The two- and $n$-nucleon ($3 \leq n \leq 6$) sectors have been pushed to fourth and third order, respectively, with encouraging signs of "convergence." Compton scattering off the deuteron, $\pi$d scattering, nuclear parity violation, solar fusion, and other processes have been investigated in the EFT approach. The quark mass dependence of the nucleon–nucleon interaction has also been studied.

# Eigenfunctions of Quantum Completely Integrable Systems

**J A Toth**, McGill University, Montreal, QC, Canada

## Introduction

This article is an introduction to eigenfunctions of quantum completely integrable (QCI) systems. For these systems, one can understand asymptotics of eigenfunctions better than for other systems, so it is natural to study them. It is useful to begin the discussion with the most important geometric example given by the quantum Hamiltonian, $P_1 = -\sqrt{\Delta}$. We fix a basis of eigenfunctions, $\varphi_j, j = 1, 2, \ldots$, with

$$-\sqrt{\Delta}\varphi_j = \lambda_j\varphi_j, \quad \langle\varphi_i, \varphi_j\rangle = \delta_{ij}$$

and assume that there exist functionally independent (pseudo)differential operators $P_2, \ldots, P_n$ with the property that

$$[P_i, P_j] = 0, \quad i, j = 1, \ldots, n$$

In this case, $P_1$ is said to be QCI and the operators, $P_k, k = 1, \ldots, n$, can be simultaneously diagonalized. It is therefore natural to study the special basis of Laplace eigenfunctions which are joint eigenvectors of the $P_k's$. From now on, the $\phi_j$'s are always assumed to be joint eigenfunctions of the commuting operators, $P_k, k = 1, \ldots, n$. The classical observables corresponding to the operators $P_k, k = 1, \ldots, n$, are the respective principal symbols, $p_k \in C^\infty(T^*M), j = 1, \ldots, n$. In particular, the bicharacteristic flow of $p_1(x, \xi) = |\xi|_g$ is the classical "geodesic flow"

$$G_t : T^*M \longrightarrow T^*M$$

Examples of manifolds with QCI Laplacians include tori and spheres of revolution, Liouville metrics on tori and spheres, large families of metrics on homogeneous spaces, as well as hyperellipsoids with distinct axes in arbitrary dimension. There are also many inhomogeneous QCI examples (see the next section). It is of interest to understand the asymptotics of both eigenvalues and eigenfunctions. There is a large literature devoted to eigenvalue asymptotics, including trace formulas and Bohr–Sommerfeld rules (see Colin de Verdiere (1994a, b), Helffer and Sjoestrand (1990), and Colin de Verdiere and Vu Ngoc (2003)). We will concentrate here on the corresponding problem of determining eigenfunction asymptotics. The key property of eigenfunctions in the QCI case is localization in phase space, $T^*M$. This allows one to study more effectively the concentration and blow-up properties than in any other setting. It is important to contrast this with, for example, the situation in the ergodic case. Moreover, in the QCI case, there is a particularly strong connection between dynamics of the geodesic flow, $G_t : T^*M \to T^*M$, and the asymptotics of individual eigenfunctions. In the general case, one can usually only relate the dynamics to spectral averages, such as in the trace formula (Duistermaat and Guillemin 1975).

For the most part, the literature on eigenfunction asymptotics addresses the following basic problems:

1. determining sharp upper and lower bounds for $\varphi_j$ as $\lambda_j \to \infty$ and
2. describing the link between the blow-up properties of $\varphi_j$ as $\lambda_j \to \infty$ and the dynamics of the geodesic flow, $G_t$.

The starting point in the study of eigenfunction asymptotics in the QCI case is the fact that the joint eigenfunctions, $\varphi_j$, have masses that localize on the level sets, $\mathcal{P}^{-1}(b) := \{(x, \xi) \in T^*M; p_j(x, \xi) = b_j, j = 1, \ldots, n\}$. Moreover, by the Liouville–Arnol'd theorem, for generic levels (indexed by $b \in \mathbb{R}$),

$$\mathcal{P}^{-1}(b) = \sum_{k=1}^{m} \Lambda_k(b) \qquad [1]$$

where the $\Lambda_k(b) \subset T^*M$ are Lagrangian tori. The affine symplectic coordinates in a neighborhood of $\Lambda_k(b)$ are called "action-angle variables" $(\theta_1^{(k)}, \ldots, \theta_n^{(k)}; I_1^{(k)}, \ldots, I_n^{(k)}) \in \mathbb{T}^n \times \mathbb{R}^n$. Written in terms of these coordinates, the classical Hamilton equations defining the geodesic flow assume the form

$$\frac{d\theta}{dt} = F(I), \qquad \frac{dI}{dt} = 0$$

and this system of ordinary differential equations (ODEs) is solved by quadrature. This explains why one refers to such systems as completely integrable. At the quantum level, one can construct semiclassical Lagrangian distributions,

$$\Phi_\lambda(x) := \int_{\mathbb{R}^n} e^{i\lambda\varphi^{(k)}(x,\eta)} a(x, \eta; \lambda)\, d\eta \qquad [2]$$

which microlocally concentrate on $\Lambda^{(k)}(b)$ as $\lambda \to \infty$ and satisfy $P_j\Phi_\lambda = b_j\lambda\Phi_\lambda + \mathcal{O}(\lambda^{-\infty})$ in $L^2(M)$. An important fact is that the actual joint eigenfunctions, $\varphi_j$, are approximated to $\mathcal{O}(\lambda^{-\infty})$-accuracy in $L^2(M)$ by suitable linear combinations of the quasimodes, $\Phi_\lambda$. However, there are subtleties underlying this correspondence which are often neglected in the physics literature:

3. The actual joint eigenfunctions $\phi_j$ localize on the level sets $\mathcal{P}^{-1}(b)$ which usually consist of many

connected components. Consequently, the eigenfunctions are approximated by (sometimes large) linear combinations of Lagrangian quasimodes attached to the different component tori. The precise splitting of mass amongst these different components is a difficult and, in general, unsolved problem in microlocal tunneling.

4. The local torus foliation given by action-angle variables tends to degenerate and Lagrangian quasimodes are no longer approximate solutions to the (joint) eigenvalue equations near the singularities of the foliation. The singularities and their relative configurations can be complicated (Colin de Verdiere and Vu Ngoc 2003) and most of the interesting asymptotic blow-up properties of eigenfunctions tend to be associated with these degeneracies. The main tool for studying joint eigenfunctions near degeneracies is the quantum analog of the Eliasson normal form (Eliasson 1984, Vu Ngoc 2000). We will refer to this as the "quantum Birkhoff normal form" (QBNF).

## Background on QCI Systems

Let $(M^n, g)$ be a compact, closed Riemannian manifold and $P_1 := Op_\hbar(p_1)$ be a formally self-adjoint, elliptic (in the classical sense) $\hbar$-pseudodifferential operator. In local coordinates, the Schwarz kernel of $P_1$ is of the form,

$$P_1(x, y; \hbar) = (2\pi\hbar)^{-n} \int_{\mathbb{R}^n} e^{i\langle x-y,\xi\rangle/\hbar} p_1(x, \xi; \hbar)\, d\xi$$

where $p_1(x,\xi;\hbar) \in S^{0,m}_{cl}(T^*M)$; that is, $p_1(x,\xi;\hbar) \sim \sum_{j=0}^{\infty} p_{1,j}(x,\xi)\hbar^j$ with $\partial_x^\alpha \partial_\xi^\beta p_{1,j}(x,\xi) = \mathcal{O}_{\alpha,\beta}\langle\xi\rangle^{m-j-|\beta|}$ (Dimassi and Sjoestrand 1999). It is often convenient to work with $\hbar$-pseudodifferential operators rather than their classical counterparts. In the homogeneous case, one chooses $\hbar^{-1} \in \mathrm{Spec}\sqrt{\Delta}$.

$P_1 \in Op_\hbar(S^{0,m}_{cl})$ is said to be QCI if there exist self-adjoint $P_j = Op_\hbar(p_j) \in Op_\hbar(S^{0,m'}_{cl}), j = 2, \ldots, n$, for some $m'$ with $[P_i, P_j] = 0, i, j = 1, \ldots, n$, such that $dp_1 \wedge \cdots \wedge dp_n \neq 0$ on a dense open subset, $\Omega_{reg} \subset T^*M$, and $P_1^2 + \cdots + P_n^2$ is elliptic in the classical sense. There are many inhomogeneous QCI examples including quantum Euler, Lagrange, and Kowalevsky tops together with quantum Neumann and Rosochatius oscillators in arbitrary dimension.

Since $\{p_i, p_j\} = 0$, the joint Hamilton flow of the $p_i$'s induces a symplectic $\mathbb{R}^n$-action on $T^*M$:

$$\Phi_t : T^*M \longrightarrow T^*M$$
$$\Phi_t(x,\xi) = \exp t_1 H_{p_1} \circ \cdots \circ \exp t_1 H_{p_n}(x,\xi)$$
$$t = (t_1, \ldots, t_n) \in R^n$$

The associated moment map is just

$$\mathcal{P} : T^*M - 0 \to R^n, \quad \mathcal{P} = (p_1, \ldots, p_n)$$

We denote the image $\mathcal{P}(T^*M - 0)$ by $\mathcal{B}$, the regular values (resp. singular values) by $\mathcal{B}_{reg}$ (resp. $\mathcal{B}_{sing}$) of the moment map.

To establish bounds for the joint eigenfunctions of $P_1, \ldots, P_n$, one imposes a "finite-complexity" assumption (Toth and Zelditch 2002) on the classical integrable system. This condition holds for all systems of interest in physics. To describe it, for each $b = (b^{(1)}, \ldots, b^{(n)}) \in \mathcal{B}$, let $m_{cl}(b)$ denote the number of $R^n$-orbits of the joint flow $\Phi_t$ on the level set $\mathcal{P}^{-1}(b)$. Then, the finite-complexity condition says that for some $M_0 > 0$,

$$m_{cl}(b) < M_0 (\forall b \in \mathcal{B})$$

In addition, when $\mathcal{P}$ is proper,

$$\mathcal{P}^{-1}(b) = \sum_{k=1}^{m_{cl}(b)} \Lambda_k(b) \qquad [3]$$

for any $b \in \mathcal{B}_{reg}$, where the $\Lambda_k(b)$ are Lagrangian tori. The starting point for analyzing joint eigenfunctions is the following correspondence principle (Zelditch 1990) which makes the eigenfunction localization alluded to in the introduction more precise:

**Theorem 1** *Let $Op_\hbar(a) \in Op_\hbar(S^0_{cl})(T^*M)$ and $P_j, j = 1, \ldots, n$, be a QCI system of commuting operators. Then, for every $b \in \mathcal{B}_{reg}$, there exists a subsequence of joint eigenfunctions $\varphi_\mu(x) := \varphi(x;\mu(\hbar))$ with $\hbar \in (0, \hbar_0]$ and joint eigenvalues $\mu(\hbar) = (\mu_1(\hbar), \ldots, \mu_n(\hbar)) \in \mathrm{Spec}(P_1, \ldots, P_n)$ with $|\mu(\hbar) - b| = \mathcal{O}(\hbar)$ such that*

$$\langle Op_\hbar(a)\varphi_\mu, \varphi_\mu\rangle = |c(\hbar)|^2 \int_{\Lambda(b)} a(x,\xi)\, d\mu_b + \mathcal{O}(\hbar)$$

*Here, $d\mu_b$ denotes Lebesgue measure on the torus, $\Lambda(b)$.*

The proof of Theorem 1 follows from the $\hbar$-microlocal, regular quantum normal construction near $\Lambda(b)$ (see the section "Birkhoff normal forms").

## Blow-Up of Eigenfunctions: Qualitative Results

Before discussing quantitative bounds for joint eigenfunctions, it is useful to prove qualitative results. Here, we review only the homogeneous case where $P_1 = \hbar\sqrt{\Delta}$, although the general case can be dealt with similarly (Toth and Zelditch 2002). Two well-known QCI examples which exhibit extremes in eigenfunction concentration are the round sphere and the flat torus. In the case of the sphere, the zonal harmonics blow-up like $\lambda^{1/2}$ at the poles, whereas, in the case of the flat torus, all the joint eigenfunctions are uniformly bounded. The rest of the article will be

essentially devoted to understanding these extreme blow-up properties (and intermediate ones) more systematically. When discussing blow-up of eigenfunctions, it is natural to start with the following:

**Question** Do there exist QCI manifolds (other than the flat torus) for which all eigenfunctions are uniformly bounded in $L^\infty$?

Toth and Zelditch (2002) have proved that, up to coverings, the flat torus is the only example with uniformly bounded eigenfunctions. Their argument used the correspondence principle in Theorem 1 combined with some deep results from symplectic geometry. To deal with the issue of multiplicities, it is convenient to define

$$L^\infty(\lambda; g) = \sup_{\varphi \in V_\lambda} \|\varphi\|_{L^\infty}$$

where $V_\lambda = \{\varphi; P_1\varphi_\lambda = \lambda\varphi_\lambda\}$ and it is assumed that $\|\varphi\|_{L^2} = 1$.

**Theorem 2** (Toth and Zelditch 2002). *Suppose that $P_1 = \sqrt{\Delta}$ is QCI on a compact, Riemannian manifold $(M, g)$ and suppose that the corresponding moment map satisfies the finite-complexity condition. Then, if $L^\infty(\lambda, g) = \mathcal{O}(1), (M, g)$ is flat.*

The proof of Theorem 2 follows by contradiction: that is, one assumes that all eigenfunctions are uniformly bounded. There are two main steps in the proof of Theorem 2: the first is entirely analytic and uses the correspondence principle in Theorem 1 and uniform boundedness to determine the topology of $M$. The second step uses two deep results from symplectic topology/geometry to determine the metric, $g$, up to coverings.

Using a local Weyl law argument and the finite-multiplicity assumption, it can be shown that for each $b \in \mathcal{B}_{reg}$, there exists a subsequence, $\varphi_\mu$, of joint eigenfunctions such that Proposition 1 holds with

$$|c(\hbar; b)|^2 \geq \frac{1}{C}$$

where $C > 0$ is a uniform constant not depending on $b \in \mathcal{B}_{reg}$. With this subsequence, one applies Theorem 1 with $a(x, \xi) = V(x) \in C^\infty(M)$. It then easily follows by the boundedness assumption that for $\hbar$ sufficiently small and appropriate constants $C_0, C_1 > 0$,

$$\left| \int_{\Lambda(b)} \left(\pi^*_{\Lambda(b)} V\right) \mathrm{d}\mu_b \right| \leq \frac{1}{C_0} \int_M |V(x)|\, |\varphi_\mu(x)|^2 \,\mathrm{dVol}(x) \leq \frac{1}{C_1} \int_M |V(x)| \,\mathrm{dVol}(x) \qquad [4]$$

where $\pi_{\Lambda(b)}$ denotes the restriction of the canonical projection $\pi : T^*M \to M$ to the Lagrangian $\Lambda(b)$. The estimate in [4] is equivalent to the statement,

$$(\pi_{\Lambda(b)})_*(\mathrm{d}\mu_b) \ll \mathrm{dVol}(x)$$

where given two Borel measures $\mathrm{d}\mu$ and $\mathrm{d}\nu$, one writes $\mathrm{d}\mu \ll \mathrm{d}\nu$ if $\mathrm{d}\mu$ is absolutely continuous with respect to $\mathrm{d}\nu$. Consequently, $\pi_{\Lambda(b)} : \Lambda(b) \to M$ has no singularities and thus, up to coverings, $M$ is topologically a torus (since $\Lambda(b)$ is).

Since there are many QCI systems on $n$-tori, it still remains to determine how the uniform-boundedness condition constrains the metric geometry of $(M, g)$. First, by a classical result of Mane, if $T^*M$ possesses a $C^1$-foliation by Lagrangians, $(M, g)$ cannot have conjugate points. By the first step in the proof, it follows that under the uniform-boundedness assumption, $M$ is a topological torus and $T^*M$ possesses a smooth foliation by Lagrangian tori. Consequently, $(M, g)$ has no conjugate points. Finally, the Burago–Ivanov proof of the Hopf conjecture says that metric tori without conjugate points are flat. Therefore, $(M, g)$ is flat.

Consistent with Theorem 2, one can show (Toth and Zelditch 2003, Lerman and Shirokova 2002) that if $(M, g)$ is integrable and not a flat torus, then there must exist a compact $\Phi_t$-orbit (i.e., an orbit of the joint flow of $X_{p_j}, j = 1, \ldots, n$) with dim $= k < n$. In the QCI case, these "singular" orbits trap eigenfunction mass for appropriate subsequences. To understand this statement in detail, it is necessary to review QBNF constructions in the context of QCI systems.

## Birkhoff Normal Forms

There are several excellent expositions on the topic of Birkhoff normal forms in the literature (see, e.g., Guillemin (1996), Iatchenko *et al.* (2002), and Zelditch (1998)), which discuss both the classical and quantum constructions. Here, we discuss the aspects which are most relevant for QCI systems.

Consider the Schrödinger operator, $P(x; \hbar D_x) = -\hbar^2(\mathrm{d}^2/\mathrm{d}x^2) + V(x)$ with $V(x + 2\pi) = V(x)$ acting on $C^\infty(\mathbb{R}/2\pi\mathbb{Z})$. Assume that the potential, $V(x)$, is Morse and that $x = 0$ is a potential minimum with $V(0) = V'(0) = 0$ and $\Omega \subset T^*(\mathbb{S}^1)$ an open neighborhood containing $(0, 0)$. In its simplest incarnation, the classical Birkhoff normal-form theorem says that for small enough $\Omega$, there exists a symplectic diffeomorphism, $\kappa^{-1} : (\Omega; (0, 0)) \longrightarrow (\Omega; (0, 0)); \kappa^{-1} : (x, \xi) \mapsto (y, \eta)$, and a (locally defined) function $F_0 \in C^\infty(\mathbb{R})$ such that

$$(p \circ \kappa)(y, \eta) = F_0(\eta^2 + y^2) \qquad [5]$$

provided $(y,\eta)\in\Omega$. At the quantum level, the analogous QBNF expansion says that there exist microlocally unitary $\hbar$-Fourier integral operators, $U(\hbar): C^\infty(\Omega)\to C^\infty(\Omega)$ and a classical symbol $F(x,\hbar)\sim\sum_{j=0}^{\infty}F_j(x)\hbar^j$, such that

$$U(\hbar)^*\circ P(\hbar)\circ U(\hbar)={}_\Omega F(\hat{I}_e;\hbar) \qquad [6]$$

with $\hat{I}_e=\hbar^2D_y^2+y^2$. Given two $\hbar$-pseudos $P$ and $Q$, the notation $P={}_\Omega Q$ means that $\|\chi(P-Q)\|_{L^2}\|_0=\mathcal{O}(\hbar^\infty)$ and $\|(P-Q)\chi\|_0=\mathcal{O}(\hbar^\infty)$, for any $\chi\in C_0^\infty(\Omega)$. Since it can be easily shown that eigenfunctions $\varphi_\mu$, with $\mu(\hbar)=\mathcal{O}(\hbar^\beta)$, $0<\beta\le 1$, localize very sharply near $x=0$, from the $\hbar$-microlocal unitary equivalence in [6], the eigenfunction and eigenvalue asymptotics (including trace formulas) can all be determined by working with the model operator on the right-hand side (RHS) of [6]. Moreover, on the model side, the eigenfunctions and eigenvalues are explicitly known.

At a potential maximum, there exist classical and quantum normal forms analogous to [5] and [6] (see Helffer and Sjoestrand (1990) and Colin de Verdiere and Parisse (1994a)) except that the harmonic oscillator action operator, $\hat{I}_e$, is replaced by the hyperbolic action operator,

$$\hat{I}_h=\hbar\left(yD_y+\tfrac{1}{2}\right) \qquad [7]$$

The 1D Schrödinger operator is the simplest example of a QCI system where $(0,0)\in T^*\mathbb{S}^1$ is a nondegenerate critical point of the classical Hamiltonian, $H(x,\xi)=\xi^2+V(x)$. Under a mild nondegeneracy hypothesis (Vu Ngoc 2000), there is an analogous normal form for arbitrary QCI systems which is valid near nondegenerate rank $k<n$ orbits of the joint flow, $\Phi_t$. At the classical level, this result is due to Eliasson (1984) and the quantum analog is due to Vu-Ngoc (2000). To state the result is general, one has to define the appropriate model operators: these are $\hat{I}_e$ and $\hat{I}_h$ together with the loxodromic model operators $\Re\hat{I}_{ch}=\hbar D_\theta, \Im\hat{I}_{ch}=\hbar\rho D_\rho+\hbar/i$, where $(\rho,\theta)$ denote polar coordinates in $\mathbb{R}^2$. The local model phase space for a rank $k<n$ orbit, $\mathcal{O}_k$, is just $T^*(\mathbb{T}^k)\times T^*(\mathbb{R}^{n-k})$. In this case, the QBNF says that, for a sufficiently small neighborhood, $\mathcal{G}_k$ of $\mathcal{O}_k$, there exists a family of $\hbar$-Fourier integral operators, $U_\kappa: C^\infty(\mathcal{G}_k)\to C^\infty(T^*(\mathbb{T}^k)\times T^*(\mathbb{R}^{n-k}))$ and symbols $f_j(\hbar)\sim\sum_{j=0}^{\infty}f_j\hbar^j$, such that

$$\begin{aligned} U_\kappa^*P_jU_\kappa &={}_{\mathcal{G}_k}\mathcal{M}_\hbar\cdot(Q_1-f_1(\hbar),\ldots,Q_n-f_n(\hbar)) \\ U_\kappa^*\circ U_\kappa &={}_{\mathcal{G}_k}\mathrm{Id} \end{aligned} \qquad [8]$$

Here, $\mathcal{M}_\hbar$ is a microlocally invertible matrix of $\hbar$-pseudodifferential operators commuting with the $Q_j$'s, and the $Q_j$'s are to be chosen from the list of model operators $\{\hat{I}_{ch},\hat{I}_h,\hat{I}_e,\hat{I}_{reg}\}$, where $\hat{I}_{reg}=(\hbar D_{\theta_1},\ldots,\hbar D_{\theta_k})$ denotes the regular model operator acting along the $k$-dimensional orbit, $\mathcal{O}_k$. Moreover, if $(y_1,\ldots,y_{n-k},\eta_1,\ldots,\eta_{n-k})\in T^*(\mathbb{R}^{n-k})$ denote the symplectic model coordinates, then the $Q_j$'s act in separate, complementary $(y_1,\ldots,y_{n-k})$-variables. The main point here is that [8] is actually a convergent normal norm in $\hbar$ in the sense that error terms in [8] are $\mathcal{O}(\hbar^\infty)$. In contrast (Guillemin 1996, Iatchenko *et al.* 2002, Zelditch 1998), the general Birkhoff normal form is only formal in the sense that error terms vanish to successively higher orders along the orbit, $\mathcal{O}_k$, but are not necessarily small in terms of the spectral parameter, $\hbar$.

Using [8], it can be shown that the joint eigenfunctions, $\varphi_\mu$, are microlocally determined in terms of the $\hbar$-Fourier integral operators, $U_\kappa$, and certain model eigenfunctions. More precisely,

$$U_\kappa^*\varphi_\mu(\theta,y;\hbar)={}_{\mathcal{G}_k}c(\hbar)\,\mathrm{e}^{\mathrm{i}m\theta}\cdot[u_h\cdot u_{ch}\cdot u_e](y;\hbar) \qquad [9]$$

where $m\in\mathbb{Z}+1/4, c(\hbar)\in\mathbb{C}(\hbar)$. The generalized eigenfunctions of the model operators, $\hat{I}_h,\hat{I}_{ch},\hat{I}_e$, acting transversely to the orbit $\mathcal{O}_k$ are $u_h(y;\mu,\hbar)=c_+(\hbar)|y|_+^{-1/2+\mathrm{i}\mu/\hbar}+c_-(\hbar)|y|_-^{-1/2+\mathrm{i}\mu/\hbar}$, $u_{ch}(\rho,\theta;t,k,\hbar)=\rho^{\mathrm{i}t/\hbar-1}\mathrm{e}^{\mathrm{i}k\theta}$ and $u_e(y;n,\hbar)=H_n(\hbar^{-1/2}y)$, where $H_n(y)$ is the $n$th Hermite function.

## Eigenfunction Lower Bounds: Quantitative Results

Let $\mathcal{O}_k$ be a singular rank $k<n$ orbit as in the previous section. From the qualitative results of the first section, it follows that there must exist joint eigenfunctions, $\varphi_\mu$, of the commuting operators, $P_j, j=1,\ldots,n$, which blow up along the orbit, $\mathcal{O}_k$. To obtain quantitative results, one could try to determine the $L^p\to L^q$ mapping properties of the $\hbar$-Fourier integral operator, $U_\kappa$. However, since the canonical transformation $\kappa$ to normal form can be complicated, this method is quite cumbersome. To avoid this complication (Toth and Zelditch 2003), it suffices to compute $L^2$-masses only, but on scales of order $\hbar^\delta$ where $0\le\delta<1/2$. Let $\pi(\mathcal{G}_k(\hbar^\delta))$ be the configuration space projection of the $\hbar^\delta$-radius tube $\mathcal{G}_k(\hbar^\delta)\supset\mathcal{O}_k$. Since

$$\|\varphi_\mu\|_{L^\infty}^2\cdot\mathrm{Vol}(\pi(\mathcal{G}_k(\hbar^\delta)))\ge\int_{\mathcal{G}_k(\hbar^\delta)}|\varphi_\mu|^2\,\mathrm{dVol} \qquad [10]$$

one is reduced to estimating $\int_{\mathcal{G}_k(\hbar^\delta)}|\phi_\mu|^2\,\mathrm{dVol}$ from below. To bound this integral from below, it suffices to

1. reduce the estimate to one involving only the model eigenfunctions in the Birkhoff normal form and
2. estimate the normalizing $\hbar$-dependent constant $c(\hbar)$ in [9].

To prove (1) one introduces a cutoff function $\chi(x,\xi;\hbar^{\delta}) \in C_0^{\infty}(\mathcal{G}_k(\hbar^{\delta}))$ and is identically equal to one near $\mathcal{O}_k$. Then, since $\pi^{-1}(\pi(\mathcal{G}_k(\hbar^{\delta}))) \supset \mathcal{G}_k(\hbar^{\delta})$, from the Garding inequality, it follows that

$$\int_{\mathcal{G}_k(\hbar^{\delta})} |\varphi_\mu|^2 \, \mathrm{dVol} \gg \langle Op_\hbar(\chi(x,\xi;\hbar^{\delta}))\varphi_\mu, \varphi_\mu\rangle \quad [11]$$

In light of the QBNF result in [8], the computation of the matrix element on the RHS of [11] is reduced to a corresponding computation for the $L^2$-normalized model eigenfunctions. Since the $U_\kappa$'s are microlocally unitary, it follows that

$$\langle Op_\hbar(\chi(x,\xi;\hbar^{\delta}))\varphi_\mu, \varphi_\mu\rangle \sim_{\hbar\to 0^+} C(\delta)\cdot |c(\hbar)|^2 \quad [12]$$

Here, the constant $C(\delta)>0$ depends only on the scale of the cutoff function. It finally remains to deal with (2). Bounding the size of $|c(\hbar)|$ from below amounts to estimating the $L^2$-mass of the joint eigenfunction $\varphi_\mu$ which must be trapped near the orbit, $\mathcal{O}_k$. Using a local (singular) Weyl law argument, it is shown in Toth and Zelditch (2003) that

$$|c(\hbar)|^2 \gg |\log \hbar|^{-\beta} \quad [13]$$

where $\beta>0$ indexes the number of hyperbolic and loxodromic model operators. The final result quantifies blow-up along a compact orbit:

**Theorem 3** (Toth and Zelditch 2003). *Let $\mathcal{O}_k$ be a rank $k<n$ orbit of the joint flow $\Phi_t$. If this orbit is compact and nondegenerate, then there exists a subsequence of $L^2$-normalized joint eigenfunctions $\varphi_{\lambda_{j_k}}, k=1,2,\ldots,$ of the QCI system $P_j, j=1,\ldots,n$, such that for any $\epsilon>0$,*

$$\|\varphi_{\lambda_{j_k}}\|_{L^\infty} \gg_\epsilon \lambda_{j_k}^{(n-k/4)-\epsilon}$$

By using the semiclassical scale $\hbar^{1/2}|\log\hbar|^{1/2}$, one can (slightly) improve the lower bound in Theorem 3 to $\|\varphi_{\lambda_{j_k}}\|_{L^\infty} \gg_\epsilon \lambda_{j_k}^{n-k/4}|\log\lambda_{j_k}|^{-\alpha}$ for some $\alpha\geq 0$ (see Sogge *et al.* (2005)).

When $(M,g)$ is not flat, there must exist a singular, compact orbit of dimension $k$ with $1\leq k\leq n-1$ and so, as an immediate corollary of Theorem 3, it follows that for some $\alpha\geq 0$,

$$L^\infty(\lambda;g) \gg \lambda^{1/4}|\log\lambda|^{-\alpha} \quad [14]$$

Since the bound in [14] is highly dependent on dimension, establishing the existence of high-codimension singular orbits would strengthen the estimate substantially. However, this appears to be a difficult and open problem.

## Maximal Blow-Up of Modes and Quasimodes

We review here a number of converses to a recent result of Sogge and Zelditch (2002) on Riemannian manifolds $(M,g)$ with maximal eigenfunction growth. These authors proved that if there exists a sequence of $L^2$-normalized eigenfunctions of the Laplacian $\Delta$ of $(M,g)$ whose $L^\infty$-norms are comparable to zonal spherical harmonics on $S^n$, then there must exist a point comparable to the north pole of $S^n$, that is, a recurrent point $z$ such that a positive measure of geodesics emanating from $z$ return to it at a fixed time $T$. The most extreme kind of recurrent point is a "blow-down point" of period $T$, where by definition all geodesics leaving $z$ return to $z$ at time $T$, that is, form geodesic loops. Poles of surfaces of revolution are blow-down points where all geodesic loops at $z$ are smoothly closed, while umbilic points of triaxial ellipsoids are examples of blow-down points where all but two geodesic loops are not smoothly closed. On real-analytic manifolds, all recurrent points are blow-down points. The converse question is the following: what kind of mode (eigenfunction) or quasimode growth must occur when a blow-down point exists?

Sogge *et al.* (2005) proved that maximal quasimode growth (Colin de Verdiere 1977) implies the existence of a blow-down point. This generalizes the main result of Sogge and Zelditch (2002) from modes (which one rarely understands) to quasimodes (which one often understands better). Conversely, existence of a blow-down point insures near-maximal quasimode growth, that is, here, maximal up to logarithmic factors. If one assumes that the geodesic flow $G^t: T^*M \to T^*M$ of $(M,g)$ is completely integrable and that $\dim M = 2$, then the results of Sogge *et al.* (2005) show that actual eigenfunctions have near maximal blow-up. Examples show that, in general, blow-up points do not necessarily cause modes to have near-maximal blow-up.

An important geometric invariant of a blow-down point is the first-return map to the cotangent fiber over the blow-down point:

$$G_z^T : S_z^*M \to S_z^*M \quad [15]$$

$G_z^T$ is also an important analytic invariant: the blow-up rate of modes or quasimodes, specifically the occurrence of the logarithmic factors, depends on the fixed-point structure of this map. When all geodesic loops at $z$ are smoothly closed, that is, when the first-return map is the identity, then there exist quasimodes of maximal growth. When the first-return map has fixed points, the maximal growth is modified by logarithmic factors.

To put these results in context, we first recall the local Weyl law of Avakumovich–Levitan (Duistermaat and Guillemin 1975), which states that

$$\sum_{\lambda_\nu \le \lambda} |\varphi_\nu(x)|^2 = (2\pi)^{-n} \int_{p(x,\xi)\le\lambda} \mathrm{d}\xi + R(\lambda, x) \qquad [16]$$

with uniform remainder bounds

$$|R(\lambda, x)| \le C\lambda^{n-1} \quad x \in M$$

It follows that

$$L^\infty(\lambda, g) = 0(\lambda^{(n-1)/2}) \qquad [17]$$

on any compact Riemannian manifold. Riemannian manifolds for which the equality

$$L^\infty(\lambda, g) = \Omega(\lambda^{(n-1)/2}) \qquad [18]$$

is achieved for some subsequence of eigenfunctions are said to be of maximal eigenfunction growth. In addition to modes, and almost inseparable from them, are the quasimodes of the Laplacian (Colin de Verdiere 1977). As the name suggests, quasimodes are approximate eigenfunctions. The crudest type of quasimode is quasimode $\{\psi_k\}$ of order 0, namely a sequence of $L^2$-normalized functions which solve

$$\|(\Delta - \mu_k)\psi_k\|_{L^2} = O(1)$$

for a sequence of quasieigenvalues $\mu_k$. By the spectral theorem, it follows that there must exist true eigenvalues in the interval $[\mu_k - \delta, \mu_k + \delta]$ for some $\delta > 0$. $(M, g)$ is said to have maximal 0-order quasimode growth if there exists a sequence of quasimodes of order 0 for which $\|\psi_k\|_{L^\infty} = \Omega(\lambda^{(n-1)/2})$. There are analogous definitions for more refined quasimodes, for example, quasimodes of higher order or (most refined) quasimodes defined by oscillatory integrals. It is natural to include quasimodes in this study because they often reflect the geometry and dynamics of the geodesic flow more strongly than actual modes. For quasimodes, there is the following result:

**Theorem 4** (Sogge *et al.* 2005). Let $(M^n, g)$ *be a compact Riemannian manifold with Laplacian* $\Delta$. *Then*:

(i) *If there exists a quasimode sequence* $\{(\psi_k, \mu_k)\}$ *of order 0 with* $\|\psi_k\|_{L^\infty} = \Omega(\mu_k^{(n-1)/2})$, *then there exists a recurrent point* $z \in M$ *for the geodesic flow. If* $(M, g)$ *is real analytic, then there exists a blow-down point.*

(ii) *Conversely, if there exists a blow-down point and if the map* $G_z^T = \mathrm{id}$, *then there exists a quasimode sequence* $\{(\psi_k, \mu_k)\}$ *of order 0 with* $\|\psi_k\|_{L^\infty} = \Omega(\mu_k^{n-1})$.

(iii) *Let* $n = 2$ *and* $(M^n, g)$ *be real analytic. Then, if* $G_z^T$ *has a finite number of nondegenerate fixed points, there exists a quasimode sequence* $\{(\psi_k, \mu_k)\}$ *of order 0 with* $\|\psi_k\|_{L^\infty} = \Omega(\mu_k^{1/2} \times |\log \mu_k|^{-1/2})$.

The assumption that $G_z^T = \mathrm{id}$ is the same as saying that all geodesics leaving $z$ smooth close up at $z$ again. As mentioned above, poles of surfaces of revolution have this property. On the contrary, the umbilic points of triaxial ellipsoids in $\mathbb{R}^3$ are blow-down points for which $G_z^T \ne \mathrm{id}$. That is, every geodesic leaving an umbilic point returns at the same time, but only two closed geodesics in this family are closed, and they give rise to fixed points of $G_z^t$. One can show (see Toth 1996) that there exists a sequence of eigenfunctions in this case for which $L^\infty(g, \lambda) \sim \lambda^{1/2} |\log \lambda|^{-1/2}$. Hence, the above result is sharp. Moreover, it is clear from the proof that the fixed points are responsible for the logarithmic correction to maximal eigenfunction growth: they cause a change in the normal form of the Laplacian near the blow-down point.

Theorem 4 illustrates the intimate connection between maximal blow-up of quasimodes and existence of blow-down points. It is natural to ask, however, when blow-down points cause blow-up in modes, that is, actual eigenfunctions. As mentioned above, this is not generally the case and some further mechanism is needed to ensure it. In the case of QCI surfaces, one can prove:

**Theorem 5** (Sogge *et al.* 2005). *Let* $(M, g)$ *be a smooth, compact surface,* $P_1 = \sqrt{\Delta}$, $P_2$ *be an Eliasson nondegenerate QCI system on* $M$ *and* $\varphi_k$ *be an* $L^2$*-normalized joint eigenfunction of* $P_1, P_2$ *with* $\sqrt{\Delta}\varphi_k = \lambda_k \varphi_k$. *Suppose that there exists a blow-down point* $z \in M$ *for the geodesic flow* $G_t := \exp tX_{p_1}$. *Then, there exists a subsequence of (joint) Laplace eigenfunctions,* $\varphi_{j_k}, k = 1, 2, \ldots$, *such that for any* $\epsilon > 0$,

$$\|\varphi_{j_k}\|_{L^\infty} \gg_\epsilon \lambda_{j_k}^{(1/2)-\epsilon}$$

The role of complete integrability is to force joint eigenfunctions to localize on level sets of the moment map and thus to blow up at blow-down points. The proofs of Theorems 4 and 5 are similar. To prove the latter, by the same reasoning as in the orbit case (Theorem 3), one needs to bound from below the integral

$$\int_{B(z;\hbar^\delta)} |\varphi_\mu|^2 \mathrm{dVol} \qquad [19]$$

for an appropriate subsequence of $\varphi_\mu$s, where $B(z;\hbar^\delta)$ denotes a ball of radius $\hbar^\delta$ centered at the blow-down point, $z \in M$. The blow-down condition implies that $S^*_z M \subset \mathcal{P}^{-1}(b)$ for some $b \in \mathcal{B}$. The relevant subsequence of eigenfunctions, $\varphi_\mu$, are the ones with joint eigenvalues satisfying $|\mu(\hbar) - b| = \mathcal{O}(\hbar)$. Since the eigenfunctions $\varphi_\mu$ are microlocally concentrated on the set $\mathcal{P}^{-1}(b)$, by Gärding,

$$\int_{B(z;\hbar^\delta)} |\varphi_\mu|^2 \mathrm{dVol} \gg \langle Op_\hbar(\chi(x,\xi;\hbar^\delta))\varphi_\mu, \varphi_\mu\rangle \quad [20]$$

where $\chi(x,\xi,\hbar^\delta)$ is a cutoff localized on an $\hbar^\delta$-neighborhood of $\Omega = \pi^{-1}(z) \cap \mathcal{P}^{-1}(b)$. The matrix elements on the RHS of [20] are estimated by passing to QBNF. The subtlety here lies in the choice of scale, $\delta$. For $0 < \delta < 1/2$, the $\hbar$-pseudodifferential operators $Op_\hbar(\chi(x,\xi;\hbar^\delta))$ are contained in a standard calculus (Dimassi and Sjoestrand 1999) and so they automatically satisfy the $\hbar$-Egorov theorem. In particular, the passage to normal form by conjugating with the $U_\kappa$'s is automatic. The crucial point here is that to obtain the (near)-maximal blow-up near a blow-down point $z \in M$, one needs to able to choose $0 \le \delta < 1$. Using second-microlocal methods similar to the ones in Sjoestrand and Zworski (1999), it is shown in Sogge *et al.* (2005) that the blow-down geometry implies that the microlocal cutoffs are contained in an $\hbar$-pseudodifferential operator calculus and, in particular, the relevant $\hbar$-Egorov theorem needed to pass to QBNF is satisfied for any $0 \le \delta < 1$. Then, by explicit computation for the model eigenfunctions, one can show that

$$Op_\hbar(\chi(x,\xi;\hbar^\delta))\varphi_\mu, \varphi_\mu\rangle \gg_\delta \hbar^\delta \quad [21]$$

for any $\delta$ with $0<\delta<1$. The result in Theorem 5 then follows from the bound

$$\|\varphi_\mu\|^2_{L^\infty} \cdot \mathrm{Vol}(B(z;\hbar^\infty)) \gg_\delta \hbar^\delta \quad [22]$$

where one takes $\delta$ arbitrarily close to 1. By analyzing the $U_\kappa s$ carefully (Sogge *et al.* 2005), the lower bound in Theorem 5 can be improved slightly by replacing the $\lambda^{-\epsilon}$ by $|\log\lambda|^{-\alpha}$ for some $\alpha > 0$, although the sharp constant, $\alpha > 0$, appears to be difficult to determine in general. In cases where the geometry of the first-return map, $G^T_z$, is particularly simple, one can sometimes get sharp $|\log\lambda|$-power improvements in Theorem 5 (see Theorem 4 (iii)).

## Eigenfunction Upper Bounds: Quantitative Results

In light of the $\Omega$-bounds in Theorem 5, it is natural to ask whether there are analogous upper bounds for $L^\infty(\lambda;g)$ in the QCI case. The following result holds in the case of real-analytic surfaces:

**Theorem 6** (Sogge *et al.* 2005). *Let $(M,g)$ be a real-analytic Riemannian 2-manifold and $P_1 = \sqrt{\Delta}$ and $P_2$ be a QCI system on $(M,g)$ where, the principal symbol, $p_2$, of $P_2$ is a metric form on $T^*M$.*

(i) *If $M \cong T^2$,*

$$L^\infty(\lambda;g) = \mathcal{O}(\lambda^{1/4})$$

(ii) *If $M \cong S^2$, let $M_{\mathrm{rec}}$ be the set of completely recurrent points for the geodesic flow, $G_t : T^*M \to T^*M$ and let $\Omega_{\mathrm{rec}} \subset M$ be an open neighborhood of $M_{\mathrm{rec}}$. Then,*

$$L^\infty(\lambda;g)|_{M-\Omega_{\mathrm{rec}}} = \mathcal{O}(\lambda^{1/4})$$

An old result of Kozlov says that if the surface $(M,g)$ is analytic, then topologically either $M \cong S^2$ or $M \cong T^2$, so that the estimates in Theorem 6 cover all possible cases in two dimensions. The assumptions in Theorem 6 are satisfied in many examples including surfaces of revolution, Liouville surfaces, and ellipsoids with distinct axes in $\mathbb{R}^3$.

The proof of Theorem 6 follows from a pointwise (joint) trace formula argument (Duistermaat and Guillemin 1975). Namely, in Sogge *et al.* (2005), it is shown that if there are no blow-down points for $G_t$, then for appropriate $\rho \in \mathcal{S}(R)$ with $\rho \ge 0$ and $\hat\rho \in C_0^\infty(R)$,

$$\sum_{j=1}^{\infty} \rho\Big(\hbar^{-1}\Big[\mu_j^{(1)}(\hbar) - b_1\Big]\Big) \cdot \rho\Big(\hbar^{-1}\Big[\mu_j^{(2)}(\hbar) - b_2\Big]\Big) \times |\varphi_\mu(x;\hbar)|^2 = \mathcal{O}(\hbar^{-1/2}) \quad [23]$$

where the estimate in [23] is uniform in $x \in M$ and locally uniform in $b = (b_1, b_2) \in \mathcal{B}$. Part (ii) follows from this. To prove part (i), one applies a simple homological argument to show that if $M \cong T^2$, there cannot exist blow-down points for the geodesic flow (see also Sogge and Zelditch (2002)).

## Open Problems

Most questions related to eigenfunction blow-up are completely open and general results are rare (Sogge and Zelditch 2002). Specific results/conjectures in the ergodic case can be found in Quantum Ergodicity and Mixing of Eigenfunctions. We would like to point out here some specific questions related to the above results in the QCI case:

1. All the known examples with blow-down points turn out to be integrable. Is this necessarily always the case?
2. Does the maximal bound $L^\infty(\lambda;g) \sim \lambda^{(n-1)/2}$ necessarily imply that $(M,g)$ is QCI?

3. At the other extreme, does the minimal bound $L^\infty(\lambda; g) \sim 1$ necessarily imply that $(M, g)$ is flat, or do there exist nonflat manifolds (which are necessarily not QCI) satisfying $L^\infty(\lambda; g) \sim 1$?

# Eight Vertex and Hard Hexagon Models

**P A Pearce**, University of Melbourne, Parkville, VIC, Australia

## Introduction

The goal of statistical mechanics is to calculate the macroscopic properties of matter from a knowledge of the fundamental interactions between the constituent microscopic components. For simplicity, let us assume discrete states. The mathematical problem, as formulated by Gibbs, is then to calculate the partition function

$$Z_N = \sum_{\text{states } \sigma} e^{-\beta H(\sigma)} \qquad [1]$$

where $\beta = 1/k_B T$ is the inverse temperature, $k_B$ is the Boltzmann constant, and the Hamiltonian $H$ describes the interaction energy of the state $\sigma$ of the $N$ constituent degrees of freedom. The formidable nature of the problem ensues from the fact that $Z_N$ is needed in the limit of an arbitrarily large system to obtain the bulk free energy $\psi(T)$ or partition function per site $\kappa$ in the thermodynamic limit

$$-\beta\psi(T) = \lim_{N\to\infty} \frac{1}{N} \log Z_N = \log \kappa \qquad [2]$$

This limit generally exists because the free energy of a finite system is extensive, that is, it grows proportionally with the system size. Once the bulk free energy is known, the other thermodynamic potentials are obtained, in principle, by taking derivatives with respect to the temperature $T$ and other thermodynamic fields such as the volume $V$ or the external magnetic field $h$. Phase transitions and the accompanying critical phenomena are associated with singularities of the bulk free energy as a function of the thermodynamic fields. Up until the beginning of the 1970s, there were

only a handful of two-dimensional lattice models that had yielded exact solution, most notably, the Ising model (free-fermion or dimer model), the spherical model, the square ice, and six-vertex models. This situation changed dramatically with Baxter's solution of the eight-vertex and hard-hexagon models. The methods developed by Baxter make it possible to solve an infinite plethora of two-dimensional lattice models. In this article, we compare and contrast the remarkable properties of these two prototypical models that played such a pivotal role in the emergence of the modern theory of Yang–Baxter integrability.

## Definition of the Models

### Eight-Vertex Model

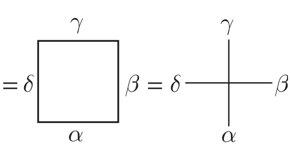
The eight-vertex model emerged from the study of two-dimensional ferroelectrics. The local degrees of freedom are arrow states $\alpha, \beta, \gamma, \delta = \pm 1$ which live on the edges of the elementary faces of the square lattice and describe the local polarization within the ferroelectric material. Of the 16 possible configurations around a face, the local configurations of an elementary square face are restricted to the eight configurations shown in Figure 1.

The partition function is

$$Z_N = \sum_{\text{arrow states}} \prod_{\text{faces}} W\begin{pmatrix} & \gamma & \\ \delta & & \beta \\ & \alpha & \end{pmatrix} \qquad [3]$$

where the Boltzmann face weights are given alternative graphical representations as a face or vertex

$$W\begin{pmatrix} & \gamma & \\ \delta & & \beta \\ & \alpha & \end{pmatrix} = \qquad [4]$$



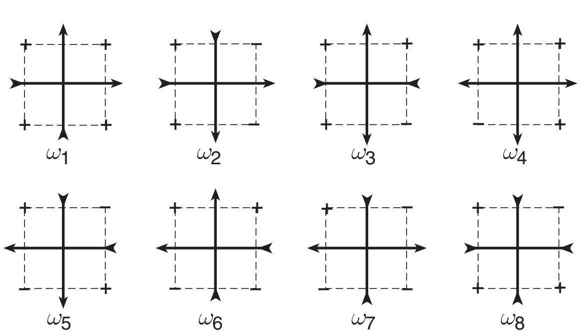


**Figure 1** The eight vertex configurations of the eight-vertex model showing one of the two corresponding configurations of the related Ising model. The model is solvable in the symmetric case, $\omega_1 = \omega_5, \omega_2 = \omega_6, \omega_3 = \omega_7, \omega_4 = \omega_8$, when the Boltzmann weights are equal in pairs under arrow reversal.

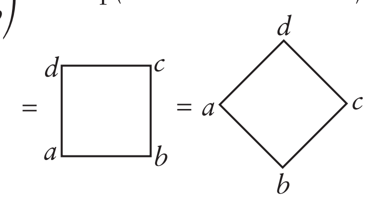
In the face representation, the arrow states are often called bond variables. Formally, the Hamiltonian is a sum over local energies $H = \sum_{\text{faces}} E(\alpha, \beta, \gamma, \delta)$, where $W(\alpha, \beta, \gamma, \delta) = \exp(-\beta E(\alpha, \beta, \gamma, \delta))$ but we use face weights since $E$ is infinite for excluded configurations. The general eight-vertex model includes many other ferroelectric models including the rectangular Ising model, Slater's model of potassium dihydrogen phosphate (KDP), the Rys F model of an antiferroelectric, the square ice model and the six-vertex model solved by Lieb. In the case of the six-vertex model, $\omega_4 = \omega_8 = 0$, so arrows are conserved with "two in" and "two out" at each vertex.

The eight-vertex model can be formulated as an Ising model with spins $a, b, c, d = \pm 1$ at the corners of the elementary faces and Boltzmann face weights

$$W\begin{pmatrix} d & c \\ a & b \end{pmatrix} = R \exp(Kac + Lbd + Mabcd) \qquad [5]$$



The four independent vertex weights are related to $R, K, L, M$ by

$$\begin{aligned} \omega_1 &= \omega_5 = Re^{K+L+M} \\ \omega_2 &= \omega_6 = Re^{-K-L+M} \\ \omega_3 &= \omega_7 = Re^{K-L-M} \\ \omega_4 &= \omega_8 = Re^{-K+L-M} \end{aligned} \qquad [6]$$

This is not the usual rectangular Ising model since it involves four-spin interactions in addition to two-spin interactions. The spins and arrows are related by

$$\alpha = ab, \quad \beta = bc, \quad \gamma = cd, \quad \delta = da \qquad [7]$$

This mapping is one-to-two, since we can arbitrarily fix one spin somewhere on the lattice. It follows that $Z_{\text{Ising}} = 2Z_{\text{vertex}}$. The eight-vertex model obviously includes the six-vertex ($\omega_4 = \omega_8$) and the rectangular Ising models ($M = 0$). Although it is not at all obvious, the three-spin Ising model is also included as a special case ($K = M, L = 0$).

Notice that the eight-vertex face weights are invariant under spin reversal of the spins on either diagonal. This $\mathbb{Z}_2 \times \mathbb{Z}_2$ symmetry, which the eight-vertex model shares with the Ashkin–Teller model, is peculiar because it allows the model to exhibit continuously varying critical exponents. Because of symmetries and duality, it is sufficient to consider the regime $\omega_1 > \omega_2 + \omega_3 + \omega_4$ with $\omega_2, \omega_3, \omega_4 > 0$. In terms of spins, this corresponds to the

ferromagnetically ordered phase; in terms of vertices or arrows, this corresponds to the ferroelectric phase. The eight-vertex model is critical on the four surfaces

$$\begin{aligned} \omega_1 &= \omega_2 + \omega_3 + \omega_4, \qquad & \omega_2 &= \omega_1 + \omega_3 + \omega_4 \\ \omega_3 &= \omega_1 + \omega_2 + \omega_4, \qquad & \omega_4 &= \omega_1 + \omega_2 + \omega_3 \end{aligned} \quad [8]$$

A convenient parameter to measure the departure from criticality $t = (T - T_c)/T_c$ is

$$\begin{aligned} t = -\frac{1}{16\omega_1\omega_2\omega_3\omega_4}[(\omega_1 - \omega_2 - \omega_3 - \omega_4) \\ \times (\omega_1 - \omega_2 + \omega_3 + \omega_4) \\ \times (\omega_1 + \omega_2 - \omega_3 + \omega_4) \\ \times (\omega_1 + \omega_2 + \omega_3 - \omega_4)] \end{aligned} \quad [9]$$

Because of the unusual four-spin interaction, it is difficult to realize the eight-vertex model experimentally in the laboratory.

### Hard-Hexagon Model

The hard-hexagon model is a two-dimensional lattice model of a gas of hard nonoverlapping particles. The particles are placed on the sites of a triangular lattice with nearest-neighbor exclusion so that no two particles are together or adjacent. Effectively, the triangular lattice is partially covered with nonoverlapping hard tiles of hexagonal shape. Let us draw the triangular lattice as a square lattice with one set of diagonals as in Figure 2. The partition function for the hard-hexagon model is

$$Z_N = \sum_{n=0}^{N} z^n g(n, N) \quad [10]$$

where $z > 0$ is the activity and $g(n, N)$ is the number of ways of placing $n$ particles on the $N$ sites such that no two particles are together or adjacent. To each lattice site $j$, assign a spin or occupation

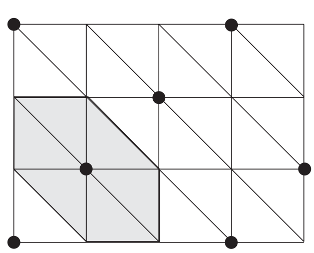


**Figure 2** The triangular lattice drawn as a square lattice with one set of diagonals. The close-packed arrangement of particles (solid circles) fills one of the three independent sublattices. One of the nonoverlapping hard hexagons is shown shaded. At low activities, the hard hexagons are sparsely scattered on the lattice with no preferential occupation of a particular sublattice.

number $\sigma_j$; if the site is empty, $\sigma_j = 0$; if the site is full, $\sigma_j = 1$. The partition function can then be written in terms of spins as

$$Z_N = \sum_{\text{spins } \sigma} \prod_{\langle ij \rangle} z^{(\sigma_i + \sigma_j)/6}(1 - \sigma_i\sigma_j) \quad [11]$$

where the product is over all bonds $\langle ij \rangle$ of the triangular lattice and the sum is over all configurations of the $N$ spins or occupation numbers $\sigma_j = 0, 1$. The exponent of $z$ arises because the activity is shared out between the six bonds incident at each site. The remaining term, $(1 - \sigma_i\sigma_j) = 0, 1$, ensures that neighboring sites are not occupied simultaneously by excluding such terms from the sum.

The activity $z$ gives the *a priori* probability of finding a particle at a given site and can be written as $z = e^{-\beta\mu}$, where $\mu$ is the chemical potential. The density of particles increases monotonically as the activity increases but only a third of the total lattice sites can be occupied. At low activities, there are only a few particles scattered randomly so the $S_3$ sublattice symmetry of the triangular lattice is preserved. However, at higher activities approaching the close-packing limit, there is a sudden change and one of the three sublattices is preferentially occupied so the $S_3$ sublattice symmetry is spontaneously broken. This dramatic change signals an order–disorder phase transition at some critical value $z_c$ of the activity. The system is disordered below the critical activity but is ordered above it. The fundamental problem is to obtain the statistical properties of this model such as the bulk free energy and the sublattice densities

$$\begin{aligned} \rho_k &= \langle \sigma_k \rangle \\ &= \{\text{fraction of spins sitting on} \\ &\qquad \text{sublattice } k = 1, 2, 3\} \end{aligned} \quad [12]$$

in the thermodynamic limit $N \to \infty$. The mean density is

$$\rho = (\rho_1 + \rho_2 + \rho_3)/3 \leq 1/3 \quad [13]$$

Assuming that sublattice $k = 1$ is preferentially occupied, an order parameter is defined by

$$R = \rho_1 - \rho_2 \quad [14]$$

The order parameter vanishes in the disordered regime but is nonzero in an ordered regime. Notice that the symmetry between sublattices $k = 2$ and 3 is not broken.

Unlike the eight-vertex model, the hard-hexagon model can be realized by a physical system in the laboratory, namely helium adsorbed on a graphite surface. The graphite substrate is composed of hexagonal cells formed by six carbon atoms with

an interatom distance of 2.46 Å. Energetically, the adsorbed helium atoms prefer to sit in the potential well at the center of the hexagonal cells. The diameter of the helium atom, however, is 2.56 Å, which precludes the simultaneous occupation of neighboring cells by excluded volume effects. Some beautiful experiments carried out by Bretz indicate that this system undergoes a phase transition. Indeed, Bretz took precise measurements of the specific heat as the temperature or, equivalently, the activity $z$, is varied, and obtained a symmetric power-law divergence at the critical point

$$C \sim |z - z_c|^{\alpha}, \quad \alpha \approx 0.36 \qquad [15]$$

with critical exponent $\alpha$ close to 1/3. Of course, one does not actually see divergences experimentally. Rather, it is the presence of dramatic peaks in the specific heat that are the hallmarks of a second-order transition.

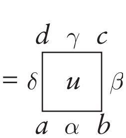
## Yang–Baxter Equations and Commuting Transfer Matrices

### Yang–Baxter Equations

The eight-vertex and hard-hexagon models were solved by Rodney Baxter at the beginning of the 1970s and 1980s, respectively. Although the two models are quite different in nature, they are quintessential of exactly solvable lattice models. The seminal work of Baxter gives a precise criterion to decide if a two-dimensional lattice model is exactly solvable: it is exactly solvable if its local face weights satisfy the celebrated Yang–Baxter equation. We present a general formulation of the Yang–Baxter equations and commuting transfer matrices and then show how Baxter implemented these for the eight-vertex and hard-hexagon models.

The first important step in the exact solution of a two-dimensional lattice model is the parametrization of the Boltzmann weights in terms of a distinguished variable $u$ called the spectral parameter. Typically, critical models involve trigonometric or hyperbolic functions and off-critical models involve elliptic functions of the spectral parameter. In terms of $u$, the local Boltzmann weights of a general two-dimensional lattice model take the form

$$W\left(\begin{matrix} d & \gamma & c \\ \delta & & \beta \\ a & \alpha & b \end{matrix}\middle|\, u\right) = \qquad [16]$$

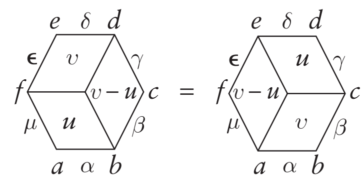


where the allowed values of the spins $a, b, c, \ldots$ and arrows (or bond variables) $\alpha, \beta, \gamma, \ldots$ may be restricted by certain constraints. The spins $a, b, c, d$ are absent for the eight-vertex model and the arrows $\alpha, \beta, \gamma, \delta$ are absent for the hard-hexagon model.

The general Yang–Baxter equations take the following algebraic and graphical forms:

$$\sum_{g,\eta,\xi,\zeta} W\left(\begin{matrix} f & \zeta & g \\ \mu & & \eta \\ a & \alpha & b \end{matrix}\middle|\, u\right) W\left(\begin{matrix} e & \delta & d \\ \epsilon & & \xi \\ f & \zeta & g \end{matrix}\middle|\, v\right) W\left(\begin{matrix} d & \gamma & c \\ \xi & & \beta \\ g & \eta & b \end{matrix}\middle|\, v-u\right)$$

$$= \sum_{g,\eta,\xi,\zeta} W\left(\begin{matrix} e & \eta & g \\ \epsilon & & \xi \\ f & \mu & a \end{matrix}\middle|\, v-u\right) W\left(\begin{matrix} g & \zeta & c \\ \xi & & \beta \\ a & \alpha & b \end{matrix}\middle|\, v\right) W\left(\begin{matrix} e & \delta & d \\ \eta & & \gamma \\ g & \zeta & c \end{matrix}\middle|\, u\right)$$



[17]

Graphically, this equation can be interpreted as saying that the diamond-shaped face with spectral parameter $v - u$ can be pushed through from the right to the left with the effect of interchanging the spectral parameters $u$ and $v$ in the remaining two faces.

### Commuting Transfer Matrices

A square lattice is built up row-by-row using the row transfer matrix $T(u)$ with matrix elements

$$\langle a, \alpha | \, T(u) \, | c, \gamma \rangle = \sum_{\beta_1, \beta_2, \ldots, \beta_N = \pm 1} \prod_{j=1}^{N} W\left(\begin{matrix} c_j & \gamma_j & c_{j+1} \\ \beta_j & & \beta_{j+1} \\ a_j & \alpha_j & a_{j+1} \end{matrix}\middle|\, u\right) \qquad [18]$$

= 

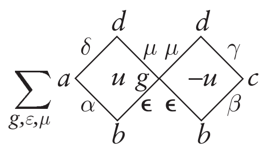
[19]

Here there are $N$ columns, and periodic boundary conditions are applied so that $a_{N+1} = a_1, \beta_{N+1} = \beta_1$, and so on. The significance of the Yang–Baxter equations is that they imply a one-parameter family of commuting transfer matrices

$$\boldsymbol{T}(u)\boldsymbol{T}(v) = \boldsymbol{T}(v)\boldsymbol{T}(u) \qquad [20]$$

Pictorially, the product on the left is represented by two rows, one above the other, the lower row with spectral parameter $u$ and the upper row with spectral parameter $v$. The matrix product implies

that the spins and arrows on the intervening row are summed out. Inserting a diamond-shaped face with spectral parameter $v-u$ and then using the local Yang–Baxter equation to progressively push it from right to left around the period interchanges all of the spectral parameters $u$ with the spectral parameter $v$. At the end, the diamond-shaped face is removed again. This heuristic argument was made rigorous by Baxter, who showed quite generally, and for the eight-vertex and hard-hexagon models in particular, that the diamond faces are in fact invertible:



$$= \rho(u)\ \delta(a, c)\ \delta(\alpha, \beta)\ \delta(\gamma, \delta) \qquad [21]$$

independent of $b, d$ where the scalar function $\rho(u)$ is model dependent. This equation is called the inversion relation.

Invariably, the existence of commuting transfer matrices leads to functional equations satisfied by the transfer matrices. Typically, the transfer matrices can be simultaneously diagonalized and so the functional equations can be solved for the eigenvalues of the transfer matrices. Mathematically, this is where Yang–Baxter techniques derive their power. For example, building up the lattice row-by-row, we see that the partition function of an $M \times N$ lattice is

$$Z_{MN} = \operatorname{tr} \boldsymbol{T}(u)^M = \sum_n T_n(u)^M \qquad [22]$$

where $T_n(u)$ are the eigenvalues of $\boldsymbol{T}(u)$. Typically, by the Perron–Frobenius theorem, the largest eigenvalue $T_0(u)$ is real, positive, and nondegenerate:

$$T_0(u) > |T_1(u)| \geq |T_2(u)| \geq \cdots \qquad [23]$$

Consequently,

$$\begin{aligned} -\beta\psi &= \lim_{N\to\infty} \lim_{M\to\infty} \frac{1}{MN} \log \sum_n T_n(u)^M \\ &= \lim_{N\to\infty} \frac{1}{N} \log T_0(u) \end{aligned} \qquad [24]$$

Thus the calculation of the bulk free energy is reduced to the problem of finding the largest eigenvalue of the transfer matrix.

### Parametrization of the Eight-Vertex Model

Using the spin formulation of the eight-vertex model, Baxter showed that two transfer matrices $\boldsymbol{T}(K, L, M), \boldsymbol{T}(K', L', M')$ commute whenever

$$\Delta(K, L, M) = \Delta(K', L', M') \qquad [25]$$

where

$$\begin{aligned} \Delta(K, L, M) = \sinh 2K \sinh 2L \\ + \tanh 2M \cosh 2K \cosh 2L \end{aligned} \qquad [26]$$

If $M$ and $\Delta$ are regarded as fixed, this is seen to be a symmetric biquadratic relation between $e^{2K}$ and $e^{2L}$ and is naturally parametrized in terms of elliptic functions. Unfortunately, many different notations and conventions for these elliptic functions appear in the literature which can be confusing to the uninitiated. Let

$$s = \frac{\vartheta_1(u)}{\vartheta_1(\lambda)}, \quad s_\pm = \frac{\vartheta_1(\lambda \pm u)}{\vartheta_1(\lambda)}, \quad \eta = \frac{\vartheta_1^2(\lambda)}{\vartheta_4^2(\lambda)} \qquad [27]$$

$$c = \frac{\vartheta_4(u)}{\vartheta_4(\lambda)}, \quad c_\pm = \frac{\vartheta_4(\lambda \pm u)}{\vartheta_4(\lambda)}, \quad \mu = \frac{\vartheta_4(0)}{\vartheta_4(\lambda)} \qquad [28]$$

where $\vartheta_1(u) = \vartheta_1(u, q)$ and $\vartheta_4(u) = \vartheta_4(u, q)$ are standard elliptic theta functions of nome $q$. Then the vertex weights can be parametrized as

$$\begin{aligned} \omega_1 &= R\mu^{-1} c c_-, & \omega_2 &= R\eta\mu^{-1} s s_- \\ \omega_3 &= R\mu^{-1} c s_-, & \omega_4 &= R\mu^{-1} c_- s \end{aligned} \qquad [29]$$

In the ferromagnetic regime $u$, $\lambda$, and $\tau$ are all pure imaginary with $0 < q < 1$ and $0 < \operatorname{Im} u < \operatorname{Im} \lambda < (\pi/2) \operatorname{Im} \tau$. The critical line occurs in the limit $q \to 1$. In this sense, we are using a low-temperature elliptic parametrization. Another elliptic parametrization, which is useful to study the critical limit, is obtained by transforming to the conjugate nome $q'$. If $q = e^{-\pi\epsilon}$ then the conjugate nome is defined by $q' = e^{-\pi/\epsilon}$ so that $q' \to 0$ as $q \to 1$.

We regard the crossing parameter $\lambda$ as constant, $u$ as a variable, and write the transfer matrix as $\boldsymbol{T}(u)$. It follows from this parametrization that $M$ and $\Delta$ are constants, independent of $u$. Furthermore, any two transfer matrices $\boldsymbol{T}(u)$ and $\boldsymbol{T}(v)$ commute and hence $\boldsymbol{T}(u)$ is a one-parameter family of commuting transfer matrices. For interest, we point out that the integrable $XYZ$ quantum spin chain belongs to this family. Specifically, the logarithmic derivative of the eight-vertex transfer matrix yields

$$\frac{d}{du} [\log \boldsymbol{T}(u)]_{u=0} = H_{XYZ} \qquad [30]$$

where

$$H_{XYZ} = -\frac{1}{2} \sum_{j=1}^{N} \left( J_x \sigma_j^x \sigma_{j+1}^x + J_y \sigma_j^y \sigma_{j+1}^y + J_z \sigma_j^z \sigma_{j+1}^z \right) \qquad [31]$$

and $\sigma_j^x, \sigma_j^y, \sigma_j^z$ are the usual Pauli spin matrices.

### Parametrization of the Hard-Hexagon Model

Actually, Baxter did not solve the hard-hexagon model directly. Instead, he solved a generalized hard-hexagon model, which is a model of hard squares with interactions along the diagonals of the elementary squares as shown in Figure 3. This in turn corresponds to the $A_4$ case of the more general solvable $A_L$ restricted solid-on-solid (RSOS) models of Andrews, Baxter, and Forrester.

The face weights of the generalized hard-hexagon model are

$$W\begin{pmatrix} d & c \\ a & b \end{pmatrix} = mz^{(a+b+c+d)/4}t^{-a+b-c+d}(1-ab) \times (1-bc)(1-cd)(1-da) \times \exp(Lac+Mbd) \qquad [32]$$

Here the activity $z$ has been shared out between the four faces adjacent to a site, $m$ is a trivial normalization constant, and $t$ is a gauge parameter that cancels out of the partition function and transfer matrix. The anisotropy between $L$ and $M$ introduces an additional parameter which will play the role of the spectral parameter $u$. In fact, using the Yang–Baxter equation, Baxter showed that this model is exactly solvable on the manifold

$$z = (1-e^{-L})(1-e^{-M})/(e^{L+M}-e^{L}-e^{M}) \qquad [33]$$

Specifically, two transfer matrices $\boldsymbol{T}(z,L,M)$ and $\boldsymbol{T}(z',L',M')$ commute whenever

$$\Delta(z,L,M) = \Delta(z',L',M') \qquad \Delta(z,L,M) = z^{-1/2}(1-ze^{L+M}) \qquad [34]$$

The hard-hexagon model is recovered in the limit $L=0$, $M=-\infty$ which forbids simultaneous occupation of sites joined by one set of diagonals. In this special limit, the activity $z$ is unconstrained. It is curious to note that the pure hard-square model with $L=M=0$ is not solvable.

Eliminating $z$ between the above relations gives a symmetric biquadratic relation between $e^L$ and $e^M$, which is naturally parametrized in terms of elliptic functions. Choosing $m$ and $t$ appropriately, the Boltzmann weights are

$$W\begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} = \frac{\theta(2\lambda+u)}{\theta(2\lambda)}$$
$$W\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} = W\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = \frac{\theta(u)}{[\theta(\lambda)\theta(2\lambda)]^{1/2}}$$
$$W\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = W\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \frac{\theta(\lambda-u)}{\theta(\lambda)} \qquad [35]$$
$$W\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \frac{\theta(2\lambda-u)}{\theta(2\lambda)}$$
$$W\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \frac{\theta(\lambda+u)}{\theta(\lambda)}$$

Here the crossing parameter is $\lambda=\pi/5$, $-\lambda<u<2\lambda$, and

$$\theta(u) = \theta(u,q^2) = \sin u\prod_{n=1}^{\infty}(1-q^{2n}e^{2iu}) \times (1-q^{2n}e^{-2iu})(1-q^{2n}) \qquad [36]$$

is a nonstandard elliptic theta function of nome $q^2$. Despite the deceiving notation, the nome $q^2$ lies in the range $-1<q^2<1$ and is determined by the relation

$$\Delta^2 = \left[\frac{\theta(\lambda)}{\theta(2\lambda)}\right]^5 = z(1-ze^{L+M})^2 \qquad [37]$$

Regarding $q^2$ as fixed and $u$ as a variable, it follows that $\boldsymbol{T}(u)$ is a one-parameter family of commuting transfer matrices.

The regimes relevant to the hard-hexagon model are:

$$\begin{aligned} &\text{Regime I (disordered)}: && -1<q^2<0,\ -\lambda<u<0 \\ &\text{Regime II (triangular ordered)}: && 0<q^2<1,\ -\lambda<u<0 \end{aligned} \qquad [38]$$

The borderline case $q^2=0$ corresponds to a line of critical points. The original hard-hexagon model is obtained in the limit $u\to-\lambda=-\pi/5$, so it follows that the critical point occurs at

$$z_c = \left(\frac{1+\sqrt{5}}{2}\right)^5 = \frac{1}{2}(11+5\sqrt{5}) \qquad [39]$$

Away from criticality the activity is related to the nome $q^2$ by

$$z = z_c\prod_{n=1}^{\infty}\left[\frac{1-2q^{2n}\cos(4\pi/5)+q^{4n}}{1-2q^{2n}\cos(2\pi/5)+q^{4n}}\right]^5 \qquad [40]$$

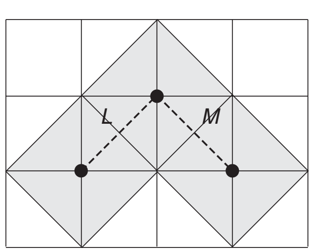


**Figure 3** Interacting hard squares showing the diagonal interactions $L$ and $M$. The hard-hexagon model corresponds to the limit $L=0, M=-\infty$..

## Functional Equations

### Baxter's $T-Q$ Relation

In a *tour de force* Baxter showed that the transfer matrix of the eight-vertex model satisfies the functional equation

$$T(u)Q(u) = \phi(u)Q(u-\lambda) + \phi(u-\lambda)Q(u+\lambda) \quad [41]$$

where $\phi(u) = (cs)^N = [\vartheta_1(u)\vartheta_4(u)/\vartheta_1(\lambda)\vartheta_4(\lambda)]^N$ and $Q(u)$ is an auxiliary family of mutually commuting transfer matrices satisfying $[Q(u), Q(v)] = [Q(u), T(v)] = 0$. In principle, these equations, which are intimately related to the Bethe ansatz, can be solved to obtain all the eigenvalues of the transfer matrix. Without entering into the intricacies of solving these equations, we summarize the results for the partition function per site $\kappa$, correlation length $\xi$, and interfacial tension $\sigma$. As we have seen, the largest eigenvalue of the transfer matrix yields $\kappa$. The interfacial tension $\sigma$ and correlation length $\xi$ were obtained, respectively, by Baxter and by Johnson, Krinsky, and McCoy by integrating over (continuous) bands of eigenvalues. In the ferromagnetic regime, their results are

$$\log(\kappa/\omega_1) = \sum_{n=1}^{\infty} \frac{x^{-n}(x^{2n}-q^n)^2(x^n+x^{-n}-z^n-z^{-n})}{n(1-q^{2n})(1+x^{2n})} \quad [42]$$

$$\xi^{-1} = -\tfrac{1}{2}\log k(x^2), \qquad \sigma = k_B T/\xi \quad [43]$$

where $x = e^{\pi i \lambda/2}$, $z = x^{-1}e^{\pi i u}$, and $k$ is the elliptic modulus of nome $x^2$:

$$k(x^2) = 4x\prod_{n=1}^{\infty}\left(\frac{1+x^{4n}}{1+x^{4n-2}}\right)^4 \quad [44]$$

Detailed analysis shows that near $T_c$ the free energy $\psi$ in general behaves as

$$\psi \sim \cot(\pi^2/2\bar{\mu})t^{\pi/\bar{\mu}} \sim t^{2-\alpha}, \quad t \to 0 \quad [45]$$

where $t = (T - T_c)/T_c$,

$$\tan(\bar{\mu}/2) = (\omega_3\omega_4/\omega_1\omega_2)^{1/2} = e^{-2M} \quad [46]$$

and $\alpha = 2 - \pi/\bar{\mu}$ with $0 < \bar{\mu} < \pi$. Exceptional cases occur, however, if $\pi/\bar{\mu}$ is an integer. This occurs, for example, in the case of the rectangular Ising model ($M = 0, \bar{\mu} = \pi/2$), which exhibits a logarithmic singularity in the specific heat ($\alpha = 0_{\log}$). Similarly, using $\log k(x^2) \sim (-t)^{\pi/2\bar{\mu}}$, the other associated critical exponents are

$$\xi^{-1} \sim (-t)^{\nu}, \quad \sigma \sim (-t)^{\mu}, \quad \nu = \mu = \pi/2\bar{\mu} \quad [47]$$

Notice that, due to the special symmetries of the eight-vertex model, these critical exponents vary continuously as the four-spin interaction is varied. This violates the universality hypothesis, which asserts that the exponents should only depend on the dimensionality and symmetries and not on the details of the interactions. Suzuki has suggested that it is more natural to use the inverse correlation length $\xi^{-1}$, rather than the temperature difference $T - T_c$, to measure the departure from criticality with the effect that it is the renormalized critical exponents

$$\hat{\alpha} = (2-\alpha)/\nu, \quad \hat{\beta} = \beta/\nu, \quad \hat{\mu} = \mu/\nu \quad [48]$$

that are independent of the details of the interactions.

### Hard-Hexagon Functional Equation

Baxter and Pearce showed that the normalized row transfer matrix of the generalized hard-hexagon model,

$$t(u) = \left[\frac{\theta(u+2\lambda)\theta(\lambda)}{\theta(u+\lambda)\theta(u-2\lambda)}\right]^N T(u) \quad [49]$$

satisfies the simple functional equation

$$t(u)t(u+\lambda) = I + t(u-2\lambda) \quad [50]$$

where $\lambda = \pi/5$. Since $T(u)$ is a commuting family of matrices, this equation can be solved for the eigenvalues $T(u)$ to obtain the partition function per site $\kappa$, correlation length $\xi$, and interfacial tension $\sigma$. Let $p = |q^2|$, $s = |q^2|^{5/6}$, then the results are summarized as

$$\kappa = \begin{cases} \kappa_c \displaystyle\prod_{n=1}^{\infty} \frac{[1-2q^{2n}\cos(4\pi/5)+q^{4n}]^2(1-q^{2n})^2(1-p^{5n})(1-p^{10(2n-1)/3})^3}{[1-2q^{2n}\cos(2\pi/5)+q^{4n}]^3(1-p^{5n/3})^3(1-p^{10(2n-1)})}, & z \le z_c \\ \kappa_c \displaystyle\prod_{n=1}^{\infty} \frac{[1-2q^{2n}\cos(4\pi/5)+q^{4n}]^2(1-q^{2n})^2(1-p^{5n})}{[1-2q^{2n}\cos(2\pi/5)+q^{4n}]^3(1-p^{5n/3})^3}, & z > z_c \end{cases} \quad [51]$$

$$\kappa_c = \left[\frac{27(25+11\sqrt{5})}{250}\right]^{1/2} \quad [52]$$

$$e^{-\xi^{-1}} = \begin{cases} \prod_{n=1}^{\infty} \frac{1-\sqrt{3}s^{2n-1}+s^{4n-2}}{1+\sqrt{3}s^{2n-1}+s^{4n-2}}, & z \le z_c \\ \min_{0<\alpha<\pi} \left[\prod_{n=1}^{\infty} \frac{1-2s^{2n-1}\cos\left(\frac{2\pi}{3}-\alpha\right)+s^{4n-2}}{1-2s^{2n-1}\cos\left(\frac{2\pi}{3}+\alpha\right)+s^{4n-2}}\right]^2, & z > z_c \end{cases} \quad [53]$$

$$\sigma = \begin{cases} 0, & z \le z_c \\ \frac{1}{2}k_B T/\xi, & z > z_c \end{cases} \quad [54]$$

It follows that $\kappa(z)$, $\xi(z)$, and $\sigma(z)$ are analytic functions of $z$, except at the critical point $z = z_c$.

The associated critical exponents

$$\psi \sim (z-z_c)^{2-\alpha}, \qquad \xi \sim (z-z_c)^{-\nu}$$
$$\sigma \sim (z-z_c)^{-\mu}, \quad \alpha = 1/3, \quad \nu = \mu = 5/6 \quad [55]$$

agree with experiments on helium adsorbed on graphite.

## Corner Transfer Matrices

The one-point functions and order parameters of the eight-vertex and hard-hexagon models were obtained by Baxter by using corner transfer matrices (CTMs). The idea is to build up the square lattice quadrant-by-quadrant as shown in Figure 4. The partition function and one-point function are then

$$Z = \operatorname{tr} \boldsymbol{ABCD}, \qquad \langle \sigma_1 \rangle = \frac{\operatorname{tr} \boldsymbol{SABCD}}{\operatorname{tr} \boldsymbol{ABCD}} \quad [56]$$

where $\boldsymbol{S}$ is the diagonal matrix with entries $S_{\sigma,\sigma} = \sigma_0$ and the entries $A_{\sigma,\sigma'}$ are labeled by half-rows of spins $\sigma = (\sigma_0, \sigma_1, \sigma_2, \dots)$ and $\sigma' = (\sigma_0, \sigma'_1, \sigma'_2, \dots)$.

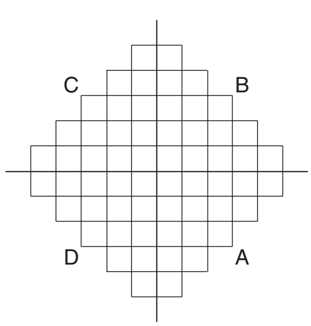

**Figure 4** The square lattice divided into four quadrants corresponding to the CTMs ***A***, ***B***, ***C***, ***D***. The spin at the center is $\sigma_0$.. The spins on the boundaries are fixed by the boundary conditions.

The CTMs have some remarkable properties. If the Boltzmann weights are invariant under reflections about the diagonals, as is the case for the eight-vertex model, Baxter argued that, in the limit of a large lattice,

$$\boldsymbol{A}(u) = \boldsymbol{C}(u) = \boldsymbol{B}(\lambda - u) = \boldsymbol{D}(\lambda - u) \quad [57]$$

where $\boldsymbol{A}(u)$ is a commuting family of matrices. Since these are block matrices in the center spin $\sigma_0$, they also commute with $\boldsymbol{S}$. Moreover, Baxter showed that the eigenvalues of $\boldsymbol{A}(u)$ are exponentials of the form

$$A(u)_\sigma = m_\sigma \exp(uE_\sigma) \quad [58]$$

where the constants $m_\sigma$ and $E_\sigma$ can be evaluated in the low-temperature limit. It follows that

$$\langle \sigma_0 \rangle = \frac{\sum_\sigma \sigma_0 m_\sigma^4 e^{2\lambda E_\sigma}}{\sum_\sigma m_\sigma^4 e^{2\lambda E_\sigma}} \quad [59]$$

When the Boltzmann weights do not exhibit symmetry about the diagonals, which is the case for hard hexagons, the above arguments need to be modified.

### One-Point Functions of the Eight-Vertex Model

For the eight-vertex model, Baxter showed that

$$m_\sigma = 1, \quad E_\sigma = \frac{1}{2}\pi i \sum_{j=1}^{N} jH(\sigma_{j-1}, \sigma_j, \sigma_{j+1})$$
$$H(\sigma_{j-1}, \sigma_j, \sigma_{j+1}) = 1 - \sigma_{j-1}\sigma_{j+1} \quad [60]$$

subject to the boundary condition $\sigma_N = \sigma_{N+1} = +1$. Introducing a new set of spins

$$\mu_j = \sigma_{j-1}\sigma_{j+1}, \quad j = 1, 2, \dots, N \quad [61]$$

we have $\sigma_0 = \mu_1\mu_3\mu_5 \dots$. Setting $s = (xz)^{1/2} = e^{\pi i u/2}$, $t = (x/z)^{1/2} = e^{\pi i(\lambda - u)/2}$ and taking the limit of large $N$, the diagonalized matrices are direct products of $2 \times 2$ matrices:

$$\boldsymbol{S} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \otimes \cdots \quad [62]$$

$$\boldsymbol{A}(u) = \boldsymbol{C}(u) = \begin{pmatrix} 1 & 0 \\ 0 & s \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & s^2 \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & s^3 \end{pmatrix} \otimes \cdots \quad [63]$$

$$\boldsymbol{B}(u) = \boldsymbol{D}(u) = \begin{pmatrix} 1 & 0 \\ 0 & t \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & t^2 \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & t^3 \end{pmatrix} \otimes \cdots \quad [64]$$

It follows that the magnetization is

$$\langle \sigma_0 \rangle = \prod_{n=1}^{\infty} \frac{1 - x^{4n-2}}{1 + x^{4n+2}} = (k')^{1/4} = (1 - k^2)^{1/8} \quad [65]$$

where $k' = k'(x^2)$ is the conjugate elliptic modulus of nome $x^2$ and the associated critical exponent is

$$\langle \sigma_0 \rangle \sim (-t)^\beta, \quad \beta = \pi/16\bar{\mu} \qquad [66]$$

The polarization of the eight-vertex model is

$$\langle \alpha \rangle = \langle \sigma_0 \sigma_1 \rangle = \prod_{n=1}^{\infty} \left( \frac{1 - x^{2n}}{1 + x^{2n}} \frac{1 + q^n}{1 - q^n} \right)^2 \qquad [67]$$

This cannot be obtained by a direct application of CTMs but was conjectured by Baxter and Kelland and subsequently derived by Jimbo, Miwa, and Nakayashiki using difference equations.

### One-Point Functions of the Hard-Hexagon Model

For hard hexagons, the working is more complicated because one must keep track of the sublattice of the central spin $\sigma_0$, but fascinating connections emerge with the Rogers–Ramanujan functions:

$$\begin{aligned} G(x) &= \prod_{n=1}^{\infty} \frac{1}{(1 - x^{5n-4})(1 - x^{5n-1})} \\ H(x) &= \prod_{n=1}^{\infty} \frac{1}{(1 - x^{5n-3})(1 - x^{5n-2})} \end{aligned} \qquad [68]$$

For hard hexagons, Baxter showed that

$$\rho_k = \frac{\operatorname{tr} \boldsymbol{S}(\boldsymbol{A}_k \boldsymbol{B}_k)^2}{\operatorname{tr} (\boldsymbol{A}_k \boldsymbol{B}_k)^2} = \frac{\sum_\sigma \sigma_0 r_0^{2\sigma_0} w_0^{2E_\sigma}}{\sum_\sigma r_0^{2\sigma_0} w_0^{2E_\sigma}} \qquad [69]$$

where $k = 1, 2, 3$ labels the sublattice of the triangular lattice. Here the spin configurations $\sigma = (\sigma_0, \sigma_1, \sigma_3, \ldots)$ with $\sigma_j = 0, 1$ are subject to the constraint $\sigma_j \sigma_{j+1} = 0$ for all $j$. If $|q^2| = \mathrm{e}^{-\epsilon}$ and $g(x) = H(x)/G(x)$ then

$$\begin{aligned} &x = -\mathrm{e}^{-\pi^2/5\epsilon}, \; r_0^2 = -x/g(x), \; w_0 = -x^3 &&\text{for } z \le z_c \\ &x = \mathrm{e}^{-4\pi^2/5\epsilon}, \; r_0^2 = x^{-1} g(x), \; w_0 = x^{-3/2} &&\text{for } z > z_c \end{aligned} \qquad [70]$$

and

$$E_\sigma = \begin{cases} \sum_{j=1}^{\infty} j(\sigma_j - s_j), & z \le z_c \\ \sum_{j=1}^{\infty} j(\sigma_j - \sigma_{j-1}\sigma_{j+1} \\ \qquad - s_j + s_{j-1}s_{j+1}), & z > z_c \end{cases} \qquad [71]$$

For large $N$, $\sigma_j \to s_j$, where the ground-state values $s_j$ determined by the boundary conditions are

$$z \le z_c : \quad s_j = 0 \qquad [72]$$

$$z > z_c : \quad s_{3j+k} = 1, \; s_{3j+k\pm 1} = 0, \; k = 1, 2, 3 \qquad [73]$$

After applying some Rogers–Ramanujan identities and introducing the elliptic functions

$$\begin{aligned} Q(x) &= \prod_{n=1}^{\infty} (1 - x^n) \\ P(x) &= \frac{Q(x)}{Q(x^2)} = \prod_{n=1}^{\infty} (1 - x^{2n-1}) \end{aligned} \qquad [74]$$

the expressions for the sublattice densities simplify in the limit of large $N$ giving

$$\rho = \rho_1 = \rho_2 = \rho_3 = -\frac{x G(x) H(x^6) P(x^3)}{P(x^2)}, \quad z \le z_c \qquad [75]$$

in the disordered fluid phase and

$$\begin{aligned} \rho_1 &= \frac{H(x) Q(x) [G(x) Q(x) + x^2 H(x^9) Q(x^9)]}{Q(x^3)^2} \\ \rho_2 = \rho_3 &= \frac{x^2 H(x) H(x^9) Q(x) Q(x^9)}{Q(x^3)^2} \end{aligned} \qquad [76]$$

$$\begin{aligned} R = \rho_1 - \rho_2 &= \frac{Q(x) Q(x^5)}{Q(x^3)^2} \\ &= \prod_{n=1}^{\infty} \frac{(1 - x^n)(1 - x^{5n})}{(1 - x^{3n})^2}, \qquad z > z_c \end{aligned} \qquad [77]$$

in the triangular ordered phase. In principle, the dependence on $x$ can be eliminated by observing that

$$z = \begin{cases} -x[H(x)/G(x)]^5, & z \le z_c \\ x^{-1}[G(x)/H(x)]^5, & z > z_c \end{cases} \qquad [78]$$

In practice, this is quite nontrivial. Although it is far from obvious, because $x \to 1$ is a subtle limit, the critical exponent associated with the order parameter $R$ is

$$R \sim (z - z_c)^\beta \sim (q^2)^\beta, \quad \beta = 1/9 \qquad [79]$$

## Summary

Baxter's exact solutions of the eight-vertex and hard-hexagon models have been reviewed. These prototypical examples clearly illustrate the mathematical power and elegance of commuting transfer matrices and Yang–Baxter techniques. The results for the principal thermodynamic quantities, including free energies, correlation lengths, interfacial tensions, and one-point functions, have been summarized. For convenience in comparison, the associated critical exponents are collected in Table 1. All these exponents confirm the hyperscaling relation $2 - \alpha = d\nu$ for lattice dimensionality $d = 2$.

More recently, Yang–Baxter techniques have been applied to solve an infinite variety of lattice models in two dimensions. Commuting transfer methods have

**Table 1** Comparison of the exactly calculated critical exponents of the rectangular Ising, eight-vertex and hard-hexagon models. The rectangular Ising model corresponds to the special case $\bar{\mu}=\pi/2$ of the eight-vertex model. The eight-vertex exponents vary continuously with $0<\bar{\mu}<\pi$.. The critical exponents of the hard-hexagon model, with its $S_3$ symmetry, lie in the universality class of the three-state Potts model.

| *Model* | $\alpha$ | $\beta$ | $\nu$ | $\mu$ |
|---|---|---|---|---|
| Rectangular Ising | $0_{\log}$ | 1/8 | 1 | 1 |
| Eight vertex | $2-\pi/\bar{\mu}$ | $\pi/16\bar{\mu}$ | $\pi/2\bar{\mu}$ | $\pi/2\bar{\mu}$ |
| Hard hexagons | 1/3 | 1/9 | 5/6 | 5/6 |

also been adapted to study integrable boundaries and associated boundary critical behavior. Lastly, it should be mentioned that, in the continuum scaling limit, there are deep connections with conformal field theory and integrable quantum field theory. On the one hand, the lattice can often provide a convenient way to regularize the infinities that occur in these continuous field theories. On the other hand, the field theories can predict and explain the universal properties of lattice models such as critical exponents.

# Einstein Equations: Exact Solutions

**Jiří Bičák**, Charles University, Prague, Czech Republic and Albert Einstein Institute, Potsdam, Germany

## Introduction

Even in a linear theory like Maxwell's electrodynamics, in which sufficiently general solutions of the field equations can be obtained, one needs a good sample, a useful kit, of explicit exact fields like the homogeneous field, the Coulomb monopole field, the dipole, and other simple solutions, in order to gain a physical intuition and understanding of the theory. In Einstein's general relativity, with its nonlinear field equations, the discoveries and analyses of various specific explicit solutions revealed most of the unforeseen features of the theory. Studies of special solutions stimulated questions relevant to more general situations, and even after the formulation of a conjecture about a general situation, newly discovered solutions can play a significant role in verifying or modifying the conjecture. The cosmic censorship conjecture assuming that "singularities forming in a realistic gravitational collapse are hidden inside horizons" is a good illustration.

Albert Einstein presented the final version of his gravitational field equations (or the Einstein's equations, EEs) to the Prussian Academy in Berlin on 18 November 1915:

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = \frac{8\pi G}{c^4} T_{\mu\nu} \qquad [1]$$

Here, the spacetime metric tensor $g_{\mu\nu}(x^\rho), \mu, \nu, \rho, \ldots = 0, 1, 2, 3$, determines the invariant line element $g = g_{\mu\nu}\, dx^\mu\, dx^\nu$, and acts also as a dynamical variable describing the gravitational field; the Ricci tensor $R_{\mu\nu} = g^{\rho\sigma} R_{\rho\mu\sigma\nu}$, where $g^{\mu\rho} g_{\rho\nu} = \delta^\mu_\nu$, is formed from the Riemann curvature tensor $R_{\rho\mu\sigma\nu}$; both depend nonlinearly on $g_{\alpha\beta}$ and $\partial_\mu g_{\alpha\beta}$, and linearly on $\partial_\mu \partial_\nu g_{\alpha\beta}$; the scalar curvature $R = g^{\mu\nu} R_{\mu\nu}$. $T_{\mu\nu}(x^\rho)$ is the energy–momentum tensor of matter ("sources"); and Newton's gravitational constant $G$ and the velocity of light $c$ are fundamental constants. If not stated otherwise, we use the geometrized units in which $G = c = 1$, and the same conventions as in Misner *et al.* (1973) and Wald (1984). For example, in the case of perfect fluid with density $\rho$, pressure $p$, and 4-velocity $U^\mu$, the energy–momentum tensor reads $T_{\mu\nu} = (\rho + p)\; U_\mu U_\nu + p g_{\mu\nu}$. To obtain a (local) solution of [1] in coordinate patch $\{x^\rho\}$ means to find "physically plausible" (i.e., complying with one of the positive-energy conditions) functions $\rho(x^\rho), p(x^\rho), U_\mu(x^\rho)$, and metric $g_{\mu\nu}(x^\rho)$ satisfying [1]. In vacuum $T_{\mu\nu} = 0$ and [1] implies $R_{\mu\nu} = 0$.

In 1917, Einstein generalized [1] by adding a cosmological term $\Lambda g_{\mu\nu}$ ($\Lambda = \text{const.}$):

$$R_{\mu\nu} - \tfrac{1}{2} g_{\mu\nu} R + \Lambda g_{\mu\nu} = 8\pi T_{\mu\nu} \qquad [2]$$

A homogeneous and isotropic static solution of [2] (with metric [8], $k = +1, a = \text{const.}$), in which the "repulsive effect" of $\Lambda > 0$ compensates the gravitational attraction of incoherent dust ("uniformly distributed galaxies") – the Einstein static universe – marked the birth of modern cosmology. Although it is unstable and lost its observational relevance after the discovery of the expansion of the universe in the late 1920s, in 2004 a "fine-tuned" cosmological scenario was suggested according to which our universe starts asymptotically from an initial Einstein static state and later enters an inflationary era, followed by a standard expansion epoch (*see* Cosmology: Mathematical Aspects). There are many other examples of "old" solutions which turned out to act as asymptotic states of more general classes of models.

## Invariant Characterization and Classification of the Solutions

### Algebraic Classification

The Riemann tensor can be decomposed as

$$R_{\alpha\beta\gamma\delta} = C_{\alpha\beta\gamma\delta} + E_{\alpha\beta\gamma\delta} + G_{\alpha\beta\gamma\delta} \qquad [3]$$

where $E$ and $G$ are constructed from $R_{\alpha\beta}$, $R$, and $g_{\alpha\beta}$ (see, e.g., Stephani *et al.* (2003)); the Weyl conformal tensor $C_{\alpha\beta\gamma\delta}$ can be considered as the "characteristic of the pure gravitational field" since, at a given point, it cannot be determined in terms of the matter energy–momentum tensor $T_{\alpha\beta}$ (as $E$ and $G$ can using EEs). Algebraic classification is based on a classification of the Weyl tensor. This is best formulated using two-component spinors $\alpha_A (A = 1, 2)$, in terms of which any Weyl spinor $\Psi_{ABCD}$ determining $C_{\alpha\beta\gamma\delta}$ can be factorized:

$$\Psi_{ABCD} = \alpha_{(A} \beta_B \gamma_C \delta_{D)} \qquad [4]$$

brackets denote symmetrization; each of the spinors determines a principal null direction, say, $k^\alpha = \alpha^A \bar{\alpha}^{A'}$ (*see* Spinors and Spin Coefficients). The Petrov–Penrose classification is based on coincidences among these directions. A solution is of type *I* (general case), *II*, *III*, and *N* ("null") if all null directions are different, or two, three, and all four coincide, respectively. It is of type *D* ("degenerate")

if there are two double null directions. The equivalent tensor equations are simplest for type $N$:

$$C_{\alpha\beta\gamma\delta}k^{\delta} = 0, \qquad C_{\alpha\beta\gamma\delta}C^{\alpha\beta\gamma\delta} = 0, \qquad C_{\alpha\beta\gamma\delta}C^{*\alpha\beta\gamma\delta} = 0 \qquad [5]$$

where $C^{*}_{\alpha\beta\gamma\delta} = (1/2)\epsilon_{\alpha\beta\rho\sigma}C^{\rho\sigma}{}_{\gamma\delta}$, $\epsilon$ is the Levi-Civita pseudotensor.

### Classification According to Symmetries

Most of the available solutions have some exact continuous symmetries which preserve the metric. The corresponding group of motions is characterized by the number and properties of its Killing vectors $\xi^{\alpha}$ satisfying the Killing equation $(£_{\xi}g)_{\alpha\beta} = \xi_{\alpha;\beta} + \xi_{\beta;\alpha} = 0$ ($£$ is the Lie derivative) and by the nature (spacelike, timelike, or null) of the group orbits. For example, axisymmetric, stationary fields possess two commuting Killing vectors, of which one is timelike. Orbits of the axial Killing vector are closed spacelike curves of finite length, which vanishes at the axis of symmetry. In cylindrical symmetry, there exist two spacelike commuting Killing vectors. In both cases, the vectors generate a two-dimensional abelian group. The two-dimensional group orbits are timelike in the stationary case and spacelike in the cylindrical symmetry.

If a timelike $\xi^{\alpha}$ is hypersurface orthogonal, $\xi_{\alpha} = \lambda\Phi_{,\alpha}$ for some scalar functions $\lambda, \Phi$, the spacetime is "static." In coordinates with $\xi = \partial_t$, the metric is

$$g = -e^{2U}dt^2 + e^{-2U}\gamma_{ik}dx^i dx^k \qquad [6]$$

where $U, \gamma_{ik}$ do not depend on $t$. In vacuum, $U$ satisfies the potential equation $U^{:a}_{:a} = 0$, the covariant derivatives (denoted by :) are with respect to the three-dimensional metric $\gamma_{ik}$. A classical result of Lichnerowicz states that if the vacuum metric is smooth everywhere and $U \to 0$ at infinity, the spacetime is flat (for refinements, see Anderson (2000)).

In cosmology, we are interested in groups whose regions of transitivity (points can be carried into one another by symmetry operations) are three-dimensional spacelike hypersurfaces (homogeneous but anisotropic models of the universe). The three-dimensional simply transitive groups $G_3$ were classified by Bianchi in 1897 according to the possible distinct sets of structure constants but their importance in cosmology was discovered only in the 1950s. There are nine types: Bianchi I to Bianchi IX models. The line element of the Bianchi universes can be expressed in the form

$$g = -dt^2 + g_{ab}(t)\omega^a\omega^b \qquad [7]$$

where the time-independent 1-forms $\omega^a = E^a_{\alpha}dx^{\alpha}$ satisfy the relations $d\omega^a = -(1/2)C^a_{bc}\omega^b \wedge \omega^c$, $d$ is the exterior derivative and $C^a_{bc}$ are the structure constants (*see* Cosmology: Mathematical Aspects for more details).

The standard Friedmann–Lemaître–Robertson–Walker (FLRW) models admit in addition an isotropy group SO(3) at each point. They can be represented by the metric

$$g = -dt^2 + [a(t)]^2\left(\frac{dr^2}{1-kr^2} + r^2(d\theta^2 + \sin^2\theta d\varphi^2)\right) \qquad [8]$$

in which $a(t)$, the "expansion factor," is determined by matter via EEs, the curvature index $k = -1, 0, +1$, the three-dimensional spaces $t$=const. have a constant curvature $K = k/a^2; r \in [0,1]$ for closed ($k = +1$) universe, $r \in [0, \infty)$ in open ($k = 0, -1$) universes (for another description (*see* Cosmology: Mathematical Aspects).

There are four-dimensional spacetimes of constant curvature solving EEs [2] with $T_{\mu\nu} = 0$: the Minkowski, de Sitter, and anti-de Sitter spacetimes. They admit the same number [10] of independent Killing vectors, but interpretations of the corresponding symmetries differ for each spacetime.

If $\xi^{\alpha}$ satisfies $£_{\xi}g_{\alpha\beta} = 2\Phi g_{\alpha\beta}$, $\Phi$ = const., it is called a homothetic (Killing) vector. Solutions with proper homothetic motions, $\Phi \neq 0$, are "self-similar." They cannot in general be asymptotically flat or spatially compact but can represent asymptotic states of more general solutions. In Stephani *et al.* (2003), a summary of solutions with proper homotheties is given; their role in cosmology is analyzed by Wainwright and Ellis (eds.) (1997); for mathematical aspects of symmetries in general relativity, see Hall (2004).

There are other schemes for invariant classification of exact solutions (reviewed in Stephani *et al.* (2003)): the algebraic classification of the Ricci tensor and energy–momentum tensor of matter; the existence and properties of preferred vector fields and corresponding congruences; local isometric embeddings into flat pseudo-Euclidean spaces, etc.

## Minkowski (M), de Sitter (dS), and Anti-de Sitter (AdS) Spacetimes

These metrics of constant (zero, positive, negative) curvature are the simplest solutions of [2] with $T_{\mu\nu} = 0$ and $\Lambda = 0, \Lambda > 0, \Lambda < 0$, respectively. The standard topology of M is $R^4$. The dS has the topology $R^1 \times S^3$ and is best represented as a four-dimensional hyperboloid $-v^2 + w^2 + x^2 + y^2 + z^2 = (3/\Lambda)$ in a five-dimensional flat space with metric $g = -dv^2 + dw^2 + dx^2 + dy^2 + dz^2$. The AdS has the topology $S^1 \times R^3$; it is a four-dimensional hyperboloid $-v^2 - w^2 + x^2 + y^2 + z^2 = -(3/\Lambda)$, $\Lambda < 0$, in flat five-dimensional space

with signature (− , − , + , +, +). By unwrapping the circle $S^1$ and considering the universal covering space, one gets rid of closed timelike lines.

These spacetimes are all conformally flat and can be conformally mapped into portions of the Einstein universe (*see* Asymptotic Structure and Conformal Infinity). However, their conformal structure is globally different. In M, one can go to infinity along timelike/null/spacelike geodesics and reach five qualitatively different sets of points: future/past timelike infinity $i^{\pm}$, future/past null infinity $\mathcal{I}^{\pm}$, and spacelike infinity $i^0$. In dS, there are only past and future conformal infinities $\mathcal{I}^-, \mathcal{I}^+$, both being spacelike (on the Einstein cylinder, the dS spacetime is a "horizontal strip" with $\mathcal{I}^+/\mathcal{I}^-$ as the "upper/lower circle"). The conformal infinity in AdS is timelike.

As a consequence of spacelike $\mathcal{I}^{\pm}$ in dS, there exist both particle (cosmological) and event horizons for geodesic observers (Hawking and Ellis 1973). dS plays a (doubly) fundamental role in the present-day cosmology: it is an approximate model for inflationary paradigm near the big bang and it is also the asymptotic state (at $t \to \infty$) of cosmological models with a positive cosmological constant. Since recent observations indicate that $\Lambda > 0$, it appears to describe the future state of our universe. AdS has come recently to the fore due to the "holographic" conjecture (*see* AdS/CFT Correspondence).

Christodoulou and Klainermann, and Friedrich proved that M, dS, and AdS are stable with respect to general, nonlinear (though "weak") vacuum perturbations – result not known for any other solution of EEs (*see* Stability of Minkowski Space).

## Schwarzschild and Reissner–Nordström Metrics

These are spherically symmetric spacetimes – the $SO_3$ rotation group acts on them as an isometry group with spacelike, two-dimensional orbits. The metric can be brought into the form

$$g = -e^{2\nu} dt^2 + e^{2\lambda} dr^2 + r^2(d\theta^2 + \sin^2\theta d\varphi^2) \qquad [9]$$

$\nu(t, r), \lambda(t, r)$ must be determined from EEs. In vacuum, we are led uniquely to the Schwarzschild metric

$$g = -\left(1 - \frac{2M}{r}\right)dt^2 + \left(1 - \frac{2M}{r}\right)^{-1} dr^2 + r^2(d\theta^2 + \sin^2\theta d\varphi^2) \qquad [10]$$

where $M = \text{const.}$ has to be interpreted as mass, as test particle orbits show. The spacetime is static at $r > 2M$, that is, outside the Schwarzschild radius at $r = 2M$, and asymptotically $(r \to \infty)$ flat.

Metric [10] describes the exterior gravitational field of an arbitrary (static, oscillating, collapsing, or expanding) spherically symmetric body (spherically symmetric gravitational waves do not exist). It is the most influential solution of EEs. The essential tests of general relativity – perihelion advance of Mercury, deflection of both optical and radio waves by the Sun, and signal retardation – are based on [10] or rather on its expansion in $M/r$. Space missions have been proposed that could lead to measurements of "post-post-Newtonian" effects (*see* General Relativity: Experimental Tests, and Misner *et al.* (1973)). The full Schwarzschild metric is of importance in astrophysical processes involving compact stars and black holes.

Metric [10] describes the spacetime outside a spherical body collapsing through $r = 2M$ into a spherical black hole. In **Figure 1**, the formation of an event horizon and trapped surfaces is indicated in ingoing Eddington–Finkelstein coordinates $(v, r, \theta, \varphi)$ where $v = t + r + 2M \log(r/2M - 1)$ so that $(v, \theta, \varphi) = \text{const.}$ are ingoing radial null geodesics. The interior of the star is described by another metric (e.g., the Oppenheimer–Snyder collapsing dust solution – see below). The Kruskal extension of the Schwarzschild solution, its compactification, the concept of the bifurcate Killing horizon, etc., are analyzed

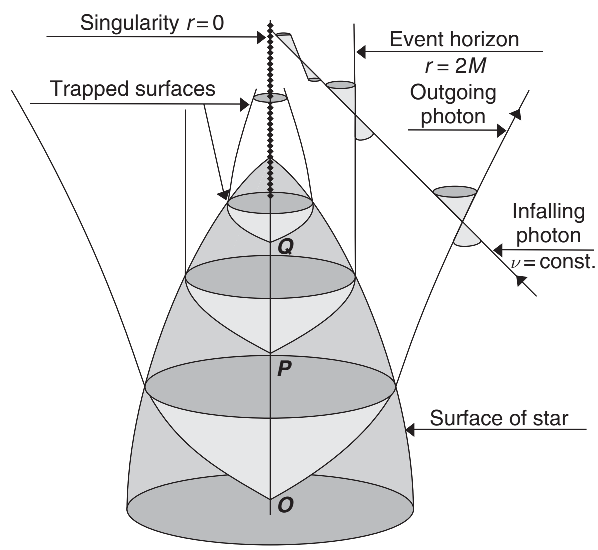

**Figure 1** Gravitational collapse of a spherical star (the interior of the star is shaded). The light cones of three events, *O*, *P*, *Q*, at the center of the star, and of three events outside the star are illustrated. The event horizon, the trapped surfaces, and the singularity formed during the collapse are also shown. Although the singularity appears to lie along the direction of time, from the character of the light cone outside the star but inside the event horizon we can see that it has a spacelike character. Reproduced from Bičák J (2000) Selected solutions of Einstein's field equations: their role in general relativity and astrophysics. In: Schmidt BG (ed.) *Einstein's Field Equations and their physical Implications*, Lecture Notes in Physics, vol. 540, pp. 1–126. Heildelberg: Springer, with permission from Springer-Verlag.

in Stationary Black Holes and in Misner *et al.* (1973), Hawking and Ellis (1973), and Bičák (2000).

The Reissner–Nordström solution describes the exterior gravitational and electromagnetic fields of a spherical body with mass $M$ and charge $Q$. The energy-momentum tensor on the right-hand side of EE [2] is that of the electromagnetic field produced by the charge; the field satisfies the curved-space Maxwell equations. The metric reads

$$g = -\left(1 - \frac{2M}{r} + \frac{Q^2}{r^2}\right)dt^2 + \left(1 - \frac{2M}{r} + \frac{Q^2}{r^2}\right)^{-1} dr^2 + r^2(d\theta^2 + \sin^2\theta d\varphi^2) \qquad [11]$$

The analytic extension of the electrovacuum metric [11] is qualitatively different from the Kruskal extension of the Schwarzschild metric. In the case $Q^2 > M^2$ there is a "naked singularity" (visible from $r \to \infty$) at $r = 0$ where curvature invariants diverge. If $Q^2 < M^2$, the metric describes a (generic) static charged black hole with two event horizons at $r = r_\pm = M \pm (M^2 - Q^2)^{1/2}$. The Killing vector $\partial/\partial t$ is null at the horizons, timelike at $r > r_+$ and $r < r_-$, but spacelike between the horizons. The character of the extended spacetime is best seen in the compactified form, **Figure 2**, in which world-lines of radial light rays are 45° lines. Again, two infinities (right and left, in regions I and III) arise (as in the Kruskal–Schwarzschild diagram, *see* Stationary Black Holes), however, the maximally extended geometry consists of an infinite chain of asymptotically flat regions connected by "wormholes" between the singularities at $r = 0$. In contrast to the Schwarzschild singularity, the singularities are timelike – they do not block the way to the future. The inner horizon $r = r_-$ represents a Cauchy horizon for a typical initial hypersurface like $\Sigma$ (**Figure 2**): what is happening in regions $V$ is in general influenced not only by data on $\Sigma$ but also at the singularities. The Cauchy horizon is unstable (for references, see Bičák (2000) and recent work by Dafermos (2005)).

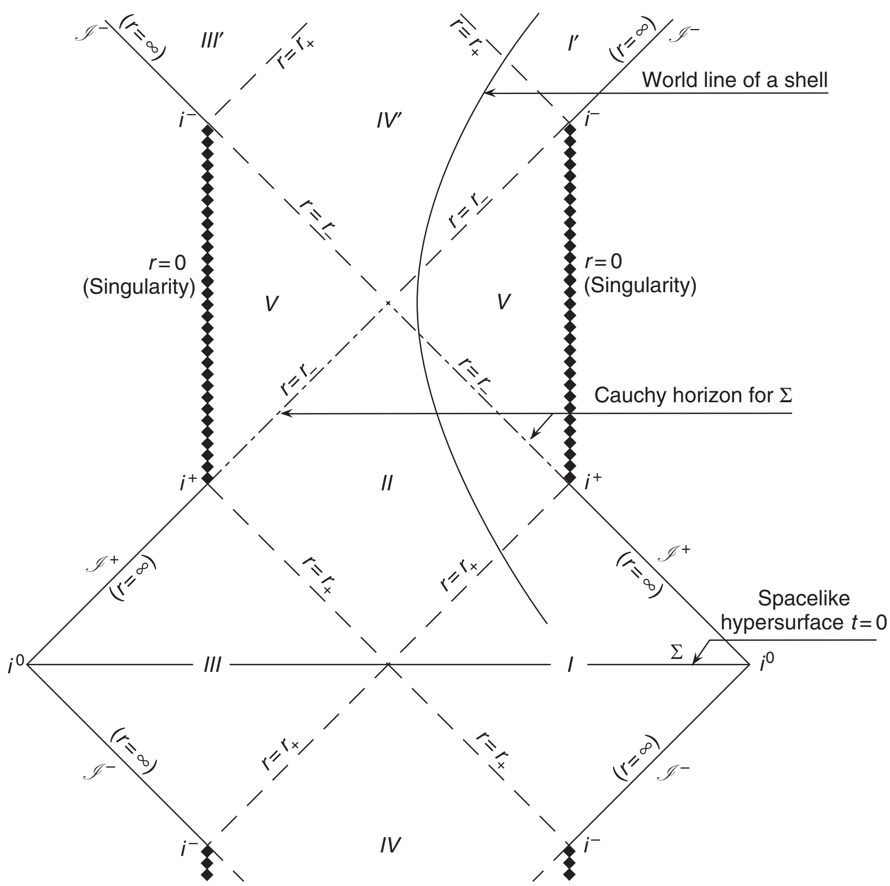

**Figure 2** The compactified Reissner–Nordström spacetime representing a non-extreme black hole consists of an infinite chain of asymptotic regions ("universes") connected by "wormholes" between timelike singularities. The world-line of a shell collapsing from "universe" *I* and re-emerging in "universe" *I′* is indicated. The inner horizon at $r = r_-$ is the Cauchy horizon for a spacelike hypersurface $\Sigma$. It is unstable and thus it will very likely prevent such a process. Reproduced from Bičák J (2000) Selected solutions of Einstein's field equations: their role in general relativity and astrophysics. In: Schmidt BG (ed.) *Einstein's Field Equations and their Physical Implications*, Lecture Notes in Physics, vol. 540, pp. 1–126. Heildelberg: Springer, with permission from Springer-Verlag.

For $M^2 = Q^2$ the two horizons coincide at $r_+ = r_- = M$. Metric [11] describes extreme Reissner–Nordström black holes. The horizon becomes degenerate and its surface gravity vanishes (*see* Stationary Black Holes). Extreme black holes play a significant role in string theory (Ortín 2004).

## Stationary Axisymmetric Solutions

Assume the existence of two commuting Killing vectors – timelike $\xi^\alpha$ and axial $\eta^\alpha$ ($\xi^\alpha \xi_\alpha < 0, \eta^\alpha \eta_\alpha > 0$), $\xi^\alpha$ normalized at (asymptotically flat) infinity, $\eta^\alpha$ at the rotation axis. They generate two-dimensional orbits of the group $G_2$. Assume there exist 2-spaces orthogonal to these orbits. This is true in vacuum and also in case of electromagnetic fields or perfect fluids whose 4-current or 4-velocity lies in the surfaces of transitivity of $G_2$ (e.g., toroidal magnetic fields are excluded). The metric can then be written in Weyl's coordinates $(t, \rho, \varphi, z)$

$$g = -e^{2U}(dt + A d\varphi)^2 + e^{-2U}[e^{2k}(d\rho^2 + dz^2) + \rho^2 d\varphi^2] \qquad [12]$$

$U$, $k$, and $A$ are functions of $\rho, z$.

The most celebrated vacuum solution of the form [12] is the Kerr metric for which $U$, $k$, $A$ are ratios of simple polynomials in spheroidal coordinates (simply related to $(\rho, z)$). The Kerr solution is characterized by mass $M$ and specific angular momentum $a$. For $a^2 > M^2$, it describes an asymptotically flat spacetime with a naked singularity. For $a^2 \leq M^2$, it represents a rotating black hole that has two horizons which coalesce into a degenerate horizon for $a^2 = M^2$ – an extreme Kerr black hole. The two horizons are located at $r_\pm = M \pm (M^2 - a^2)^{1/2}$ ($r$ being the Boyer–Lindquist coordinate (*see* Stationary Black Holes)). As with the Reissner–Nordström black hole, the singularity inside is timelike and the inner horizon is an (unstable) Cauchy horizon. The analytic extension of the Kerr metric resembles **Figure 2** (see Frolov and Novikov (1998), Hawking and Ellis (1973), Misner *et al.* (1973), Ortín (2004), Semerák *et al.* (2002), Stephani *et al.* (2003), and Wald (1984) for details).

Thanks to the black hole uniqueness theorems (*see* Stationary Black Holes), the Kerr metric is the unique solution describing all rotating black holes in vacuum. If the cosmic censorship conjecture holds, Kerr black holes represent the end states of gravitational collapse of astronomical objects with supercritical masses. According to prevalent views, they reside in the nuclei of most galaxies. Unlike with a spherical collapse, there are no exact solutions available which would represent the formation of a Kerr black hole. However, starting from metric [12] and identifying, for example, $z = b =$ const. and $z = -b$ (with the region $-b < z < b$ being cut off), one can construct thin material disks which are physically plausible and can be the sources of the Kerr metric even for $a^2 > M^2$ (see Bičák (2000) for details).

In a general case of metric [12], EEs in vacuum imply the "Ernst equation" for a complex function $f$ of $\rho$ and $z$:

$$(\Re f)\left[f_{,\rho\rho} + f_{,zz} + \frac{1}{\rho} f_{,\rho}\right] = f_{,\rho}^2 + f_{,z}^2 \qquad [13]$$

or, equivalently, $(\Re f)\triangle f = (\nabla f)^2$, where $f = e^{2U} + ib$, $U$ enters [12], and $b(\rho, z)$ is a "potential" for $A(\rho, z)$: $A_{,\rho} = \rho e^{-4U} b_{,z}$, $A_{,z} = -\rho e^{-4U} b_{,\rho}$; $k(\rho, z)$ in [12] can be determined from $U$ and $b$ by quadratures. Tomimatsu and Sato (TS) exploited symmetries of [13] to construct metrics generalizing the Kerr metric. Replacing $f$ by $\xi = (1 - f)/(1 + f)$, one finds that in case of the Kerr metric $\xi^{-1}$ is a linear function in the prolate spheroidal coordinates, whereas for TS solutions $\xi$ is a quotient of higher-order polynomials. A number of other solutions of eqn [13] were found but they are of lower significance than the Kerr solution (cf. Stephani *et al.* (2003), Chapter 20).

These solutions inspired "solution-generating methods" in general relativity. The Ernst equation can be regarded as the integrability condition of a system of linear differential equations. The problem of solving such a system can be reformulated as the Riemann–Hilbert problem in complex function theory (*see* Riemann–Hilbert Problem and Integrable Systems: Overview). We refer to Stephani *et al.* (2003) and Belinski and Verdaguer (2001) where these techniques using Bäcklund transformations, inverse-scattering method, etc., are also applied in the nonstationary context of two spacelike Killing vectors (waves, cosmology). In the stationary case, all asymptotically flat, stationary, axisymmetric vacuum solutions can, in principle, be generated. It is known how to generate fields with given values of multipole moments, though the required calculations are staggering. By solving the Riemann–Hilbert problem with appropriate boundary data, Neugebauer and Meinel constructed the exact solution representing a rigidly rotating thin disk of dust (cf. Stephani *et al.* (2003) and Bičák (2000)).

A subclass of metrics [12] is formed by static Weyl solutions with $A = b = 0$. Equation [13] then becomes the Laplace equation $\Delta U = 0$. The nonlinearity of EEs enters only the equations for $k$: $k_{,\rho} = \rho(U_{,\rho}^2 - U_{,z}^2)$, $k_{,z} = 2\rho U_{,\rho} U_{,z}$. The class contains some explicit solutions of interest: the "linear superposition" of collinear particles with string-like singularities between them which keep the system in static equilibrium; solutions representing external

fields of counter-rotating disks, for example, those which are "inspired" by galactic Newtonian potentials; disks around black holes and some other special solutions (Stephani *et al.* 2003, Bonnor 1992, Bičák 2000, Semerák *et al.* 2002).

There are solutions of the Einstein–Maxwell equations representing external fields of masses endowed with electric charges, magnetic dipole moments, etc. (Stephani *et al.* 2003). Best known is the Kerr–Newman metric characterized by parameters $M$, $a$, and charge $Q$. For $M^2 \geq a^2 + Q^2$ it describes a charged, rotating black hole. Owing to the rotation, the charged black hole produces also a magnetic field of a dipole type. All the black hole solutions can be generalized to include a nonvanishing $\Lambda$ (for various applications, see Semerák *et al.* 2002)). Other generalizations incorporate the so-called Newman–Unti–Tamburino (NUT) parameter (corresponding to a "gravomagnetic monopole") or an "external" magnetic/electric field or a parameter leading to "uniform" acceleration (see Stephani *et al.* (2003) and Bičák (2000)). Much interest has recently been paid to black hole (and other) solutions with various types of gauge fields and to multidimensional solutions. References Frolov and Novikov (1998) and Ortín (2004) are two examples of good reviews.

## Radiative Solutions

### Plane Waves and Their Collisions

The best-known class are "plane-fronted gravitational waves with parallel rays" (pp-waves) which are defined by the condition that the spacetime admits a covariantly constant null vector field $k^\alpha$: $k_{\alpha;\beta} = 0$. In suitable null coordinates $u$, $v$ such that $k_\alpha = u_{,\alpha}$, $k^\alpha = (\partial/\partial v)^\alpha$, and complex coordinate $\zeta$ which spans the wave 2-surfaces $u = \text{const.}$, $v = \text{const.}$ with Euclidean geometry, the metric reads

$$g = 2d\zeta d\bar{\zeta} - 2du dv - 2H(u, \zeta, \bar{\zeta}) du^2 \qquad [14]$$

$H(u, \zeta, \bar{\zeta})$ is a real function. The vacuum EEs imply $H_{,\zeta\bar{\zeta}} = 0$ so that $2H = f(u, \zeta) + \bar{f}(u, \bar{\zeta})$, $f$ is an arbitrary function of $u$, analytic in $\zeta$. The Weyl tensor satisfies eqns [5] – the field is of type $N$ as is the field of plane electromagnetic waves. In the null tetrad $\{k^\alpha, l^\alpha, m^\alpha(\text{complex})\}$ with $l^\alpha k_\alpha = -1, m^\alpha \bar{m}_\alpha = 1$, all other products vanishing, the only nonzero projection of the Weyl tensor, $\Psi = C_{\alpha\beta\gamma\delta} l^\alpha \bar{m}^\beta l^\gamma m^\delta = H_{,\bar{\zeta}\bar{\zeta}}$, describes the transverse component of a wave propagating in the $k^\alpha$ direction. Writing $\Psi = \mathcal{A}e^{i\Theta}$, the real $\mathcal{A} > 0$ is the amplitude of the wave, $\Theta$ describes polarization. Waves with $\Theta = \text{const.}$ are called linearly polarized. Considering their effect on test particles, one finds that plane waves are transverse.

The simplest waves are homogeneous in the sense that $\Psi$ is constant along the wave surfaces. One gets $f(u, \zeta) = (1/2)\mathcal{A}(u)e^{i\Theta(u)}\zeta^2$. Instructive are "sandwich waves," for example, waves with a "square profile": $\mathcal{A} = 0$ for $u < 0$ and $u > a^2$, $\mathcal{A} = a^{-2} = \text{const.}$ for $0 \leq u \leq a^2$. This example demonstrates, within exact theory, that the waves travel with the speed of light, produce relative accelerations of test particles, focus astigmatically generally propagating parallel rays, etc. The focusing effects have a remarkable consequence: there exists no global spacelike hypersurface on which initial data could be specified – plane wave spacetimes contain no global Cauchy hypersurface.

"Impulsive" plane waves can be generated by boosting a "particle" at rest to the velocity of light by an appropriate limiting procedure. The ultrarelativistic limit of, for example, the Schwarzschild metric (the so-called Aichelburg–Sexl solution) can be employed as a "limiting incoming state" in black hole encounters (cf. monograph by d'Eath (1996)). Plane-fronted waves have been used in quantum field theory. For a review of exact impulsive waves, see Semerák *et al.* (2002).

A collision of plane waves represents an exceptional situation of nonlinear wave interactions which can be analyzed exactly. **Figure 3** illustrates a typical case in which the collision produces a spacelike singularity. The initial-value problem with data given at $v = 0$ and $u = 0$ can be formulated in terms of the equivalent matrix Riemann–Hilbert problem (*see* Riemann–Hilbert Problem); it is related to the hyperbolic counterpart of the Ernst equation [13]. For reviews, see Griffiths (1991), Stephani *et al.* (2003), and Bičák (2000).

### Cylindrical Waves

Discovered by G Beck in 1925 and known today as the Einstein–Rosen waves (1937), these vacuum solutions helped to clarify a number of issues, such as energy loss due to the waves, asymptotic structure of radiative

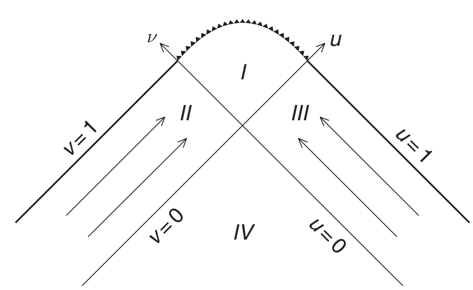

**Figure 3** A spacetime diagram indicating a collision of two plane-fronted gravitational waves which come from regions *II* and *III*, collide in region *I*, and produce a spacelike singularity. Region *IV* is flat. Reproduced from Bičák J (2000) Selected solutions of Einstein's field equations: their role in general relativity and astrophysics. In: Schmidt BG (ed.) *Einstein's Field Equations and their Physical Implications*, Lecture Notes in Physics, vol. 540, pp. 1–126. Heildelberg: Springer, with permission from Springer-Verlag.

spacetimes, dispersion of waves, quasilocal mass–energy, cosmic censorship conjecture, or quantum gravity in the context of midisuperspaces (see Bičák (2000) and Belinski and Verdaguer (2001)).

In the metric

$$g = e^{2(\gamma-\psi)}(-dt^2 + d\rho^2) + e^{2\psi}dz^2 + \rho^2 e^{-2\psi}d\varphi^2 \quad [15]$$

$\psi(t, \rho)$ satisfies the flat-space wave equation and $\gamma(\rho, t)$ is given in terms of $\psi$ by quadratures. Admitting a "cross term" $\sim \omega(t, \rho)\, dz\, d\phi$, one acquires a second degree of freedom (a second polarization) which makes all field equations nonlinear.

### Boost-Rotation Symmetric Spacetimes

These are the only explicit solutions available which are radiative and represent the fields of finite sources. Figure 4 shows two particles uniformly accelerated in opposite directions. In the space diagram (left), the "string" connecting the particles is the "cause" of the acceleration. In "Cartesian-type" coordinates and the $z$-axis chosen as the symmetry axis, the boost Killing vector has a flat-space form, $\zeta = z(\partial/\partial t) + t(\partial/\partial z)$, the same is true for the axial Killing vector. The metric contains two functions of variables $\rho^2 \equiv x^2 + y^2$ and $\beta^2 \equiv z^2 - t^2$. One satisfies the flat-space wave equation, the other is determined by quadratures.

The unique role of these solutions is exhibited by the theorem which states that in axially symmetric, locally asymptotically flat spacetimes, in the sense that a null infinity (*see* Asymptotic Structure and Conformal Infinity) exists but not necessarily globally, the only additional symmetry that does not exclude gravitational radiation is the boost symmetry. Various radiation characteristics can be expressed explicitly in these spacetimes. They have been used as tests in numerical relativity and approximation methods. The best-known example is the C-metric (representing accelerating black holes, in general charged and rotating, and admitting $\Lambda$), see Bonnor *et al.* (1994), Bičák (2000), Stephani *et al.* (2003), and Semerák *et al.* (2002).

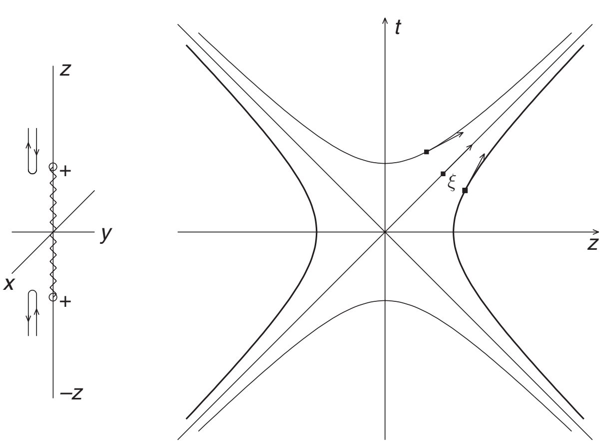

**Figure 4** Two particles uniformly accelerated in opposite directions. Orbits of the boost Killing vector (thinner hyperbolas) are spacelike in the region $t^2 > z^2$. Reproduced from Bičák J (2000) Selected solutions of Einstein's field equations: their role in general relativity and astrophysics. In: Schmidt BG (ed.) *Einstein's Field Equations and their Physical Implications*, Lecture Notes in Physics, vol. 540, pp. 1–126. Heildelberg: Springer, with permission from Springer-Verlag.

### Robinson–Trautman Solutions

These solutions are algebraically special but in general they do not possess any symmetry. They are governed by a function $P(u, \zeta, \bar{\zeta})$ ($u$ is the retarded time, $\zeta$ a complex spatial coordinate) which satisfies a fourth-order nonlinear parabolic differential equation. Studies by Chruściel and others have shown that RT solutions of Petrov type II exist globally for all positive "times" $u$ and converge asymptotically to a Schwarzschild metric, though the extension across the "Schwarzschild-like" horizon can only be made with a finite degree of smoothness. Generalization to the cases with $\Lambda > 0$ gives explicit models supporting the cosmic no-hair conjecture (an exponentially fast approach to the dS spacetime) under the presence of gravitational waves. See Bonnor *et al.* (1994), Bičák (2000), and Stephani *et al.* (2003).

## Material Sources

Finding physically sound material sources in an analytic form even for some simple vacuum metrics remains an open problem. Nevertheless, there are solutions representing regions of spacetimes filled with matter which are of considerable interest.

One of the simplest solutions, the spherically symmetric Schwarzschild interior solution with incompressible fluid as its source, represents "a star" of uniform density, $\rho = \rho_0 = \text{const.}$:

$$g = -\left[\frac{3}{2}\sqrt{1 - AR^2} - \frac{1}{2}\sqrt{1 - Ar^2}\right]^2 dt^2 + \frac{dr^2}{1 - Ar^2} + r^2(d\theta^2 + \sin^2\theta d\varphi^2) \quad [16]$$

$A = 8\pi\rho_0/3 = \text{const.}$, $R$ is the radius of the star.

The equation of hydrostatic equilibrium yields pressure inside the star:

$$8\pi p = 2A\frac{\sqrt{1 - Ar^2} - \sqrt{1 - AR^2}}{3\sqrt{1 - AR^2} - \sqrt{1 - Ar^2}} \quad [17]$$

Solution [16] can be matched at $r = R$, where $p = 0$, to the exterior vacuum Schwarzschild solution [10] if the Schwarzschild mass $M = (1/2)AR^3$. Although "incompressible fluid" implies an infinite speed of sound, the above solution provides an instructive

model of relativistic hydrostatics. A Newtonian star of uniform density can have an arbitrarily large radius $R = \sqrt{3p_c/2\pi\rho_0^2}$ and mass $M = (p_c/\rho_0^2)\ \sqrt{6p_c/\pi}$, $p_c$ is the central pressure. However, [17] implies that (1) $M$ and $R$ satisfy the inequality $2M/R \leq 8/9$, (2) equality is reached as $p_c$-becomes infinite and $R$ and $M$ attain their limiting values $R_{\lim} = (3\pi\rho_0)^{-1/2} = (9/4)M_{\lim}$. For a density typical in neutron stars, $\rho_0 = 10^{15}$ g cm$^{-3}$, we get $M_{\lim} \doteq 3.96 M_\odot$ ($M_\odot$ solar mass) – even this simple model shows that in Einstein's theory neutron stars can only be a few solar masses. In addition, one can prove that the "Buchdahl's inequality" $2M/R \leq 8/9$ is valid for an arbitrary equation of state $p = p(\rho)$. Only a limited mass can thus be contained within a given radius in general relativity. The gravitational redshift $z = (1 - 2M/R)^{-1/2} - 1$ from the surface of a static star cannot be higher than 2.

Many other explicit static perfect fluid solutions are known (we refer to Stephani *et al.* (2003) for a list), however, none of them can be considered as really "physical." Recently, the dynamical systems approach to relativistic spherically symmetric static perfect fluid models was developed by Uggla and others which gives qualititative characteristics of masses and radii.

The most significant nonstatic spacetime describing a bounded region of matter and its external field is undoubtedly the Oppenheimer–Snyder model of "gravitational collapse of a spherical star" of uniform density and zero pressure (a "ball of dust"). The model does not represent any new (local) solution: the interior of the star is described by a part of a dust-filled FLRW universe (cf. [8]), the external region by the Schwarzschild vacuum metric (cf. eqn [10], **Figure 1**).

Since Vaidya's discovery of a "radiating Schwarzschild metric," null dust ("pure radiation field") has been widely used as a simple matter source. Its energy–momentum tensor, $T_{\alpha\beta} = \varrho k_\alpha k_\beta$, where $k_\alpha k^\alpha = 0$, may be interpreted as an incoherent superposition of waves with random phases and polarizations moving in a single direction, or as "lightlike particles" (photons, neutrinos, gravitons) that move along $k^\alpha$. The "Vaidya metric" describing spherical implosion of null dust implies that in case of a "gentle" inflow of the dust, a naked singularity forms. This is relevant in the context of the cosmic censorship conjecture (cf., e.g., Joshi (1993)).

## Cosmological Models

There exist important generalizations of the standard FLRW models other than the above-mentioned Bianchi models, particularly those that maintain spherical symmetry but do not require homogeneity. The best known are the Lemaître–Tolman–Bondi models of inhomogeneous universes of pure dust, the density of which may vary (Krasiński 1997).

Other explicit cosmological models of principal interest involve, for example, the Gödel universe – a homogeneous, stationary spacetime with $\Lambda < 0$ and incoherent rotating matter in which there exist closed timelike curves through every point; the Kantowski–Sachs solutions – possessing homogeneous spacelike hypersurfaces but (in contrast to the Bianchi models) admitting no simply transitive $G_3$; and vacuum Gowdy models ("generalized Einstein–Rosen waves") admitting $G_2$ with compact 2-tori as its group orbits and representing cosmological models closed by gravitational waves. See Cosmology: Mathematical Aspects and references Stephani *et al.* (2003), Belinski and Verdaguer (2001), Bičák (2000), Hawking and Ellis (1973), Krasiński (1997) and Wainwright and Ellis (1997).

# Einstein Equations: Initial Value Formulation

**J Isenberg**, University of Oregon, Eugene, OR, USA

## Introduction

Einstein's theory of gravity models a gravitating physical system $\mathcal{S}$ using a spacetime $(M^4, g, \psi)$ which satisfies the Einstein field equations

$$G_{\mu\nu}(g) = \kappa T_{\mu\nu}(g, \psi) \quad [1]$$

$$\mathcal{F}(g, \psi) = 0 \quad [2]$$

Here, $M^4$ is a four-dimensional spacetime manifold, $g$ is a Lorentz signature metric on $M$, $\psi$ represents the nongravitational ("matter") fields of interest, $G_{\mu\nu} := R_{\mu\nu} - (1/2)g_{\mu\nu}R$ is the Einstein curvature tensor, $\kappa$ is a constant, $T_{\mu\nu}$ is the stress–energy tensor for the field $\psi$, and $\mathcal{F} = 0$ represents the nongravitational field equations (e.g., $\nabla_\mu F^\mu_\nu = 0$ for the Einstein–Maxwell theory).

By far the most widely used way to obtain and to study spacetime solutions $(M^4, g, \psi)$ of equations [1]–[2] is via the initial-value (or Cauchy) formulation. The idea is as follows:

1. One chooses a set of initial data $\mathcal{D}$ which consists of geometric as well as matter information on a spacelike slice of $M^4$. This data must satisfy a system of constraint equations, which comprise a portion of the field equations [1]–[2], and are analogous to the Maxwell constraint equation $\nabla \cdot E = 0$.
2. One fixes a time and coordinate choice to be used in evolving the fields into the spacetime (e.g., maximal time slicing and zero shift). This choice should result in a fixed set of evolution equations for the data.
3. Using the evolution equations, one evolves the data into the future and the past. From the evolved data, one constructs the spacetime solution $(M^4, g, \psi)$.

Why is this procedure so popular? First, because we have known for over 50 years that at least for a short time, it works. That is, as shown by Choquet-Bruhat (Foures-Bruhat 1952), the Cauchy formulation is well posed. Second, because it fits with the way we like to model physical systems. That is, we first specify what the system is like now, and we then use the equations to determine the behavior of the system as it evolves into the future (or the past). Third, because the formulation is eminently amenable to numerical treatment. Indeed, virtually all numerical simulations of colliding black hole systems as well as of most other relativistic astrophysical systems are done using some version of the initial-value formulation. Finally, because the initial-value formulation casts the Einstein equations into a form which is readily accessible to many of the tools of geometric analysis. Questions such as cosmic censorship are turned into conjectures which can be analyzed and proved mathematically, and the proofs of both the positivity of mass and the Penrose mass inequality rely on an initial-value interpretation.

There are of course drawbacks to the Cauchy formulation. Foremost, Einstein's theory of general relativity is inherently a spacetime-covariant theory; why break spacetime apart into space plus time when covariance has played such a key role in the theory's success? As well, we have learned over and over again that null cones and null hypersurfaces play a major role in general relativity; the initial-value formulation is not especially good at handling them. These drawbacks show that there are analyses in general relativity for which the initial-value formulation may not be well suited. However, there is a preponderance of applications for which this formulation is an invaluable tool, as evidenced by its ubiquitous use.

A complete treatment of the initial-value formulation for Einstein's equations would include discussion of each of the following topics:

1. A statement and proof of well-posedness theorems, including a discussion of the regularity of the data needed for such results.
2. A space + time decomposition of the fields, and a formal derivation of the Einstein constraint equations and the Einstein evolution equations.

3. An outline of the Hamiltonian version of the initial-value formulation.
4. A listing of those choices of field variables and gauge choices for which the system is manifestly hyperbolic.
5. A description of the known methods for finding and parametrizing solutions of the Einstein constraint equations.
6. A comparison of the virtues and drawbacks of various choices of time foliation and coordinate threading.
7. A compendium of results concerning long-time behavior of solutions.
8. An account of the difficulties which arise in attempts to construct solutions numerically using the Cauchy formulation.
9. A recounting of cases in which the initial-value formulation has been used to model physically interesting systems.
10. A note regarding the extent to which the initial-value formulation (and the various aspects of it just enumerated) generalize to dimensions other than $3+1$ (three space and one time).
11. A determination of which nongravitational fields may be coupled to Einstein's theory in such a way that the resulting coupled theory admits an initial-value formulation.

We do not have the space here for such a complete treatment. So we choose to focus on those topics directly related to the Einstein constraint equations. Generalizing a bit to the Einstein–Maxwell theory (thereby including representative nongravitational fields), we first carry out the space plus time "$3+1$" decomposition of the gravitational and electromagnetic fields. Then, applying the Gauss–Codazzi–Mainardi equations to the spacetime curvature, we turn the spacetime-covariant Einstein–Maxwell equations into a set of constraint equations restricting the choice of initial data together with a set of evolution equations developing the data in time. Next, we discuss the most widely used approach for obtaining sets of initial data which satisfy the constraint equations: the conformal method. We include in this discussion an account of some of what is known about the extent to which the equations which are produced by the conformal method admit solutions in various situations (e.g., working on a closed manifold, or working with asymptotically Euclidean data). We then discuss alternate procedures which have been used to obtain and analyze solutions of the constraints, including the conformal thin sandwich approach, the quasispherical method, and various gluing procedures. Finally, we make concluding remarks. For more details on some of the topics discussed here, and for treatment of some of the other topics listed above, see the recent review paper of Bartnik and Isenberg (2004).

## Space + Time Field Decomposition and Derivation of the Constraint Equations

To understand what sort of initial data one needs to choose in order to construct a spacetime via the initial-value formulation, it is useful to consider a spacetime $(M^4, g)$ which satisfies the Einstein (–Maxwell) field equations and contains a Cauchy surface $i_0 : \Sigma^3 \to M^4$. We note that the existence of a Cauchy surface in $(M^4, g, A)$ is not automatic; if one exists, the spacetime is said to be (by definition) "globally hyperbolic."[1]

Among its other properties, a Cauchy surface is a spacelike embedded submanifold of a Lorentz geometry. It immediately follows that the spacetime $(M^4, g, A)$ induces on $\Sigma^3$ a Riemannian metric $\gamma$, a timelike normal vector field $e_\perp$, an intrinsic ($\gamma$-compatible) covariant derivative $\nabla$, and a symmetric "extrinsic curvature" tensor field $K$ (second fundamental form). It also follows that certain components of the spacetime curvature tensor can be written in terms of these Cauchy surface quantities $(\gamma, e_\perp, \nabla, K)$ along with other geometric quantities related to them, such as the spatial curvature $R$ corresponding to the induced covariant derivative $\nabla$ (Gauss–Codazzi equations).

To complete the curvature $3+1$ decomposition (i.e., to carry it out for all components of the spacetime curvature), we need not just one Cauchy surface, but rather a full local foliation $i_t : \Sigma^3 \to M^4$ of the spacetime by such submanifolds. This foliation allows one to define $e_\perp$ as a smooth vector field on an open neighborhood of the Cauchy surface $i_0(\Sigma^3)$ in $M^4$. It also results in a threading of spacetime by a congruence of timelike paths (see Figure 1). This threading may be viewed as a spacetime-filling family of observers. It also defines for the spacetime a set of coordinates relative to which one can measure and calculate the dynamics of the spacetime geometry.

It is useful for later purposes to note that at each spacetime point $p \in \Sigma_t \subset M^4$ (Here $\Sigma_t := i_t(\Sigma^3)$.) the vector $\partial/\partial t$ tangent to the threading path through $p$ may be decomposed as

$$\frac{\partial}{\partial t} = N e_\perp + X \qquad [3]$$

[1]The Taub–NUT spacetime is an example of a spacetime which is *not* globally hyperbolic.

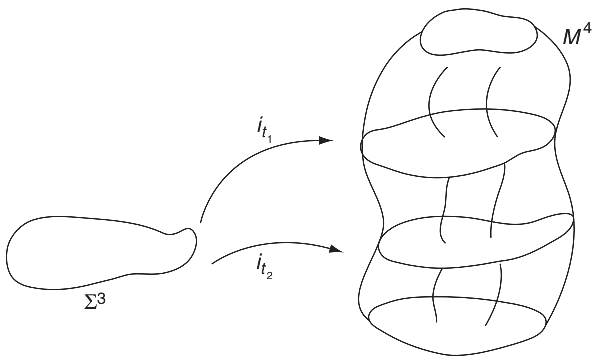

**Figure 1** 3 + 1 Foliation and threading of spacetime.

with the "shift vector" $X$ tangent to the surface ($X \in T_p\Sigma_t$), and with the "lapse" $N$ a scalar (see Figure 2). Using these quantities, we can write the spacetime metric in the form

$$\begin{aligned} g &= \gamma - \theta^\perp \otimes \theta^\perp \\ &= \gamma_{ab}(\mathrm{d}x^a + X^a \mathrm{d}t)(\mathrm{d}x^b + X^b \mathrm{d}t) - N^2 \mathrm{d}t^2 \end{aligned} \quad [4]$$

where $\theta^\perp$ is the unit length timelike 1-form which annihilates all vectors tangent to the hypersurfaces of the foliation.

Relying on the following 3 + 1 decomposition of the spacetime-covariant derivative ${}^4\nabla$ (Here $\{\partial_a\}$ is a coordinate basis for the vectors tangent to the hypersurfaces of the foliation; $\{\partial_a, e_\perp\}$ constitutes a basis for the full set of spacetime vectors at $p$.):

$${}^4\nabla_{\partial_a}\partial_b = \nabla_{\partial_a}\partial_b - K_{ab}e_\perp \quad [5]$$

$${}^4\nabla_{\partial_a}e_\perp = -K_a^m\partial_m \quad [6]$$

$${}^4\nabla_{e_\perp}\partial_b = -K_b^m\partial_m + [e_\perp, \partial_b] + \frac{\partial_b N}{N}e_\perp \quad [7]$$

$${}^4\nabla_{e_\perp}e_\perp = \gamma^{mn}\frac{\partial_m N}{N}\partial_n \quad [8]$$

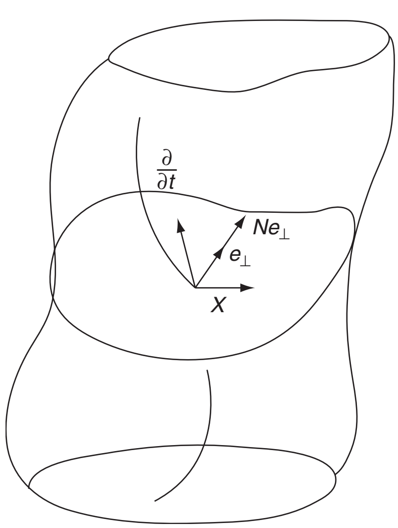

**Figure 2** Decomposition of the time evolution vector field $\partial/\partial t$.

one readily derives the (Gauss–Codazzi–Mainardi) 3 + 1 decomposition of the curvature: [2]

$${}^4R^e_{abc} = R^e_{abc} + K_{ac}K^e_b - K_{ab}K^e_c \quad [9]$$

$${}^4R^\perp_{abc} = \nabla_{\partial_c}K_{ab} - \nabla_{\partial_b}K_{ac} \quad [10]$$

$${}^4R^\perp_{a\perp b} = -\mathcal{L}_{e_\perp}K_{ab} - K_{am}K^m_b + \frac{\nabla_{\partial_a}\nabla_{\partial_b}N}{N} \quad [11]$$

where $\mathcal{L}$ denotes the surface-projected Lie derivative.

Since we are interested here in the 3 + 1 formulation of the Einstein–Maxwell system, we need a 3 + 1 decomposition for the electromagnetic as well as the gravitational field. The spacetime 1-form "vector potential" ${}^4A$ pulls back on each Cauchy surface $\Sigma_t$ to a spatial 1-form $A$. One may then write

$${}^4A = A + \mu\theta^\perp = A_b\mathrm{d}x^b + (N\mu + A_bX^b)\,\mathrm{d}t \quad [12]$$

for a scalar $\mu$. Based on this decomposition, one has the following 3 + 1 decomposition for the electromagnetic 2-form $F$:

$${}^4F_{\perp a} = \gamma_{ac}E^c \quad [13]$$

$${}^4F_{ab} = \nabla_{\partial_a}A_b - \nabla_{\partial_b}A_a \quad [14]$$

where $E^c$ is the electric vector field.

We may now use all of these decomposition formulas to write out the 14 field equations for the Einstein–Maxwell theory

$${}^4G_{\alpha\beta} = F^\mu_\alpha F_{\beta\mu} - \tfrac{1}{4}g_{\alpha\beta}F^{\mu\nu}F_{\mu\nu} \quad [15]$$

$${}^4\nabla_\mu\left({}^4F^\mu_\alpha\right) = 0 \quad [16]$$

in terms of the spatial fields $(\gamma, K, N, X; A, E, \mu)$ and their derivatives. We obtain

$$R - K^{mn}K_{mn} + (\mathrm{tr}\,K)^2 = \tfrac{1}{2}E^mE_m + \tfrac{1}{2}B^mB_m \quad [17]$$

$$\nabla_m K^m_a - \nabla_{\partial_a}(\mathrm{tr}\,K) = \epsilon_{amn}E^mB^n \quad [18]$$

$$\begin{aligned} \mathcal{L}_{e_\perp}K_{ab} &= R_{ab} - 2K^m_aK_{mb} + (\mathrm{tr}\,K)K_{ab} \\ &\quad + E_aE_b + B_aB_b - \frac{\nabla_{\partial_a}\nabla_{\partial_b}N}{N} \end{aligned} \quad [19]$$

$$\nabla_{\partial_m}E^m = 0 \quad [20]$$

$$\mathcal{L}_{e_\perp}E^a = \epsilon^{amn}\nabla_{\partial_m}B_n \quad [21]$$

where $\epsilon_{abc}$ is the alternating Levi-Civita symbol (component representation of the Hodge dual), and where we have used $B_a := \epsilon_a^{mn}(\nabla_{\partial_m}A_n - \nabla_{\partial_n}A_m)$ as a convenient shorthand.

---

[2]Here and throughout this article, we use the Misner–Thorne–Wheeler (MTW) (Misner *et al.* 1973) conventions for the definition of the Riemann curvature, for the signature $-+++$ of the metric, for the index labels (Greek indices run over $\{0, 1, 2, 3\}$ while Latin indices run over $\{1, 2, 3\}$), etc.

It is immediately evident that nine of these equations ([19] and [21]) involve time derivatives of the spatial fields, while five of them ([17], [18], and [20]) do not. Thus, we may split the field equations of the Einstein–Maxwell theory into two sets: (1) the constraint equations [17], [18], and [20], which restrict our choice of the Einstein–Maxwell initial data $(\gamma, K, A, E)$; and (2) the evolution equations, which describe how to evolve the data $(\gamma, K, A, E)$ in time, presuming that one has also prescribed (freely!) the "atlas fields" $(N, X, \mu)$.[3] We note that the complete system of evolution equations for the Einstein–Maxwell field equations includes equations which are based on the definitions of $K$ and $E$. Written in terms of (surface-projected) Lie derivatives along $\partial/\partial_t$, the full system takes the form

$$\mathcal{L}_{\frac{\partial}{\partial_t}}\gamma_{ab} = -2NK_{ab} + \mathcal{L}_X\gamma_{ab} \quad [22]$$

$$\mathcal{L}_{\frac{\partial}{\partial_t}}K_{ab} = N\big(R_{ab} - 2K_a^m K_{mb} + K_m^m K_{ab} + E_a E_b + B_a B_b\big) - \nabla_{\partial_a}\nabla_{\partial_b}N + \mathcal{L}_X K_{ab} \quad [23]$$

$$\mathcal{L}_{\frac{\partial}{\partial_t}}A_a = N(E_a + \nabla_{\partial_a}\mu) + \mathcal{L}_X A_a \quad [24]$$

$$\mathcal{L}_{\frac{\partial}{\partial_t}}E^a = N\epsilon^{amn}\nabla_{\partial_m}B_n + \mathcal{L}_X E^a \quad [25]$$

As noted earlier, well-posedness theorems[4] guarantee that initial data satisfying the constraint equations [17], [18], and [20] on a manifold $\Sigma^3$ can always at least locally be evolved into a spacetime solution $(\Sigma^3 \times I, g, {}^4A)$ (for $I$ some interval in $R^1$) of the Einstein–Maxwell equations. We now turn our attention to the issue of finding sets of data which do satisfy the constraints.

## The Conformal Method

We seek to find sets of data $(\gamma, K, A, E)$ on a manifold $\Sigma^3$ which satisfy the constraint equations

$$R - K^{mn}K_{mn} + (\mathrm{tr}\,K)^2 = \tfrac{1}{2}E^m E_m + \tfrac{1}{2}B^m B_m \quad [26]$$

$$\nabla_m K_a^m - \nabla_a(\mathrm{tr}\,K) = \epsilon_{amn}E^m B^n \quad [27]$$

$$\nabla_m E^m = 0 \quad [28]$$

[3]The collective name "atlas field" for the lapse $N$, the shift $X$, the electric potential $\mu$, and other such fields which are neither constrained by the constraint equations nor evolved by the evolution equations, derives from their role in controlling the evolution of coordinate charts and bundle atlases in the course of the construction of spacetime solutions of relativistic field equations like the Einstein Maxwell system.

[4]While the work cited earlier (Foures-Bruhat 1952) proves well posedness for the vacuum Einstein equations only, the extension to the Einstein–Maxwell system is straightforward

(Here and below, for convenience, we replace $\nabla_{\partial_a}$ by $\nabla_a$.) This is an underdetermined problem, with five equations to be solved for 18 functions.

The idea of the conformal method is to divide the initial data on $\Sigma^3$ into two sets – the "free (conformal) data," and the "determined data" – in such a way that, for a given choice of the free data, the constraint equations become a determined elliptic partial differential equation (PDE) system, to be solved for the determined data. There are a number of ways to do this; we focus here on one of them – the "semidecoupling split" or "method $A$." After describing this version of the conformal method, and discussing what one can do with it, we note some of its drawbacks and then later (in the next section) consider some alternatives. (See Choquet-Bruhat and York (1980) and Bartnik and Isenberg (2004) for a more complete discussion of these alternatives.)

For the Einstein–Maxwell theory, the split of the initial data is as follows:

**Free ("conformal") data**

- $\lambda_{ij}$ – a Riemannian metric, specified up to conformal factor;
- $\sigma_{ij}$ – a divergence-free[5] $(\nabla^i\sigma_{ij} = 0)$, tracefree $(\lambda^{ij}\sigma_{ij} = 0)$; symmetric tensor;
- $\tau$ – a scalar field;
- $\alpha_a$ – a 1-form;
- $\mathcal{E}^b$ – a divergence-free vector field;

**Determined data**

- $\phi$ – a positive-definite scalar field;
- $W^i$ – a vector field;
- $\xi$ – a scalar field.

For a given choice of the free data, the five equations to be solved for the five functions of the determined data take the form

$$\Delta\xi = 0 \quad [29]$$

$$\nabla_m(LW)_a^m = \tfrac{2}{3}\phi^6\nabla_{\partial_a}\tau + \epsilon_{amn}\mathcal{E}^m\beta^n \quad [30]$$

$$\Delta\phi = \tfrac{1}{8}R\phi - \tfrac{1}{8}(\sigma^{mn} + LW^{mn})(\sigma_{mn} + LW_{mn})\phi^{-7} + \tfrac{1}{16}(\mathcal{E}^m\mathcal{E}_m + \beta^m\beta_m)\phi^{-3} + \tfrac{1}{12}\tau^2(\phi^5) \quad [31]$$

where the Laplacian $\Delta$ and the scalar curvature $R$ are based on the $\lambda_{ab}$-compatible covariant derivative $\nabla_i$, where $L$ is the corresponding conformal Killing operator, defined by

$$(LW)_{ab} := \nabla_a W_b + \nabla_b W_a - \tfrac{2}{3}\lambda_{ab}\nabla_m W^m \quad [32]$$

[5]In the free data, the divergence-free condition is defined using the Levi-Civita-covariant derivative compatible with the conformal metric $\lambda_{ij}$.

and where $\beta_a := \epsilon_a^{mn}(\nabla_{\partial_m}\alpha_n - \nabla_{\partial_n}\alpha_m)$. Presuming that for the chosen free data one can indeed solve equations [29]–[31] for $\xi, \phi$, and $W$, then the initial data $(\gamma, K, A, E)$ constructed via the formulas

$$\gamma_{ab} = \phi^4 \lambda_{ab} \qquad [33]$$

$$K_{ab} = \phi^{-2}(\sigma_{ab} + LW_{ab}) + \tfrac{1}{3}\phi^4\lambda_{ab}\tau \qquad [34]$$

$$A_b = \alpha_b \qquad [35]$$

$$E^a = \phi^{-6}(\mathcal{E}_a + \nabla_{\partial a}\xi) \qquad [36]$$

satisfy the Einstein–Maxwell constraint equations [26]–[28].

Before discussing the extent to which one can solve equations [29]–[31] and consequently use the conformal method to generate solutions, we wish to comment on how these equations are derived. Three formulas are key to this derivation. The first is the formula for the scalar curvature of the metric $\gamma_{ab} = \phi^4\lambda_{ab}$, expressed in terms of the scalar curvature for $\lambda_{ab}$ and derivatives of $\phi$:

$$R(\gamma) = \phi^{-4}R(\lambda) - 8\Delta_\lambda\phi \qquad [37]$$

We note that if we were to use a different power of $\phi$ as the conformal factor multiplying $\lambda_{ab}$, then this formula would involve squares of first derivatives of $\phi$ as well. The second key formula relates the divergence of a traceless symmetric tensor $\rho_{ab}$ with respect to the covariant derivatives $\nabla_{(\gamma)}$ and $\nabla_{(\lambda)}$ compatible with conformally related metrics. One obtains

$$\nabla^m_{(\gamma)}\rho_{mb} = \phi^{-2}\nabla^m_{(\lambda)}(\phi^2\rho_{mb}) \qquad [38]$$

The third key formula does the same thing for a vector field $\zeta^a$:

$$\nabla_{(\gamma)m}\zeta^m = \phi^{-6}\nabla^m_{(\lambda)}(\phi^6\zeta_m) \qquad [39]$$

In addition to helping us derive equations [29]–[31] from the substitution of formulas [33]–[36] into [26]–[28], these key formulas indicate to some extent how the choice of the explicit decomposition of the initial data into free and determined data is made (see Isenberg, Maxwell, and Pollack for further elaboration).

It is easy to see that there are some choices of the free data for which [29]–[31] do not admit any solutions. Let us choose, for example, $\Sigma^3$ to be the 3-sphere, and let us set $\lambda$ to be the round sphere metric, $\sigma$ to be zero everywhere, $\tau$ to be unity everywhere, and both $\alpha$ and $\mathcal{E}$ to vanish everywhere. We then readily determine that eqn [29] requires that $\xi$ be constant and that eqn [30] requires that $LW_{ab}$ be zero. The remaining equation [31] now takes the form $\Delta\phi = (1/8)R\phi + (1/12)\phi^5$. Since the right-hand side of this equation is positive definite (recall the requirement that $\phi > 0$), it follows from the maximum principle on closed (compact without boundary) manifolds that there is no solution.

In light of this example, one would like to know exactly for which sets of free data eqns [29]–[31] can be solved, and for which sets they cannot. Since one readily determines that every set of initial data which satisfies the Einstein–Maxwell constraints [26]–[28] can be obtained via the conformal method, such a classification effectively provides a parametrization of the space of solutions of the constraints.[6]

What we know and do not know about classifying free data for the solubility of eqns [29]–[31] is largely determined by whether or not the function $\tau$ is chosen to be constant on $\Sigma^3$. If $\tau$ is chosen to be constant, then eqns [29]–[31] effectively decouple, and the classification is essentially completely known. Sets of initial data generated from free data with constant $\tau$ are called "constant mean curvature" (CMC) sets, since the mean curvature of the initial slice embedded in its spacetime development is given by $\tau$. We also know a considerable amount about the classification if $|\nabla\tau|$ is sufficiently small ("near CMC"), while virtually nothing is known for the general non-CMC case.

A full account of the classification results known to date is beyond the scope of this article. Indeed, such an account must separately deal with a number of alternatives regarding manifold and asymptotic conditions (data on a closed manifold; asymptotically Euclidean data; asymptotically hyperbolic data; data on an incomplete manifold with boundaries) and regularity (analytic data, smooth data, $C^k$ data, or data contained in various Hölder or Sobolev spaces), among other things. We will, however, now summarize some of the results; see, for example, Bartnik and Isenberg (2004) or Choquet-Bruhat for more complete surveys.

### CMC Data on Closed Manifolds

Generalizing the $S^3$ example given above, we note that for any set of free data $(\Sigma^3, \lambda_{ab}, \sigma_{ab}, \tau, \alpha_a, \mathcal{E}^b)$ with constant $\tau$ and with no conformal Killing fields, eqn [29] is easily solved for $\xi$, and then eqn [30] takes the form

$$\nabla_m(LW)^m_a = \epsilon_{amn}\mathcal{E}^m\beta^n \qquad [40]$$

[6] Of course, in claiming that appropriate sets of the free data parametrize the space of solutions of the constraints, one needs to determine if inequivalent sets of free data are mapped to the same set of solutions. We discuss this below.

which is a linear elliptic PDE for $W_m$ with invertible operator.[7] This equation admits a unique solution, and then the problem of solving the constraints reduces to the analysis of the "Lichnerowicz equation" [31].

To determine if this equation admits a solution for the given set of free data, we use the following classification criteria: (1) The metric is labeled positive $\mathcal{Y}^{+}(\Sigma^3)$, zero $\mathcal{Y}^{0}(\Sigma^3)$, or negative $\mathcal{Y}^{-}(\Sigma^3)$ Yamabe class depending upon whether the metric $\lambda_{ab}$ on $\Sigma^3$ can be conformally deformed so that its scalar curvature is everywhere positive, everywhere zero, or everywhere negative.[8] (2) The $(\sigma_{ab}, \alpha_a, \mathcal{E}^b)$ portion of the data is labeled either $\equiv$ or $\not\equiv$, depending upon whether the quantity $\sigma_{mn}\sigma^{mn} + \mathcal{E}^m\mathcal{E}_m + \beta^m\beta_m$ is identically zero, or not. (3) The mean curvature $\tau$ is labeled "max" or "nonmax" depending upon whether the constant $\tau$ is zero or not. In terms of these criteria, we have 12 classes of free data, and one can prove (Choquet-Bruhat and York 1980, Isenberg 1995) the following:

- Solutions exist for the classes $(\mathcal{Y}^{+}, \not\equiv, \text{max})$, $(\mathcal{Y}^{+}, \not\equiv, \text{nonmax})$, $(\mathcal{Y}^{0}, \equiv, \text{max})$, $(\mathcal{Y}^{0}, \not\equiv, \text{max})$, $(\mathcal{Y}^{-}, \equiv, \text{nonmax})$, $(\mathcal{Y}^{-}, \not\equiv, \text{nonmax})$ and
- Solutions do not exist for the classes $(\mathcal{Y}^{+}, \equiv, \text{max})$, $(\mathcal{Y}^{+}, \equiv, \text{nonmax})$, $(\mathcal{Y}^{0}, \equiv, \text{nonmax})$, $(\mathcal{Y}^{0}, \not\equiv \text{max})$, $(\mathcal{Y}^{-}, \equiv, \text{max})$, $(\mathcal{Y}^{-}, \not\equiv, \text{max})$.

This classification is exhaustive, in the sense that every set of CMC data on a closed manifold fits neatly into exactly one of the classes. We note that the proofs of existence of solutions can generally be done using the sub–super solution technique, while the nonexistence results follow from application of the maximum principle.

### Maximal Asymptotically Euclidean Data

Just as is the case for data on a closed manifold, the constraint equations [29] and [30] decouple from the Lichnerowicz equation [31] for asymptotically Euclidean data with constant $\tau$. We note that $\tau \neq 0$ is inconsistent with the data being asymptotically Euclidean, so we restrict to the maximal case, $\tau = 0$.

The criterion for solubility of the constraints in conformal form for maximal asymptotically Euclidean free data is quite a bit simpler to state than that for CMC data on a closed manifold. It involves the metric $\lambda$ only; the rest of the free data is irrelevant. Specifically, as shown by Brill and Cantor (with a correction by Maxwell (2005)), a solution exists if and only if for every nonvanishing, compactly supported, smooth function $f$ on $\Sigma^3$, we have

$$\inf_{\{f \neq 0\}} \frac{\int_M (|\nabla f|^2 + Rf^2)\sqrt{\det \lambda}}{\|f\|^2_{L^2}} > 0 \qquad [41]$$

## Alternative Methods for Finding Solutions to the Constraint Equations

While the conformal method has proved to be a very useful tool for generating and analyzing solutions of the Einstein constraint equations, it does have some minor drawbacks: (1) The free data is remote from the physical data, since the conformal factor can vastly change the physical scale on different regions of space. (2) While casting the constraints into a determined PDE form has the advantage of producing PDEs of a relatively familiar (elliptic) form, one does give up certain flexibilities inherent in an underdetermined set of PDEs. (We expand upon this point below in the course of discussing gluing.). (3) In choosing a set of free data, one does have to first project out a divergence-free vector field ($\mathcal{E}$) and a divergence-free tracefree tensor field ($\sigma$). (4) While the choice of CMC free data for the conformal method is conformally covariant in the sense that conformally related sets of CMC free data $(\Sigma^3, \lambda_{ab}, \sigma_{ab}, \tau, \alpha_a, \mathcal{E}^b)$ and $(\Sigma^3, \theta^4\lambda_{ab}, \theta^{-2}\sigma_{ab}, \tau, \alpha_a, \theta^{-6}\mathcal{E}^b)$ produce the same physical solution to the constraints, this is not the case for non-CMC free data.

### Conformal Thin Sandwich

The last two of these problems can be removed by modifying the conformal method in a way which York (1999) has called the "conformal thin sandwich" (CTS) approach. The basic idea of the CTS approach is the same as that of the conformal method. However, CTS free data sets are larger – the divergence-free tracefree symmetric tensor field $\sigma$ is replaced by a tracefree symmetric tensor field $U$,

---

[7] A metric $\lambda$ has a conformal Killing field if the equation $LY = 0$ has a nontrivial solution $Y$. Geometrically, the existence of a conformal Killing field $Y$ indicates that the flow of $(\Sigma^3, \lambda_{ab})$ along $Y$ is a conformal isometry. While free data with nonvanishing conformal Killing fields can be handled, for convenience we shall stick to data without them here.

[8] Work on the Yamabe problem (Aubin 1998) shows that every Riemannian metric on a closed manifold is contained in one and only one of these classes. In fact, the Yamabe theorem (Schoen 1984) shows that every metric can be conformally deformed so that its scalar curvature is $+1, 0$, or $-1$, but this result is not needed for the analysis of the constraint equations.

and an extra scalar field $\eta$ is added – and after solving the CTS constraint equations

$$\Delta\xi = 0 \quad [42]$$

$$\nabla_m((2\eta)^{-1}(LX))_a^m = \tfrac{2}{3}\Phi^6\nabla_a\tau + \epsilon_{amn}\mathcal{E}^m\beta^n + \nabla_m\left((2\eta)^{-1}U_a^m\right) \quad [43]$$

$$\Delta\Phi = \tfrac{1}{8}R\Phi - \tfrac{1}{8}(U^{mn} + LY^{mn})(U_{mn} + LY_{mn})\Phi^{-7} + \tfrac{1}{16}(\mathcal{E}^m\mathcal{E}_m + \beta^m\beta_m)\Phi^{-3} + \tfrac{1}{12}\tau^2\Phi^5 \quad [44]$$

for the vector field $Y$ and the conformal factor $\Phi$, one obtains not just the full set of physical initial data satisfying the constraint equations [26]–[28]

$$\gamma_{ab} = \phi^4\lambda_{ab} \quad [45]$$

$$K_{ab} = \Phi^{-2}(-U_{ab} + LY_{ab}) + \tfrac{1}{3}\Phi^4\lambda_{ab}\tau \quad [46]$$

$$A_b = \alpha_b \quad [47]$$

$$E^a = \Phi^{-6}(\mathcal{E}_a + \nabla_a\xi) \quad [48]$$

but also the lapse $N$ and shift $X$

$$N = \Phi^6\eta \quad [49]$$

$$X^a = Y^a \quad [50]$$

Clearly, in using the CTS approach, one need not project out a divergence-free part of a symmetric tracefree tensor. One also readily checks that the CTS method is conformally covariant in the sense discussed above: the physical data generated from CTS free data $(\lambda_{ab}, U_{ab}, \tau, \eta, \alpha_a, \mathcal{E}^b)$ and from data $(\theta^4\lambda_{ab}, \theta^{-2}U_{ab}, \tau, \theta^6\eta, \alpha_a, \theta^{-6}\mathcal{E}^b)$ are the same. Furthermore, since the mathematical form of eqns [42]–[44] is very similar to that of [29]–[31], the solvability results for the conformal method can be essentially carried over to the CTS approach.

There is, however, one troubling feature of the CTS approach. The problem arises if we seek CMC initial data with the lapse function chosen so that the evolving data continue to have CMC (such a gauge choice is often used in numerical relativity). In the case of the conformal method, after solving [29]–[31] to obtain initial data $(\gamma_{ab}, K_{ab}, A_a, E^b)$ which satisfies the constraints, one achieves this by proceeding to solve a linear homogeneous elliptic PDE for the lapse function. One easily verifies that solutions to this extra equation always exist. By contrast, in the CTS approach, the extra equation takes the form

$$\Delta(\Phi^7\eta) = \tfrac{1}{8}\Phi^7\eta R + \tfrac{5}{2}(\Phi\eta)^{-1}(U - LX)^2 + \tfrac{1}{16}(\Phi\eta)^{-1}(\mathcal{E}^2 + \beta^2) + \Phi^5 Y^m\nabla_{\partial_m}\tau - \Phi^5 \quad [51]$$

which is coupled to the system [42]–[44]. The coupling is fairly intricate; hence little is known about the existence of solutions to the system, and it has been seen that there are problems with uniqueness. Such problems of course do not arise if one makes no attempt to preserve CMC.

### The Quasispherical Ansatz and Parabolic Methods

Applying either the conformal method or the CTS approach to the constraint equations results in systems of elliptic equations. Another approach, pioneered by Bartnik (1993), produces instead parabolic equations. In the simplest version of this approach, known as the "quasispherical ansatz," one works on a manifold $\Sigma^3 = R^3\backslash B_3$, where $B_3$ is a 3-ball; one presumes that there exist coordinates $(r, \theta, \phi)$ on $\Sigma^3$ in terms of which the metric takes the "quasispherical" form

$$\gamma_{QS} = u^2\mathrm{d}r^2 + (r\mathrm{d}\theta + \beta^\theta\mathrm{d}r)^2 + (r\sin\theta\,\mathrm{d}\phi + \beta^\phi\mathrm{d}r)^2 \quad [52]$$

for functions $u(r,\theta,\phi)$, $\beta^\theta(r,\theta,\phi)$, $\beta^\phi(r,\theta,\phi)$, and then one attempts to satisfy the time-symmetric constraint $R_{(\gamma_{QS})} = 0$ on $\Sigma^3$.[9] Calculating the scalar curvature for the metric in this form, one finds that the equation $R_{(\gamma_{QS})} = 0$ can be written as

$$(r\partial_r - \beta^\theta\partial_\theta - \beta^\phi\partial_\phi)u - u^2\Delta u = Q(u, \beta^\theta, \beta^\phi, r, \theta, \phi) \quad [53]$$

where $Q$ is a polynomial in the positive function $u$.

One can now show that if one specifies $\beta^\theta$ and $\beta^\phi$ everywhere on $\Sigma^3$ (subject to an upper bound on the divergence of the vector field $(\beta^\theta, \beta^\phi)$), and if one specifies regular initial data for $u$ on the inner boundary of $\Sigma^3$, then one has a well-posed initial-value problem (in terms of the "evolution" coordinate $r$) for the parabolic PDE [53]. Ideally, one can use this approach to extend solutions of the time-symmetric constraints from an isolated region (corresponding to $B_3$) out to spatial infinity.

The basic quasispherical ansatz approach just outlined can be generalized significantly (Sharples 2001, Bartnik and Isenberg 2004) to allow for more general spatial metrics, and to allow nonzero $K_{ab}, A_c$, and $E^b$. It has been an especially valuable tool for the study of mass in asymptotically Euclidean data sets. It does not, however, purport to construct general solutions of the constraint equations.

[9] This version of the constraints is called "time symmetric" since one is solving the full set of constraints with $K_{ab}$ assumed to be zero. Data with $K_{ab} = 0$ is time symmetric.

### Gluing Solutions of the Constraint Equations

Starting around the year 2000, a number of new "gluing" procedures have been developed for constructing and studying solutions of the constraint equations. Unlike the conformal method, the CTS method, and the quasispherical ansatz, all of which construct solutions from scratch, the gluing procedures construct new solutions from given ones. This feature, and the considerable flexibility of the procedures, has resulted in a wealth of applications already in the short five-year history of gluing in general relativity.

One of the gluing approaches, developed by Corvino (2000) and Corvino and Schoen (preprint) (see also Chruściel and Delay (2002)), allows one to choose a compact region $\Omega$ in almost any smooth, asymptotically Euclidean vacuum solution of the constraints, and from this produce a new smooth solution which is completely unchanged in the region $\Omega$ and is identical to Schwarzschild or Kerr outside some larger region. In proving this result, one exploits the underdetermined character of the constraint equations: such a construction could not be carried out if the constraints were a determined PDE system.[10]

The other main gluing approach, developed first by Isenberg *et al.* (2001), and then further developed with Chruściel (Chruściel *et al.* 2005) and with Maxwell (Isenberg *et al.* 2005), starts with a pair of solutions of the (vacuum) constraints $(\Sigma_1^3, \gamma_1, K_1)$ and $(\Sigma_2^3, \gamma_2, K_2)$ together with a choice of a pair of points $p_1 \in \Sigma_1^3$, $p_2 \in \Sigma_2^3$, one from each solution. From these solutions, this gluing procedure produces a new set of initial data $(\Sigma^3_{(1-2)}, \gamma_{(1-2)}, K_{(1-2)})$ with the following properties: (1) $\Sigma_{(1-2)}$ is diffeomorphic to the connected sum $\Sigma_1^3 \# \Sigma_2^3$; (2) $(\Sigma^3_{(1-2)}, \gamma_{(1-2)}, K_{(1-2)})$ is a solution of the constraints everywhere on $\Sigma^3_{(1-2)}$; (3) On that portion of $\Sigma^3_{(1-2)}$ which corresponds to $\Sigma_1^3 \backslash \{\text{ball around } p_1\}$, the data $(\gamma_{(1-2)}, K_{(1-2)})$ is isomorphic to $(\gamma_1, K_1)$, with a corresponding property holding on that portion of $\Sigma_2^3$ which corresponds to $\Sigma_2^3 \backslash \{\text{ball around } p_2\}$ (see **Figure 3**).[11]

This connected sum gluing can be carried out for very general sets of initial data. The sets can be asymptotically Euclidean, asymptotically hyperbolic, specified on a closed manifold, or indeed anything else. The only condition that the data sets must satisfy is that, in sufficiently small neighborhoods of each of the points at which the gluing is to be done, there do not exist nontrivial solutions $\xi$ to the equation $D\Theta^*_{(\gamma,K)}\zeta = 0$, where $D\Theta^*_{(\gamma,K)}$ is the operator obtained by taking the adjoint of the linearized constraint operator.[12] In work by Beig, Chruściel, and Schoen, it is shown that this condition (sometimes referred to as "No KIDs," meaning "no (localized) Killing initial data)" is indeed generically satisfied.

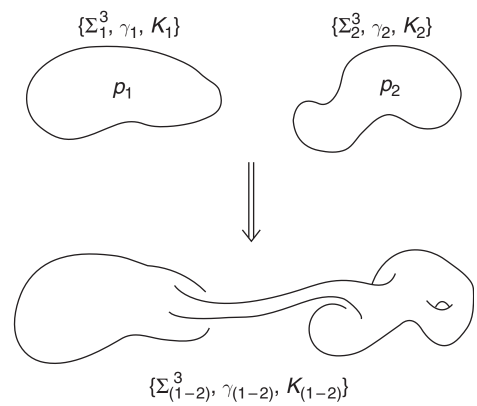

**Figure 3** Connected sum gluing.

While a discussion of the proof that connected sum gluing can be carried out to this degree of generality is beyond the scope of this paper (see Chruściel *et al.* (2005), along with references cited therein for details of the proof), we note three features of it: first, the proof is constructive in the sense that it outlines a systematic, step-by-step mathematical procedure for doing the gluing. In principle, one should be able to carry out the gluing procedure numerically. Second, connected sum gluing relies primarily on the conformal method, but it also uses a nonconformal deformation at the end (dependent on the techniques of Corvino and Schoen, and of Chruściel and Delay), so as to guarantee that the glued data is not just very close to the given data on regions away from the bridge, but is indeed identical to it. Third, while Corvino–Schoen gluing has not yet been proved to work for solutions of the constraints with source fields, connected sum gluing (up to the last step, which relies on Corvino–Schoen) has been shown to work for most matter source fields of interest (Isenberg *et al.*). It has also been shown to work for general dimensions greater than or equal to three.

---

[10]Hence if one tries to do Corvino Schoen-type gluing using a fixed conformal geometry, the gluing fails because the determined elliptic system satisfies the unique continuation property.

[11]The connected sum of the two manifolds (see property (1)) is constructed as follows: first we remove a ball from each of the manifolds $\Sigma_1^3$ and $\Sigma_2^3$. We then use a cylindrical bridge $S^2 \times I$ (where $I$ is an interval in $R^1$) to connect the resulting $S^2$ boundaries on each manifold

[12]When a solution to this equation does exist on some region $\Lambda \in \Sigma^3$, it follows from the work of Moncrief that the spacetime development of the data on $\Lambda$ admits a nontrivial isometry.

While gluing is not an efficient tool for studying the complete set of solutions to the constraints, it has proved to be very valuable for a number of applications. We note a few here.

1. *Spacetimes with regular asymptotic structure.* Until recently, it was not known whether there is a large class of solutions which admit the conformal compactification and consequent asymptotically simple structure at null and space-like infinity characteristic of the Minkowski and Schwarzschild spacetimes. Using Corvino–Schoen gluing, together with Friedrich's analyses of spacetime asymptotic structures and an argument of Chruściel and Delay (2002), one produces such a class of solutions.
2. *Multi-black hole data sets.* Given an asymptotically Euclidean solution of the constraints, connected sum gluing allows a sequence of (almost) flat space initial data sets to be glued to it. The bridges that result from this gluing each contain a minimal surface, and consequently an apparent horizon. With a bit of care, one can do this in such a way that indeed the event horizons which appear in the development of this glued data are disjoint, and therefore indicative of independent black holes.
3. *Adding a black hole to a cosmological spacetime.* Although there is no clear established definition for a black hole in a spatially compact solution of Einstein's equations, one can glue an asymptotically Euclidean solution of the constraints to a solution on a compact manifold, in such a way that there is an apparent horizon on the bridge. Studying the nature of these solutions of the constraints, and their evolution, could be useful in trying to understand what one might mean by a black hole in a cosmological spacetime.
4. *Adding a wormhole to your spacetime.* While we have discussed connected sum gluing as a procedure which builds solutions of the constraints with a bridge connecting two points on different manifolds, it can also be used to build a solution with a bridge connecting a pair of points on the same manifold. This allows one to do the following: if one has a globally hyperbolic spacetime solution of Einstein's equations, one can choose a Cauchy surface for that solution, choose a pair of points on that Cauchy surface, and glue the solution to itself via a bridge from one of these points to the other. If one now evolves this glued-together initial data into a spacetime, it will likely become singular very quickly because of the collapse of the bridge. Until the singularity develops, however, the solution is essentially as it was before the gluing, with the addition of an effective wormhole. Hence, this procedure can be used to glue a wormhole onto a generic spacetime solution.
5. *Removing topological obstructions for constraint solutions.* We know that every closed three-dimensional manifold $M^3$ admits a solution of the vacuum constraint equations. To show this, we use the fact that $M^3$ always admits a metric $\Gamma$ of constant negative scalar curvature. One easily verifies that the data $(\gamma = \Gamma, K = \Gamma)$ is a CMC solution. Combining this result with connected sum gluing, one can show that for every closed $\Sigma^3$, the manifold $\Sigma^3 \setminus \{p\}$ admits both an asymptotically Euclidean and an asymptotically hyperbolic solution of the vacuum constraint equations.
6. *Proving the existence of vacuum solutions on closed manifolds with no CMC Cauchy surface.* Based on the work of Bartnik (1988) one can show that if one has a set of initial data on the manifold $T^3 \# T^3$ with the metric components symmetric across a central sphere and the components of $K$ skew symmetric across that same central sphere, then the spacetime development of that data does not admit a CMC Cauchy surface. Using connected sum gluing, one can show that indeed initial data sets of this sort exist (Chruściel *et al.* 2005).

## Conclusion

Much is known about the Einstein constraint equations and those sets of initial data which satisfy them. We know how to use the conformal method or the CTS approach to construct (and parametrize in terms of free data) the CMC and near CMC sets of data which solve the constraints, with or without matter fields present. We know how to use the quasispherical approach to explore extensions of solutions of the constraint equations from compact regions. We know how to use gluing techniques to produce new solutions of both physical and mathematical interest from old ones, and we know how to use gluing as a tool for proving such results as the existence of vacuum spacetimes with no CMC Cauchy surfaces.

There is much that is not yet known as well. Very little is known about solutions of the constraint equations which have neither CMC nor near CMC. It is not known how to systematically extend solutions of the constraints from a compact region to all of $R^3$ in such a way that the extension is asymptotically Euclidean (unless we know *a priori* that such an extension exists). Very little is known regarding how to control the constraints during the course of

numerical evolution of solutions.[13] Most importantly, we do not yet know how to systematically find solutions of the constraint equations which serve as physically realistic model initial data sets for studying astrophysical and cosmological systems of interest.

Many of these questions concerning the Einstein constraints and their solutions are fairly daunting. However, in view of the rapid progress in our understanding during the last few years, and in view of the pressing need to further develop the initial-value formulation as a tool for studying general relativity and gravitational physics, we are optimistic that this progress will continue, and we will soon have answers to a number of these questions.

[13]If the constraints are satisfied by an initial data set and if this data set is evolved completely accurately, then the constraints remain satisfied for all time. However, during the course of a numerical evolution, there are inevitable numerical inaccuracies which result in the constraints not being exactly zero. In practice, during the majority of such numerical simulations to date, the constraints have been seen to increase very rapidly in time, calling into question the reliability of the simulation.

# Einstein Manifolds

**A S Dancer**, University of Oxford, Oxford, UK

## Introduction

The Einstein condition on a manifold $M$ with metric $g$ says that the Ricci curvature should be proportional to the metric. Of course, this condition originally appeared in relativity, but it is of tremendous interest from the point of view of pure mathematics. Demanding a metric of constant sectional curvature is a very strong condition, while metrics of constant scalar curvature always occur. The Einstein property, which is essentially a constant-Ricci-curvature condition, occupies an intermediate position between these conditions, and it is still not clear exactly how strong it is. In

dimensions higher than four, it is still unknown whether there are obstructions to a manifold admitting an Einstein metric.

The study of Einstein manifolds is a vast and rapidly expanding area, and this article can merely touch on some points of particular interest. The focus of the article is very much on the Riemannian rather than Lorentzian case (see, e.g., Hawking and Ellis (1973) or the articles by Christodoulou and Tod in LeBrun and Wang (1999) for a discussion of the Lorentzian case in general relativity). For further reading, the books of Besse (1987) and LeBrun and Wang (1999) are strongly recommended.

## Basic Properties

Let $(M, g)$ be a (pseudo)-Riemannian manifold. There is a unique connection $\nabla$, the Levi-Civita connection of $g$, with the following properties:

1. the torsion $T(X, Y) = \nabla_X Y - \nabla_Y X - [X, Y]$ vanishes and
2. $\nabla g = 0$

We can now form the Riemann curvature tensor of $g$:

$$R(X, Y)Z = \nabla_X \nabla_Y Z - \nabla_Y \nabla_X Z - \nabla_{[X,Y]} Z$$

This is a type (3,1) tensor. There is one nontrivial contraction we can perform to obtain a (2, 0) tensor, that is, the Ricci curvature

$$\mathrm{Ric}(X, Y) = \mathrm{tr}(Z \mapsto R(X, Z)Y)$$

We may perform a further contraction and obtain the scalar curvature $s = \mathrm{tr}_g \mathrm{Ric}$.

The Ricci curvature is a symmetric tensor of the same type as the metric, so we can make the following definition:

**Definition 1** A metric $g$ is Einstein if

$$\mathrm{Ric} = \Lambda g \qquad [1]$$

for some constant $\Lambda$.

In this article, we shall take $g$ to be a Riemannian (positive-definite) metric.

**Remark 1** In dimension higher than 2, we do not have to put in the assumption that $\Lambda$ is constant by hand. For, taking the divergence of [1] gives $(1/2)\mathrm{d}s = \mathrm{d}\Lambda$, while taking instead the trace gives $s = n\Lambda$, so if $n \neq 2$, we see $\mathrm{d}\Lambda = 0$.

**Remark 2** In dimension 2 and 3, the Einstein condition is equivalent to constant curvature. The only complete Einstein manifolds in these dimensions are therefore the model spaces $S^n, \mathbb{R}^n$ and hyperbolic space, and quotients of these by discrete groups of isometries.

**Remark 3** As noticed by Hilbert, the Einstein equations admit a variational interpretation. They are the variational equations for the total scalar curvature functional

$$g \mapsto \int_M s_g \, \mathrm{d}\mu_g$$

restricted to the space of volume 1 metrics (here $\mathrm{d}\mu_g$ denotes the volume form defined by $g$).

## Obstructions

The most fundamental question, we can ask is: *Given a smooth manifold M does it support an Einstein metric?*

One is also interested in the question of uniqueness of such a metric, or more generally of describing the moduli space of such metrics.

In this section we discuss obstructions to existence. In dimension 2 Remark 2 shows that any compact manifold admits an Einstein metric, while in dimension 3 the only possibilities are space forms. In particular, there is no Einstein metric on $S^1 \times S^2$.

The picture is much less clear in higher dimensions. If $\Lambda \geq 0$, one obtains some elementary obstructions just by considering the sign of the Ricci curvature:

1. If $M$ supports a complete Einstein metric with $\Lambda > 0$, then by Myers's theorem $M$ is compact and $\pi_1(M)$ is finite. Also there are obstructions coming from the positivity of the scalar curvature (e.g., if $M$ is spin and $4m$-dimensional, then the $\hat{A}$ genus vanishes).
2. If $M$ supports a complete Ricci-flat metric, then every finitely generated subgroup of $\pi_1(M)$ has polynomial growth.

However, if $\dim M \geq 5$, there is, at the time of writing, no known obstruction to $M$ supporting an Einstein metric of negative Einstein constant.

In the borderline dimension 4, Hitchin and Thorpe observed that the Einstein condition put topological constraints on the manifold. for, we have the following expressions for the Euler characteristic $\chi$ and signature $\tau$ in terms of the curvature tensor:

$$\tau = \frac{1}{12\pi^2} \int_M |W_+|^2 - |W_-|^2 \, \mathrm{d}\mu_g$$

$$\chi = \frac{1}{8\pi^2} \int_M |W_+|^2 + |W_-|^2 - |\mathrm{Ric}_0|^2 + \frac{s^2}{24} \, \mathrm{d}\mu_g$$

where $W_+$ and $W_-$ are the self-dual and anti-self-dual parts of the Weyl tensor, $s$ is the scalar curvature, and $\mathrm{Ric}_0$ is the trace-free part of the Ricci tensor.

The Einstein condition is just $\mathrm{Ric}_0 = 0$, so we immediately obtain the following inequality.

**Theorem** (Hitchin 1974). *A compact four-dimensional Einstein manifold satisfies the inequality*

$$|\tau| \leq \tfrac{2}{3}\chi$$

Note that equality is obtained if and only if $g$ is Ricci-flat and (anti)-self-dual, which is equivalent to locally hyper-Kähler for some orientation. The only examples are the flat torus, the K3 surface with the Yau metric (now $\tau = 16$ and $\chi = 24$), and two quotients of K3.

Since the mid-1990s, LeBrun (2003) has obtained a series of results which sharpen the Hitchin–Thorpe inequality by obtaining estimates on the Weyl and scalar curvature terms. These estimates are obtained by using Seiberg–Witten theory, the general theme being that nonemptiness of the Seiberg–Witten moduli space gives lower bounds on the curvature terms. LeBrun shows there are infinitely many compact smooth simply connected 4-manifolds that satisfy the Hitchin–Thorpe inequality but nonetheless do not admit Einstein metrics.

## Uniqueness and Moduli

In Yang–Mills theory, there is a highly developed theory of moduli spaces of instantons, including formulas for the dimension. The situation for Einstein metrics is far less well understood. The relevant moduli space here is the set of Einstein metrics modulo the action of the diffeomorphism group, but there are very few manifolds for which the moduli space has been determined. In dimension 2, of course, this is essentially the subject of the Teichmuller theory.

One example where the moduli space is understood is the K3 surface. As explained above, the Hitchin–Thorpe argument shows that any Einstein metric is hyper-Kähler, and the moduli space of such structures on K3 is understood as an open set in a certain noncompact symmetric space.

Some uniqueness results have been obtained in four dimensions. LeBrun used Seiberg–Witten techniques to show that the Einstein metric on a compact quotient of the complex hyperbolic plane $\mathbb{C}H^2$ is unique up to homotheties and diffeomorphisms. The analogous result for compact quotients of real hyperbolic 4-space was obtained using entropy methods by Besson, Courtois, and Gallot. It is still unknown, however, whether nonstandard Einstein metrics can exist on $S^4$.

In higher dimensions, very little is known. One can, by analogy with the theory of instantons, consider the linearization of the Einstein equations together with a further linear equation expressing orthogonality to the orbits of the diffeomorphism group. This gives a notion of formal tangent space to the Einstein moduli space. However, Koiso has shown that formal tangent vectors need not integrate to a curve of Einstein metrics. The structure of the moduli space (dimension, possible singularities) remains quite mysterious in general. It is known from the Wang–Ziller torus bundle examples that the moduli space can have infinitely many components.

## Special Holonomy

Berger classified the possible holonomy groups of simply connected, irreducible, nonsymmetric $n$-dimensional Riemannian manifolds. The generic case is that of holonomy $SO(n)$, and there are six other possibilities, each of which corresponds to some special geometry. Interestingly, four of these are automatically Ricci-flat, while a fifth is Einstein with $\Lambda \neq 0$. The remaining example, that of Kähler geometry, is not automatically Einstein, but the Einstein equations with the additional Kähler assumption reduce to a *scalar* Monge–Ampere equation and are therefore simpler than the general Einstein system.

For further reading in this section, see the articles by Boyer–Galicki, Joyce, Salamon, Tian, Yau and the author in part I of LeBrun and Wang (1999), and also the book of Joyce (2000). For the Kähler case, see also Tian (2000).

### **Kähler Manifolds** (Holonomy $U(n/2)$, $SU(n/2)$)

A Kähler manifold $(M, g)$ admits a covariant constant complex structure $I$, and associated Kähler 2-form $\omega$ defined by $\omega(X, Y) = g(IX, Y)$. The Ricci form $\rho$ is defined by $\rho(X, Y) = \mathrm{Ric}(IX, Y)$, so the Einstein condition for a Kähler manifold becomes

$$\rho = \Lambda\omega$$

On a Kähler manifold, $\rho$ is the curvature of the canonical bundle, so $[\rho/2\pi]$ is a representative for the cohomology class $c_1(M)$.

We see that a *necessary* condition for a complex manifold $(M, I)$ to admit a Kähler–Einstein metric is that $c_1$ has a definite sign. We consider, in turn, the three cases:

$c_1 < 0$

In this case, we have:

**Theorem** (Aubin, Yau). *Let $(M, I)$ be a compact complex manifold with $c_1 < 0$. Then $(M, I)$ admits a Kähler–Einstein metric with $\Lambda < 0$. The metric is unique up to homothety.*

$c_1 = 0$

This is a special case of the Calabi conjecture, proved by Yau.

**Theorem** (Yau). *Let $M$ be a compact Kähler manifold with Kähler form $\omega$. For any closed real form $\rho$ of type $(1,1)$ with $[\rho/2\pi] = c_1(M)$, there exists a unique Kähler metric with Kähler form cohomologous to $\omega$ and Ricci form equal to $\rho$.*

*In particular, if $M$ is a compact Kähler manifold with $c_1 = 0$, there exists a Ricci-flat Kähler metric on $M$.*

Ricci-flat Kähler metrics are called Calabi–Yau metrics, and are exactly the metrics with holonomy in $SU(n/2)$. They admit two parallel spinors and are of great interest to string theorists, because in some string theories spacetime is expected to be a product of the four-dimensional macroscopic factor with a compact Calabi–Yau manifold of complex dimension 3.

Yau's theorem provides many examples of Calabi–Yau spaces. For example, we can take a nonsingular complex submanifold defined as a complete intersection by the vanishing of $r$ polynomials of degree $d_1, \ldots, d_r$ in $\mathbb{CP}^n$. Now, $M$ has complex dimension $n - r$ and $c_1 = 0$ if and only if $n + 1 = \sum_{i=1}^{r} d_i$. We obtain examples of complex dimension 2 by considering a quartic in $\mathbb{CP}^3$, the intersection of a quadric and a cubic in $\mathbb{CP}^4$, or the intersection of three quadrics in $\mathbb{CP}^5$; these all give examples of K3 surfaces. A famous example of a Calabi–Yau manifold of complex dimension 3 is given by the quintic in $\mathbb{CP}^4$. This technique can be extended, for example, by considering complete intersections in weighted projective space or constructing Calabi–Yau desingularizations of singular spaces.

$c_1 > 0$

This case is the most complicated and, at the time of writing, is not yet fully understood. It is known that not every compact manifold with $c_1 > 0$ supports a Kähler–Einstein metric.

An early result of Matsushima was that the identity component of the automorphism group of a Kähler–Einstein space with $c_1 > 0$ must be reductive. This shows, for example, that the blow-up of $\mathbb{CP}^2$ at one or two points does not admit a Kähler–Einstein metric, despite having $c_1 > 0$. (The one-point blow-up does admit a Hermitian–Einstein metric due to Page.) A second obstruction is the Futaki invariant, a character of the Lie algebra of the automorphism group. This character vanishes if there is a Kähler–Einstein metric.

Both the above obstructions depend on having a nontrivial algebra of holomorphic automorphisms of $M$. More recently, Tian has discovered further obstructions (in complex dimension 3 or higher) which can be present even if the automorphism algebra is trivial.

However, for compact complex *surfaces* with $c_1 > 0$, Tian has proved that vanishing of the Futaki invariant is sufficient. In particular, the blow-up of $\mathbb{CP}^2$ at $k$ points in general position, where $3 \leq k \leq 8$, admits a Kähler–Einstein metric (note that $c_1^2 = 9 - k$ so if $k > 8$ then $c_1$ is no longer definite).

LeBrun–Catanese and Kotschick used these results to give an example of a topological 4-manifold carrying Einstein metrics of different signs. A deformation of the Barlow surface (a surface of general type) has $c_1 < 0$ and hence carries an Einstein metric with $\Lambda < 0$. But this space is homeomorphic (though not diffeomorphic) to the blow-up of $\mathbb{CP}^2$ at eight points, which carries an Einstein metric with $\Lambda > 0$. One may use this example to construct higher-dimensional examples of *diffeomorphic* manifolds carrying Einstein metrics of opposite sign.

### Hyper-Kähler Manifolds (Holonomy Sp($n$/4))

These are always Ricci-flat. They have a triple $(I, J, K)$ of covariant constant complex structures, satisfying the quaternionic multiplication relations $IJ = K = -JI$, etc., and defining Kähler forms $\omega_I, \omega_J, \omega_K$. Hyper-Kähler manifolds of dimension $n = 4N$ have $N + 1$ parallel spinors.

The most effective way of producing complete hyper-Kähler metrics has been the hyper-Kähler quotient construction (Hitchin *et al.* 1987), which was motivated by the Marsden–Weinstein quotient in symplectic geometry. Let $G$ be a group acting freely on a hyper-Kähler manifold $(M, g, I, J, K)$ preserving the hyper-Kähler structure. Subject to mild assumptions, we obtain a $G$-equivariant moment map $\mu : M \to \mathfrak{g}^* \otimes \mathbb{R}^3$, satisfying

$$d\mu_X(Y) = (\omega_I(X, Y), \omega_J(X, Y), \omega_K(X, Y))$$

Now the quotient $\mu^{-1}(0)/G$ is a hyper-Kähler manifold of dimension $\dim M - 4 \dim G$.

The power of this construction comes from the fact that even if $M$ is just flat quaternionic space, one can obtain highly nontrivial quotients by suitable choice of group $G$ (e.g., the asymptotically locally Euclidean four-dimensional examples of Kronheimer, which include as a subcase the multi-instanton metrics of Gibbons and Hawking).

Many examples of interest in mathematical physics may be obtained by taking hyper-Kähler quotients of an infinite-dimensional space of connections and Higgs fields (Hitchin 1987). Examples include moduli spaces of instantons over a hyper-Kähler base, moduli spaces of monopoles on $\mathbb{R}^3$, and moduli spaces of Higgs pairs over a Riemann surface.

The hyper-Kähler manifolds produced so far by the quotient construction have all been noncompact. Examples of compact hyper-Kähler manifolds are rarer but some are known. Beauville has produced examples in all dimensions as desingularizations of symmetric products of the basic four-dimensional compact examples (K3 and the 4-torus).

Further material for this section may be found, for example, in Hitchin (1992) and in the chapter by the author on hyper-Kähler manifolds in LeBrun and Wang (1999).

### Quaternionic Kähler Manifolds (Holonomy Sp($n$/4)) Sp(1))

These are always Einstein with nonzero Einstein constant. Instead of globally defined parallel complex structures as in the hyper-Kähler case, we have a sub-bundle $\mathcal{G}$ of End($TM$) with fiber isomorphic to the imaginary quaternions, parallel with respect to the Levi-Civita connection. Thus, we have locally defined almost-complex structures $I$, $J$, $K$, satisfying the quaternionic multiplication relations, such that covariant differentiation of one of $I$, $J$, $K$ gives a linear combination of the other two. In particular, note that quaternionic Kähler manifolds are not Kähler.

If the Einstein constant $\Lambda$ is positive, the only known complete examples are symmetric, the so-called compact Wolf spaces, which are in one-to-one correspondence with the compact simple Lie groups. It is conjectured that these are the only examples with $\Lambda > 0$, and some results in this direction have been established (e.g., it is known if $\dim M \leq 12$). It is also known that for fixed dimension, there are only finitely many types of compact quaternionic Kähler manifold with $\Lambda > 0$.

Many *orbifold* examples, however, are known to exist, for example, via the Galicki–Lawson quaternionic Kähler quotient construction.

If $\Lambda < 0$, more complete examples are known. In addition to the noncompact duals of the Wolf spaces, there are homogeneous, nonsymmetric examples due to Alekseevski, and infinite-dimensional families of inhomogeneous examples constructed via twistor methods by LeBrun (see also Biquard (2000)).

### Exceptional Holonomy ($G_2$ or Spin(7))

Such metrics exist in dimension 7 or 8, respectively. They are always Ricci-flat and admit a parallel spinor. Local examples were constructed by Bryant using Cartan–Kähler theory, and some explicit complete noncompact examples were produced by Salamon and Bryant using a cohomogeneity-1 construction. More complicated explicit noncompact examples have recently been produced by several authors (see Cvetič *et al*. (2003) for a survey). Compact examples were produced using analytical methods by Joyce, and later by Kovalev. Joyce starts with a flat singular metric on quotients of the seven- or eight-dimensional torus and constructs an approximate solution to the special holonomy condition on a resolution of this singular space. Then an analytic argument is used to show that an exact nearby solution exists.

For further reading, consult Joyce (2000) as well as the article by Joyce in LeBrun and Wang (1999).

There are also some interesting examples of Einstein metrics which, although not of special holonomy themselves, are closely related to special holonomy geometries. In recent years, these have yielded many new examples of compact Einstein manifolds in the work of Boyer, Mann, Galicki, Kollar, Rees, Piccinni, and Nakamaye.

### Einstein–Sasaki Structures

There are several different ways of defining these, but the simplest is to say that $(M, g)$ is Einstein–Sasaki if the cone $(\mathbb{R} \times M, \mathrm{d}t^2 + t^2 g)$ is Ricci-flat Kähler. Also, an Einstein–Sasaki manifold has a circle action with quotient a Kähler–Einstein orbifold. Existence theorems for such orbifold metrics have led to many examples of Einstein–Sasaki metrics, including families on odd-dimensional spheres.

### 3-Sasakian Structures

Again, we can define these in terms of cones; $(M, g)$ has a 3-Sasakian structure if the cone over it is hyper-Kähler. The basic example is $S^{4n+3}$ with associated cone $\mathbb{H}^n - \{0\}$. A 3-Sasakian manifold is always Einstein with positive Einstein constant.

The hyper-Kähler quotient construction induces a 3-Sasakian quotient, and many examples of compact 3-Sasakian manifolds have been produced as 3-Sasakian quotients of $S^{4n+3}$. In particular, there are examples in dimension 7 with arbitrarily large second Betti number, showing that one cannot, in general, expect compactness/finiteness results for Einstein moduli spaces without further assumptions.

## Homogeneous Examples

Another strategy to study the Einstein equations is to reduce the difficulty of the problem by imposing symmetries. More precisely, we consider Einstein manifolds $(M, g)$ with an isometric action of a Lie group $G$. In general, the Einstein equations with this symmetry will now involve $r$ independent variables where $r$ is the dimension of the stratified space $M/G$. We call $r$ the *cohomogeneity* of the manifold.

In this section, we consider the situation where $(M, g)$ is *homogeneous,* that is, when the action of $G$ is transitive so $r = 0$. The Einstein equations now reduce to a system of *algebraic* equations.

We may now write $M = G/K$, where $K$ is the stabilizer of a point of $M$. We choose an $\mathrm{Ad}_K$-invariant vector space complement $\mathfrak{p}$ to $\mathfrak{k}$ in $\mathfrak{g}$, and identify $\mathfrak{p}$ with the tangent space to $G/K$ at the identity coset. The key point is that $G$-invariant metrics on $M = G/K$ may now be identified with $\mathrm{Ad}_K$-invariant inner products on $\mathfrak{p}$, which may, in turn, be studied by looking at the decomposition of $\mathfrak{p}$ into irreducible representations of $K$.

In the special case when $G/K$ is isotropy irreducible (i.e., $\mathfrak{p}$ is an irreducible representation of $K$), both the metric $g$ and its Ricci tensor are proportional by Schur's lemma, and hence $g$ is automatically Einstein. Isotropy-irreducible homogeneous spaces have been classified by Kramer, Manturov, Wolf, and Wang–Ziller.

In the general case, the Einstein equations become a system of polynomial equations. Determining whether this system has a real positive solution is, in general, a highly nontrivial problem. However, the situation of homogeneous metrics is one area in which the variational formulation of the Einstein equations has proved highly successful.

We are now considering the scalar curvature functional on the finite-dimensional space of unit $G$-invariant metrics on $G/K$. The behavior of the scalar curvature functional is related to the structure of the lattice of intermediate subalgebras between the Lie algebras of $K$ and $G$.

An early result along these lines (Wang and Ziller 1986) is that if $K$ is maximal in $G$ (compact), then $G/K$ admits a $G$-invariant Einstein metric. The idea of the proof is to show that maximality of $K$ forces the scalar curvature functional on the space of volume-1 homogeneous metrics to be both bounded above and proper, and therefore to have a maximum.

These ideas have been greatly extended by Böhm, Wang, and Ziller. Given a compact connected homogeneous space $G/K$, they define a graph whose vertices are $\mathrm{Ad}(K)$-invariant subalgebras strictly intermediate between $\mathfrak{g}$ and $\mathfrak{k}$. The edges correspond to inclusions between subalgebras. A component of the graph is called toral if all subalgebras $\mathfrak{h}$ in this component are such that the identity component of $H/K$ is abelian. They now show that if the graph has at least two nontoral components, then $G/K$ admits a $G$-invariant Einstein metric. The Einstein metrics in the theorem are produced by a mountain pass argument and may have co-index 1, contrasting with the maxima of the earlier theorem.

Further advances in this direction have recently been made by Böhm. He associates to $G/K$ a simplicial complex, and shows that nonzero homology groups of the complex imply the existence of higher co-index Einstein metrics.

One can also study homogeneous noncompact Einstein spaces with $\Lambda < 0$. It is conjectured by Alekseevski that for all such examples $K$ is a maximal compact subgroup of $G$. The reader is referred to Heber (1998) for further information on the noncompact case.

The above results give some powerful existence results for Einstein metrics. However, there are examples known of homogeneous spaces $G/K$ which admit no $G$-invariant Einstein metric (Wang and Ziller 1986). One such example is $\mathrm{SU}(4)/\mathrm{SU}(2)$, where $\mathrm{SU}(2)$ is a maximal subgroup of $\mathrm{Sp}(2) \subset \mathrm{SU}(4)$.

Techniques similar to those in the homogeneous case have been used to construct Einstein metrics on total spaces of certain bundles, via Riemannian submersions. Some highlights are Jensen's exotic Einstein metrics on $(4n + 3)$-dimensional spheres, and the Wang–Ziller metrics on total spaces of torus bundles over products of Kähler–Einstein manifolds. The latter construction gives examples of spaces admitting volume-1 Einstein metrics with infinitely many Einstein constants $\Lambda$.

## Examples of Higher Cohomogeneity

One can also look for Einstein metrics of higher cohomogeneity. Most progress has been made in the cohomogeneity-1 case, that is, where the principal orbit $G/K$ of the action has real codimension one in

$M$ (see Eschenburg and Wang (2000) for background on such metrics). On the open dense set in $M$ which is the union of the principal orbits, we may write the metric as

$$dt^2 + g_t$$

where $g_t$ is a $t$-dependent homogeneous metric on $G/K$. The Einstein equations are now a system of ordinary differential equations in $t$.

One may also add a special orbit $G/H$ at one or both ends of the interval over which $t$ ranges. This will impose boundary conditions on the ODEs. For the manifold structure to extend smoothly over the special orbit, $H/K$ must be a sphere. Notice that if $\Lambda > 0$, then to obtain a complete metric $M$ must be compact, so we must add two special orbits. If $\Lambda \leq 0$ and the metric is irreducible, then a Bochner argument tells us that $M$ is noncompact. In the Ricci-flat case, the Cheeger–Gromoll theorem tells us that to obtain a complete irreducible metric, we must have exactly one special orbit, so $M$ is topologically the total space of a vector bundle over the special orbit. In fact, most of the known examples even with $\Lambda < 0$ have a special orbit too.

The system of ODEs we obtain is still highly nonlinear and difficult to analyze in general. However, there are certain situations in which the equations, or a subsystem, can be solved in closed form. If we take $G/K$ to be a principal circle bundle over a Hermitian symmetric space, Bérard Bergery (1982) showed that the resulting Einstein equations are solvable. (His work was inspired by the earlier example of Page, which corresponds to the case when $G/K = U(2)/U(1)$, a circle bundle over $\mathbb{CP}^1$.) In fact, Bérard Bergery's construction works in greater generality as we obtain the same equations if $G/K$ is replaced by any Riemannian submersion with circle fibers over a positive Kähler–Einstein space. This illustrates a general principle that systems arising as cohomogeneity-1 Einstein equations also typically arise from certain bundle ansätze without homogeneity assumptions.

Wang and Wang generalized this construction to be the case when the hypersurface in $M$ is a Riemannian submersion with circle fibers over a product of an arbitrary number of Kähler–Einstein factors. Other solvable Einstein systems have been studied by, for example, Wang and Dancer.

It may also be possible in certain situations to get existence results without an explicit solution. This observation underlies the important work of Böhm (1998). He constructs cohomogeneity-1 Einstein metrics on certain manifolds with dimension between 5 and 9, including all the spheres in this range of dimensions. The equations are not now solved in closed form, but it is possible to get a qualitative understanding of the flow and to show that certain trajectories will give metrics on the desired compact manifolds.

Böhm has also shown, in an analogous result to the homogeneous case, that there are examples of manifolds with a cohomogeneity-1 $G$-action which do not support any $G$-invariant Einstein metric.

So far, not much is known about Einstein metrics of higher cohomogeneity. An exception is the situation of self-dual Einstein metrics in dimension 4, where the self-dual condition greatly simplifies the resulting equations. Calderbank, Pedersen, and Singer have achieved a good understanding of such metrics with $T^2$ symmetry, including construction of such metrics on Hirzebruch–Jung resolutions of cyclic quotient singularities.

## Analytical Methods

So far there is no really general analytical method for proving existence of global Riemannian Einstein metrics (although, of course, such techniques do exist in more restrictive situations of special holonomy).

Although the Einstein equations admit a variational formulation, this has (except for homogeneous metrics) not yielded general existence results. Note that the Wang–Ziller torus bundle examples at the end of the section "Homogeneous examples" show that the Palais–Smale condition does not hold in full generality.

One early suggestion was to adopt a minimax procedure. In each conformal class $[g]$, one looks for a minimizer of the volume-normalized scalar curvature. Such a minimizer always exists. One then takes the supremum over all conformal classes. The resulting supremum of the functional is called the Yamabe invariant $Y(M)$ of the manifold $M$. If a maximizer $g$ exists, and $Y(M) \leq 0$, then $g$ is Einstein.

However, striking work of Petean shows that this procedure must fail to produce an Einstein metric in many cases. He proves that if $\dim M \geq 5$ and $M$ is simply connected, then the Yamabe invariant is nonnegative. So, for such an $M$, any Einstein metric produced will have $\Lambda \geq 0$, and we know that this puts constraints on the topology of $M$.

Another possible technique is to use the Hamilton Ricci flow. If this converges as $t \to \infty$, the limiting metric is Einstein. However, it seems hard in higher dimensions to get control over the flow. In particular, the Wang–Ziller example in the section "Homogeneous examples" of a homogeneous space with no invariant Einstein metric shows that the flow may fail to converge (the Hamilton flow preserves the property of $G$-invariance).

Graham–Lee and Biquard have used analytical methods to produce Einstein deformations of hyperbolic space (real, complex, quaternionic, or Cayley). The idea is to show that a sufficiently small deformation of the conformal infinity of hyperbolic space can be extended to a deformation of the hyperbolic metric.

Recently, Anderson has shown the existence of Einstein metrics with $\Lambda < 0$ on a large class of manifolds obtained by Dehn filling from hyperbolic manifolds with toral ends. The strategy is to glue on to the hyperbolic metric copies of a simple explicit asymptotically hyperbolic metric, and to show that the resulting metric can be perturbed to an exact solution of the Einstein equations.

# Einstein–Cartan Theory

**A Trautman**, Warsaw University, Warsaw, Poland

## Introduction

### Notation

Standard notation and terminology of differential geometry and general relativity are used in this article. All considerations are local, so that the four-dimensional spacetime $M$ is assumed to be a smooth manifold diffeomorphic to $\mathbb{R}^4$. It is endowed with a metric tensor $g$ of signature $(1,3)$ and a linear connection defining the covariant differentiation of tensor fields. Greek indices range from 0 to 3 and refer to spacetime. Given a field of frames $(e_\mu)$ on $M$, and the dual field of coframes $(\theta^\mu)$, one can write the metric tensor as $g = g_{\mu\nu}\theta^\mu\theta^\nu$, where $g_{\mu\nu} = g(e_\mu, e_\nu)$ and Einstein's summation convention is assumed to hold. Tensor indices are lowered with $g_{\mu\nu}$ and raised with its inverse $g^{\mu\nu}$. General-relativistic units are used, so that both Newton's constant of gravitation and the speed of light are 1. This implies $\hbar = l^2$, where $l \approx 10^{-33}$ cm is the Planck length. Both mass and energy are measured in centimeters.

### Historical Remarks

The Einstein–Cartan theory (ECT) of gravity is a modification of general relativity theory (GRT), allowing spacetime to have torsion, in addition to curvature, and relating torsion to the density of intrinsic angular momentum. This modification was put forward in 1922 by Élie Cartan, before the discovery of spin. Cartan was influenced by the work of the Cosserat brothers (1909), who considered besides an (asymmetric) force stress tensor also a moments stress tensor in a suitably

generalized continuous medium. Work done in the 1950s by physicists (Kondo, Bilby, Kröner, and other authors) established the role played by torsion in the continuum theory of crystal dislocations. A recent review (Ruggiero and Tartaglia 2003) describes the links between ECT and the classical theory of defects in an elastic medium.

Cartan assumed the linear connection to be metric and derived, from a variational principle, a set of gravitational field equations. He required, without justification, that the covariant divergence of the energy–momentum tensor be zero; this led to an algebraic constraint equation, bilinear in curvature and torsion, severely restricting the geometry. This misguided observation has probably discouraged Cartan from pursuing his theory. It is now known that conservation laws in relativistic theories of gravitation follow from the Bianchi identities and, in the presence of torsion, the divergence of the energy–momentum tensor need not vanish. Torsion is implicit in the 1928 Einstein theory of gravitation with teleparallelism. For a long time, Cartan's modified theory of gravity, presented in his rather abstruse notation, unfamiliar to physicists, did not attract any attention. In the late 1950s, the theory of gravitation with spin and torsion was independently rediscovered by Sciama and Kibble. The role of Cartan was recognized soon afterward and ECT became the subject of much research; see Hehl *et al.* (1976) for a review and an extensive bibliography. In the 1970s, it was recognized that ECT can be incorporated within supergravity. In fact, simple supergravity is equivalent to ECT with a massless, anticommuting Rarita–Schwinger field as the source. Choquet–Bruhat considered a generalization of ECT to higher dimensions and showed that the Cauchy problem for the coupled system of Einstein–Cartan and Dirac equations is well posed. Penrose (1982) has shown that torsion appears in a natural way when spinors are allowed to be rescaled by a complex conformal factor. ECT has been generalized by allowing nonmetric linear connections and additional currents, associated with dilation and shear, as sources of such a "metric-affine theory of gravity" (Hehl *et al.* 1995).

### Physical Motivation

Recall that, in special relativity theory (SRT), the underlying Minkowski spacetime admits, as its group of automorphisms, the full Poincaré group, consisting of translations and Lorentz transformations. It follows from the first Noether theorem that classical, special-relativistic field equations, derived from a variational principle, give rise to conservation laws of energy–momentum and angular momentum. Using Cartesian coordinates $(x^\mu)$, abbreviating $\partial\varphi/\partial x^\rho$ to $\varphi_{,\rho}$ and denoting by $t^{\mu\nu}$ and $s^{\mu\nu\rho} = -s^{\nu\mu\rho}$ the tensors of energy–momentum and of intrinsic angular momentum (spin), respectively, one can write the conservation laws in the form

$$t^{\mu\nu}{}_{,\nu} = 0 \qquad [1]$$

and

$$(x^\mu t^{\nu\rho} - x^\nu t^{\mu\rho} + s^{\mu\nu\rho})_{,\rho} = 0 \qquad [2]$$

In the presence of spin, the tensor $t^{\mu\nu}$ need not be symmetric,

$$t^{\mu\nu} - t^{\nu\mu} = s^{\mu\nu\rho}{}_{,\rho}$$

Belinfante and Rosenfeld have shown that the tensor

$$T^{\mu\nu} = t^{\mu\nu} + \tfrac{1}{2}(s^{\nu\mu\rho} + s^{\nu\rho\mu} + s^{\mu\rho\nu})_{,\rho}$$

is symmetric and its divergence vanishes.

In quantum theory, the irreducible, unitary representations of the Poincaré group correspond to elementary systems such as stable particles; these representations are labeled by the mass and spin.

In Einstein's GRT, the spacetime $M$ is curved; the Lorentz group – but not the Poincaré group – appears as the structure group acting on orthonormal frames in the tangent spaces of $M$. The energy–momentum tensor $T$ appearing on the right-hand side of the Einstein equation is necessarily symmetric. In GRT there is no room for translations and the tensors $t$ and $s$.

By introducing torsion and relating it to $s$, Cartan restored the role of the Poincaré group in relativistic gravity: this group acts on the affine frames in the tangent spaces of $M$. Curvature and torsion are the surface densities of Lorentz transformations and translations, respectively. In a space with torsion, the Ricci tensor need not be symmetric so that an asymmetric energy–momentum tensor can appear on the right-hand side of the Einstein equation.

## Geometric Preliminaries

### Tensor-Valued Differential Forms

It is convenient to follow Cartan in describing geometric objects as tensor-valued differential forms. To define them, consider a homomorphism $\sigma : \mathrm{GL}_4(\mathbb{R}) \to \mathrm{GL}_N(\mathbb{R})$ and an element $A = (A^\mu_\nu)$ of $\mathrm{End}\,\mathbb{R}^4$, the Lie algebra of $\mathrm{GL}_4(\mathbb{R})$. The derived representation of Lie algebras is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\sigma(\exp At)|_{t=0} = \sigma^\nu_\mu A^\mu_\nu$$

If $(e_a)$ is a frame in $\mathbb{R}^N$, then $\sigma^\nu_\mu(e_a)=\sigma^{b\nu}_{a\mu}e_b$, where $a,b=1,\ldots,N$.

A map $a=(a^\mu{}_\nu):M\to \mathrm{GL}_4(\mathbb{R})$ transforms fields of frames so that

$$e'_\mu = e_\nu a^\nu_\mu \quad \text{and} \quad \theta^\nu = a^\nu_\mu \theta'^\mu \qquad [3]$$

A differential form $\varphi$ on $M$, with values in $\mathbb{R}^N$, is said to be of type $\sigma$ if, under changes of frames, it transforms so that $\varphi'=\sigma(a^{-1})\varphi$. For example, $\theta=(\theta^\mu)$ is a 1-form of type id. If now $A=(A^\mu_\nu):M\to \mathrm{End}\,\mathbb{R}^4$, then one puts $a(t)=\exp tA:M\to \mathrm{GL}_4(\mathbb{R})$ and defines the variations induced by an infinitesimal change of frames,

$$\delta\theta = \frac{\mathrm{d}}{\mathrm{d}t}(a(t)^{-1}\theta)|_{t=0} = -A\theta$$
$$\delta\varphi = \frac{\mathrm{d}}{\mathrm{d}t}(\sigma(a(t)^{-1})\varphi)|_{t=0} = -\sigma^\nu_\mu A^\mu_\nu \varphi \qquad [4]$$

## Hodge Duals

Since $M$ is diffeomorphic to $\mathbb{R}^4$, one can choose an orientation on $M$ and restrict the frames to agree with that orientation so that only transformations with values in $\mathrm{GL}^+_4(\mathbb{R})$ are allowed. The metric then defines the Hodge dual of differential forms. Put $\theta_\mu=g_{\mu\nu}\theta^\nu$. The forms $\eta,\eta_\mu,\eta_{\mu\nu},\eta_{\mu\nu\rho}$, and $\eta_{\mu\nu\rho\sigma}$ are defined to be the duals of $1,\theta_\mu,\theta_\mu\wedge\theta_\nu,\theta_\mu\wedge\theta_\nu\wedge\theta_\rho$, and $\theta_\mu\wedge\theta_\nu\wedge\theta_\rho\wedge\theta_\sigma$, respectively. The 4-form $\eta$ is the volume element; for a holonomic coframe $\theta^\mu=\mathrm{d}x^\mu$, it is given by $\sqrt{-\det(g_{\mu\nu})}\mathrm{d}x^0\wedge\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$. In SRT, in Cartesian coordinates, one can define the tensor-valued 3-forms

$$t^\mu = t^{\mu\nu}\eta_\nu \quad \text{and} \quad s^{\mu\nu} = s^{\mu\nu\rho}\eta_\rho \qquad [5]$$

so that eqns [1] and [2] become

$$\mathrm{d}t^\mu = 0 \quad \text{and} \quad \mathrm{d}j^{\mu\nu} = 0$$

where

$$j^{\mu\nu} = x^\mu t^\nu - x^\nu t^\mu + s^{\mu\nu} \qquad [6]$$

For an isolated system, the 3-forms $t^\mu$ and $j^{\mu\nu}$, integrated over the 3-space $x^0=\text{const.}$, give the system's total energy–momentum vector and angular momentum bivector, respectively.

## Linear Connection, Its Curvature and Torsion

A linear connection on $M$ is represented, with respect to the field of frames, by the field of 1-forms

$$\omega^\mu_\nu = \Gamma^\mu_{\rho\nu}\theta^\rho$$

so that the covariant derivative of $e_\nu$ in the direction of $e_\mu$ is $\nabla_\mu e_\nu=\Gamma^\rho_{\mu\nu}e_\rho$. Under a change of frames [3], the connection forms transform as follows:

$$a^\mu_\rho \omega'^\rho_\nu = \omega^\mu_\rho a^\rho_\nu + \mathrm{d}a^\mu_\nu$$

If $\varphi=\varphi^a e_a$ is a $k$-form of type $\sigma$, then its covariant exterior derivative

$$D\varphi^a = \mathrm{d}\varphi^a + \sigma^{a\mu}_{b\nu}\omega^\nu_\mu\wedge\varphi^b$$

is a $(k+1)$-form of the same type. For a 0-form one has $D\varphi^a=\theta^\mu\nabla_\mu\varphi^a$. The infinitesimal change of $\omega$, defined similarly as in [4], is $\delta\omega^\mu_\nu=DA^\mu_\nu$. The 2-form of curvature $\Omega=(\Omega^\mu{}_\nu)$, where

$$\Omega^\mu_\nu = \mathrm{d}\omega^\mu_\nu + \omega^\mu_\rho\wedge\omega^\rho_\nu$$

is of type ad: it transforms with the adjoint representation of $\mathrm{GL}_4(\mathbb{R})$ in $\mathrm{End}\,\mathbb{R}^4$. The 2-form of torsion $\Theta=(\Theta^\mu)$, where

$$\Theta^\mu = \mathrm{d}\theta^\mu + \omega^\mu_\nu\wedge\theta^\nu$$

is of type id. These forms satisfy the Bianchi identities

$$D\Omega^\mu{}_\nu = 0 \quad \text{and} \quad D\Theta^\mu = \Omega^\mu{}_\nu\wedge\theta^\nu$$

For a differential form $\varphi$ of type $\sigma$, the following identity holds:

$$D^2\varphi^a = \sigma^{a\nu}_{b\mu}\Omega^\mu{}_\nu\wedge\varphi^b \qquad [7]$$

The tensors of curvature and torsion are given by

$$\Omega^\mu{}_\nu = \tfrac{1}{2}R^\mu{}_{\nu\rho\sigma}\theta^\rho\wedge\theta^\sigma$$

and

$$\Theta^\mu = \tfrac{1}{2}Q^\mu{}_{\rho\sigma}\theta^\rho\wedge\theta^\sigma$$

respectively. With respect to a holonomic frame, $\mathrm{d}\theta^\mu=0$, one has

$$Q^\mu{}_{\rho\sigma} = \Gamma^\mu_{\rho\sigma} - \Gamma^\mu_{\sigma\rho}$$

In SRT, the Cartesian coordinates define a radius-vector field $X^\mu=-x^\mu$, pointing towards the origin of the coordinate system. The differential equation it satisfies generalizes to a manifold with a linear connection:

$$DX^\mu + \theta^\mu = 0 \qquad [8]$$

By virtue of [7], the integrability condition of [8] is

$$\Omega^\mu{}_\nu X^\nu + \Theta^\mu = 0$$

Integration of [8] along a curve defines the Cartan displacement of $X$; if this is done along a small closed circuit spanned by the bivector $\Delta f$, then the radius vector changes by about

$$\Delta X^\mu = \tfrac{1}{2}(R^\mu{}_{\nu\rho\sigma}X^\nu + Q^\mu{}_{\rho\sigma})\Delta f^{\rho\sigma}$$

This holonomy theorem – rather imprecisely formulated here – shows that torsion bears to translations a relation similar to that of curvature to linear homogeneous transformations.

In a space with torsion, it matters whether one considers the potential of the electromagnetic field to be a scalar-valued 1-form $\varphi$ or a covector-valued 0-form $(\varphi_\mu)$. The first choice leads to a field $\mathrm{d}\varphi$ that is invariant with respect to the gauge transformation $\varphi \mapsto \varphi + \mathrm{d}\chi$. The second gives $\frac{1}{2}(\nabla_\mu\varphi_\nu - \nabla_\nu\varphi_\mu)\theta^\mu \wedge \theta^\nu = (D\varphi_\mu) \wedge \theta^\mu = \mathrm{d}\varphi - \varphi_\mu\Theta^\mu$, a gauge-dependent field.

### Metric-Affine Geometry

A metric-affine space $(M, g, \omega)$ is defined to have a metric and a linear connection that need not depend on each other. The metric alone determines the torsion-free Levi-Civita connection $\overset{\circ}{\omega}$ characterized by

$$\mathrm{d}\theta^\mu + \overset{\circ}{\omega}{}^\mu_\nu \wedge \theta^\nu = 0 \quad \text{and} \quad \overset{\circ}{D} g_{\mu\nu} = 0$$

Its curvature is

$$\overset{\circ}{\Omega}{}^\mu_\nu = \mathrm{d}\overset{\circ}{\omega}{}^\mu_\nu + \overset{\circ}{\omega}{}^\mu_\rho \wedge \overset{\circ}{\omega}{}^\rho_\nu$$

The 1-form of type ad,

$$\kappa^\mu{}_\nu = \omega^\mu_\nu - \overset{\circ}{\omega}{}^\mu_\nu \qquad [9]$$

determines the torsion of $\omega$ and the covariant derivative of $g$,

$$\Theta^\mu = \kappa^\mu{}_\nu \wedge \theta^\nu, \qquad Dg_{\mu\nu} = -\kappa_{\mu\nu} - \kappa_{\nu\mu}$$

The curvature of $\omega$ can be written as

$$\Omega^\mu{}_\nu = \overset{\circ}{\Omega}{}^\mu_\nu + \overset{\circ}{D}\kappa^\mu{}_\nu + \kappa^\mu{}_\rho \wedge \kappa^\rho{}_\nu \qquad [10]$$

The transposed connection $\tilde{\omega}$ is defined by

$$\tilde{\omega}^\mu_\nu = \omega^\mu_\nu + Q^\mu{}_{\nu\rho}\theta^\rho$$

so that, with respect to a holonomic frame, one has $\tilde{\Gamma}^\mu_{\nu\rho} = \Gamma^\mu_{\rho\nu}$. The torsion of $\tilde{\omega}$ is opposed to that of $\omega$.

### Riemann–Cartan Geometry

A Riemann–Cartan space is a metric-affine space with a connection that is metric,

$$Dg_{\mu\nu} = 0 \qquad [11]$$

The metricity condition implies that $\kappa_{\mu\nu} + \kappa_{\nu\mu} = 0$ and $\Omega_{\mu\nu} + \Omega_{\nu\mu} = 0$. In a Riemann–Cartan space, the connection is determined by its torsion $Q$ and the metric tensor. Let $Q_{\rho\mu\nu} = g_{\rho\sigma}Q^\sigma{}_{\mu\nu}$; then

$$\kappa_{\mu\nu} = \tfrac{1}{2}(Q_{\mu\sigma\nu} + Q_{\nu\mu\sigma} + Q_{\sigma\mu\nu})\theta^\sigma \qquad [12]$$

The transposed connection of a Riemann–Cartan space is metric if and only if the tensor $Q_{\rho\mu\nu}$ is completely antisymmetric. Let $\tilde{\nabla}$ denote the covariant derivative with respect to $\tilde{\omega}$. By definition, a symmetry of a Riemann–Cartan space is a diffeomorphism of $M$ preserving both $g$ and $\omega$. The one-parameter group of local transformations of $M$, generated by the vector field $v$, consists of symmetries of $(M, g, \omega)$ if and only if

$$\tilde{\nabla}^\mu v^\nu + \tilde{\nabla}^\nu v^\mu = 0 \qquad [13]$$

and

$$D\tilde{\nabla}_\nu v^\mu + R^\mu{}_{\nu\rho\sigma}v^\rho\theta^\sigma = 0 \qquad [14]$$

In a Riemannian space, the connections $\omega$ and $\tilde{\omega}$ coincide and [14] is a consequence of the Killing equation [13]. The metricity condition implies

$$D\eta_{\mu\nu\rho} = \eta_{\mu\nu\rho\sigma}\Theta^\sigma \qquad [15]$$

## The Einstein–Cartan Theory of Gravitation

### An Identity Resulting from Local Invariance

Let $(M, g, \omega)$ be a metric-affine spacetime. Consider a Lagrangian $L$ which is an invariant 4-form on $M$; it depends on $g, \theta, \omega, \varphi$, and the first derivatives of $\varphi = \varphi^a e_a$. The general variation of the Lagrangian is

$$\delta L = L_a \wedge \delta\varphi^a + \tfrac{1}{2}\tau^{\mu\nu}\delta g_{\mu\nu} + \delta\theta^\mu \wedge t_\mu$$
$$- \tfrac{1}{2}\delta\omega^\mu_\nu \wedge s^\nu{}_\mu + \text{an exact form} \qquad [16]$$

so that $L_a = 0$ is the Euler–Lagrange equation for $\varphi$. If the changes of the functions $g, \theta, \omega$, and $\varphi$ are induced by an infinitesimal change of the frames [4], then $\delta L = 0$ and [16] gives the identity

$$g_{\mu\rho}\tau^{\rho\nu} - \theta^\nu \wedge t_\mu + \tfrac{1}{2}Ds^\nu{}_\mu - \sigma^{b\nu}_{a\mu}L_a \wedge \varphi^b = 0$$

It follows from the identity that the two sets of Euler–Lagrange equations obtained by varying $L$ with respect to the triples $(\varphi, \theta, \omega)$ and $(\varphi, g, \omega)$ are equivalent. In the sequel, the first triple is chosen to derive the field equations.

### Projective Transformations and the Metricity Condition

Still under the assumption that $(M, g, \omega)$ is a metric-affine spacetime, consider the 4-form

$$8\pi K = \tfrac{1}{2}g^{\nu\rho}\eta_{\mu\rho} \wedge \Omega^\mu{}_\nu \qquad [17]$$

which is equal to $\eta R$, where $R = g^{\mu\nu}R_{\mu\nu}$ is the Ricci scalar; the Ricci tensor $R_{\mu\nu} = R^\rho_{\mu\rho\nu}$ is, in general, asymmetric. The form [17] is invariant with

respect to projective transformations of the connection,

$$\omega^{\mu}_{\nu} \mapsto \omega^{\mu}_{\nu} + \delta^{\mu}_{\nu}\lambda \qquad [18]$$

where $\lambda$ is an arbitrary 1-form. Projectively related connections have the same (unparametrized) geodesics. If the total Lagrangian for gravitation interacting with the matter field $\varphi$ is $K + L$, then the field equations, obtained by varying it with respect to $\varphi, \theta$, and $\omega$ are: $L_a = 0$,

$$\tfrac{1}{2} g^{\rho\sigma}\eta_{\mu\nu\rho} \wedge \Omega^{\nu}{}_{\sigma} = -8\pi t_{\mu} \qquad [19]$$

and

$$D(g^{\mu\rho}\eta_{\rho\nu}) = 8\pi s^{\mu}{}_{\nu} \qquad [20]$$

respectively. Put $s_{\mu\nu} = g_{\mu\rho}s^{\rho}{}_{\nu}$. If

$$s_{\mu\nu} + s_{\nu\mu} = 0 \qquad [21]$$

then $s^{\nu}{}_{\nu} = 0$ and $L$ is also invariant with respect to [18]. One shows that, if [21] holds, then, among the projectively related connections satisfying [20], there is precisely one that is metric. To implement properly the metricity condition in the variational principle, one can use the Palatini approach with constraints (Kopczyński 1975). Alternatively, following Hehl, one can use [9] and [12] to eliminate $\omega$ and obtain a Lagrangian depending on $\varphi, \theta$, and the tensor of torsion.

## The Sciama–Kibble Field Equations

From now on the metricity condition [11] is assumed, so that [21] holds and the Cartan field equation [20] is

$$\eta_{\mu\nu\rho} \wedge \Theta^{\rho} = 8\pi s_{\mu\nu} \qquad [22]$$

Introducing the asymmetric energy–momentum tensor $t_{\mu\nu}$ and the spin density tensor $s_{\mu\nu\rho} = g_{\rho\sigma}s^{\sigma}{}_{\mu\nu}$ similarly as in [5], one can write the Einstein–Cartan equations [19] and [22] in the form given by Sciama and Kibble,

$$R_{\mu\nu} - \tfrac{1}{2} g_{\mu\nu}R = 8\pi t_{\mu\nu} \qquad [23]$$

$$Q^{\rho}{}_{\mu\nu} + \delta^{\rho}_{\mu}Q^{\sigma}{}_{\nu\sigma} - \delta^{\rho}_{\nu}Q^{\sigma}{}_{\mu\sigma} = 8\pi s^{\rho}{}_{\mu\nu} \qquad [24]$$

Equation [24] can be solved to give

$$Q^{\rho}{}_{\mu\nu} = 8\pi(s^{\rho}{}_{\mu\nu} + \tfrac{1}{2}\delta^{\rho}_{\mu}s^{\sigma}{}_{\nu\sigma} + \tfrac{1}{2}\delta^{\rho}_{\nu}s^{\sigma}{}_{\sigma\mu}) \qquad [25]$$

Therefore, torsion vanishes in the absence of spin and then [23] is the classical Einstein field equation. In particular, there is no difference between the Einstein and Einstein–Cartan theories in empty space. Since practically all tests of relativistic gravity are based on consideration of Einstein's equations in empty space, there is no difference, in this respect, between the Einstein and the Einstein–Cartan theories: the latter is as viable as the former.

In any case, the consideration of torsion amounts to a slight change of the energy–momentum tensor that can be also obtained by the introduction of a new term in the Lagrangian. This observation was made in 1950 by Weyl in the context of the Dirac equation.

In Einstein's theory, one can also satisfactorily describe spinning matter without introducing torsion (Bailey and Israel 1975).

## Consequences of the Bianchi Identities: Conservation Laws

Computing the covariant exterior derivatives of both sides of the Einstein–Cartan equations, using [15] and the Bianchi identities, one obtains

$$8\pi Dt_{\mu} = \tfrac{1}{2}\eta_{\mu\nu\rho\sigma}\Theta^{\nu} \wedge \Omega^{\rho\sigma} \qquad [26]$$

and

$$8\pi Ds_{\mu\nu} = \eta_{\nu\sigma} \wedge \Omega^{\sigma}{}_{\mu} - \eta_{\mu\sigma} \wedge \Omega^{\sigma}{}_{\nu} \qquad [27]$$

Cartan required the right-hand side of [26] to vanish. If, instead, one uses the field equations [19] and [22] to evaluate the right-hand sides of [26] and [27], one obtains

$$Dt_{\mu} = Q^{\rho}{}_{\mu\nu}\theta^{\nu} \wedge t_{\rho} - \tfrac{1}{2}R^{\rho}{}_{\sigma\mu\nu}\theta^{\nu} \wedge s^{\sigma}{}_{\rho} \qquad [28]$$

and

$$Ds_{\mu\nu} = \theta_{\nu} \wedge t_{\mu} - \theta_{\mu} \wedge t_{\nu} \qquad [29]$$

Let $v$ be a vector field generating a group of symmetries of the Riemann–Cartan space $(M, g, \omega)$ so that eqns [13] and [14] hold. Equations [28] and [29] then imply that the 3-form

$$j = v^{\mu}t_{\mu} + \tfrac{1}{2}\tilde{\nabla}^{\nu}v^{\mu}s_{\mu\nu}$$

is closed, $dj = 0$. In particular, in the limit of SRT, in Cartesian coordinates $x^{\mu}$, to a constant vector field $v$ there corresponds the projection, onto $v$, of the energy–momentum density. If $A^{\mu\nu}$ is a constant bivector, then $v^{\mu} = A^{\mu}{}_{\nu}x^{\nu}$ gives $j = j^{\mu\nu}A_{\mu\nu}$, where $j^{\mu\nu}$ is as in [6].

## Spinning Fluid and the Generalized Mathisson–Papapetrou Equation of Motion

As in classical general relativity, the right-hand sides of the Einstein–Cartan equations need not necessarily be derived from a variational principle; they may be determined by phenomenological

considerations. For example, following Weyssenhoff, consider a spinning fluid characterized by

$$t^{\mu\nu} = P^{\mu}u^{\nu} \quad \text{and} \quad s^{\mu\nu\rho} = S^{\mu\nu}u^{\rho}$$

where $S^{\mu\nu} + S^{\nu\mu} = 0$ and $u$ is the unit, timelike velocity field. Let $U = u^{\mu}\eta_{\mu}$ so that

$$t_{\mu} = P_{\mu}U \quad \text{and} \quad s_{\mu\nu} = S_{\mu\nu}U$$

Define the particle derivative of a tensor field $\varphi^{a}$ in the direction of $u$ by

$$\dot{\varphi}^{a}\eta = D(\varphi^{a}U)$$

For a scalar field $\varphi$, the equation $\dot{\varphi} = 0$ is equivalent to the conservation law $d(\varphi U) = 0$. Define $\rho = g_{\mu\nu}P^{\mu}u^{\nu}$, then [29] gives an equation of motion of spin

$$\dot{S}_{\mu\nu} = u_{\nu}P_{\mu} - u_{\mu}P_{\nu}$$

so that

$$P_{\mu} = \rho u_{\mu} + \dot{S}_{\mu\nu}u^{\nu}$$

From [28] one obtains the equation of translatory motion,

$$\dot{P}_{\mu} = (Q^{\rho}{}_{\mu\nu}P_{\rho} - \tfrac{1}{2}R^{\rho\sigma}{}_{\mu\nu}S_{\rho\sigma})u^{\nu}$$

which is a generalization to the ECT of the Mathisson–Papapetrou equation for point particles with an intrinsic angular momentum.

### From ECT to GRT: The Effective Energy–Momentum Tensor

Inside spinning matter, one can use [12] and [25] to eliminate torsion and replace the Sciama–Kibble system by a single Einstein equation with an effective energy–momentum tensor on the right-hand side. Using the split [10], one can write [23] as

$$\overset{\circ}{R}_{\mu\nu} - \tfrac{1}{2}g_{\mu\nu}\overset{\circ}{R} = 8\pi T^{\text{eff}}_{\mu\nu} \qquad [30]$$

Here $\overset{\circ}{R}_{\mu\nu}$ and $\overset{\circ}{R}$ are, respectively, the Ricci tensor and scalar formed from $g$. The term in [10] that is quadratic in $\kappa$ contributes to $T^{\text{eff}}$ an expression quadratic in the components of the tensor $s_{\mu\nu\rho}$ so that, neglecting indices, one can symbolically write

$$T^{\text{eff}} = T + s^{2} \qquad [31]$$

The symmetric tensor $T$ is the sum of $t$ and a term coming from $\overset{\circ}{D}\kappa^{\mu}_{\nu}$ in [10]:

$$T^{\mu\nu} = t^{\mu\nu} + \tfrac{1}{2}\overset{\circ}{\nabla}_{\rho}(s^{\nu\mu\rho} + s^{\nu\rho\mu} + s^{\mu\rho\nu}) \qquad [32]$$

It is remarkable that the Belinfante–Rosenfeld symmetrization of the canonical energy–momentum tensor appears as a natural consequence of ECT. From the physical point of view, the second term on the right-hand side of [31], can be thought of as providing a spin–spin contact interaction, reminiscent of the one appearing in the Fermi theory of weak interactions.

It is clear from eqns [30]–[32] that whenever terms quadratic in spin can be neglected – in particular, in the linear approximation – ECT is equivalent to GRT. To obtain essentially new effects, the density of spin squared should be comparable to the density of mass. For example, to achieve this, a nucleon of mass $m$ should be squeezed so that its radius $r_{\text{Cart}}$ be such that

$$\left(\frac{l^{2}}{r^{3}_{\text{Cart}}}\right)^{2} \approx \frac{m}{r^{3}_{\text{Cart}}}$$

Introducing the Compton wavelength $r_{\text{Compt}} = l^{2}/m \approx 10^{-13}$ cm, one can write

$$r_{\text{Cart}} \approx (l^{2}r_{\text{Compt}})^{1/3}$$

The "Cartan radius" of the nucleon, $r_{\text{Cart}} \approx 10^{-26}$ cm, so small when compared to its physical radius under normal conditions, is much larger than the Planck length. Curiously enough, the energy $l^{2}/r_{\text{Cart}}$ is of the order of the energy at which, according to some estimates, the grand unification of interactions is presumed to occur.

### Cosmology with Spin and Torsion

In the presence of spinning matter, $T^{\text{eff}}$ need not satisfy the positive-energy conditions, even if $T$ does. Therefore, the classical singularity theorems of Penrose and Hawking can be overcome here. In ECT, there are simple cosmological solutions without singularities. The simplest such solution, found in 1973 by Kopczyński, is as follows. Consider a universe filled with a spinning dust such that $P^{\mu} = \rho u^{\mu}, u^{\mu} = \delta^{\mu}_{0}, S_{23} = \sigma$, and $S_{\mu\nu} = 0$ for $\mu + \nu \neq 5$, and both $\rho$ and $\sigma$ are functions of $t = x^{0}$ alone. These assumptions are compatible with the Robertson–Walker line element $dt^{2} - \mathcal{R}(t)^{2}(dx^{2} + dy^{2} + dz^{2})$, where $(x, y, z) = (x^{1}, x^{2}, x^{3})$ and torsion is determined from [25]. The Einstein equation [23] reduces to the modified Friedmann equation,

$$\tfrac{1}{2}\dot{\mathcal{R}}^{2} - M\mathcal{R}^{-1} + \tfrac{3}{2}S^{2}\mathcal{R}^{-4} = 0 \qquad [33]$$

supplemented by the conservation laws of mass and spin,

$$M = \tfrac{4}{3}\pi\rho\mathcal{R}^{3} = \text{const.}, \qquad S = \tfrac{4}{3}\pi\sigma\mathcal{R}^{3} = \text{const.}$$

The last term on the left-hand side of [33] plays the role of a repulsive potential, effective at small values of $\mathcal{R}$; it prevents the solution from vanishing. It should be

noted, however, that even a very small amount of shear in $u$ results in a term counteracting the repulsive potential due to spin. Neglecting shear and making the (unrealistic) assumption that matter in the universe at $t = 0$ consists of $\sim 10^{80}$ nucleons of mass $m$ with aligned spins, one obtains the estimate $\mathcal{R}(0) \approx 1\,\mathrm{cm}$ and a density of the order of $m^2/l^4$, very large, but much smaller than the Planck density $1/l^2$.

Tafel (1975) found large classes of cosmological solutions with a spinning fluid, admitting a group of symmetries transitive on the hypersurfaces of constant time. The models corresponding to symmetries of Bianchi types I, $\mathrm{VII}_0$, and V are nonsingular, provided that the influence of spin exceeds that of shear.

## Summary

ECT is a viable theory of gravitation that differs very slightly from the Einstein theory; the effects of spin and torsion can be significant only at densities of matter that are very high, but nevertheless much smaller than the Planck density at which quantum gravitational effects are believed to dominate. It is possible that ECT will prove to be a better classical limit of a future quantum theory of gravitation than the theory without torsion.

# Einstein's Equations with Matter

**Y Choquet-Bruhat**, Université P.-M. Curie, Paris VI, Paris, France

## Introduction

Newton's theory of gravity with absolute time and Euclidean 3-space connects the gravitational potential $U$ with its source, the density of matter $r$, by the Poisson equation

$$\Delta U = -4\pi\kappa r$$

where $\Delta$ is the Laplace operator and $\kappa$ is the gravitational constant. The trajectories of massive test particles are the flow lines of the gradient of $U$.

Newton's theory has proven to be very accurate in the laboratory as well as in the solar system (except for a small discrepancy with the observed value of Mercury perihelion). Newton's theory together with special relativity, the equivalence principle, and ideas of Mach, have been an inspiration for Einstein to uncover the equations which must be satisfied by the geometry of spacetime. They link the curvature of the spacetime metric with a phenomenological symmetric 2-tensor $T$, which must represent the energy, momentum, and stresses of all the sources, by the equality:

$$S(g) \equiv \mathrm{Ricci}(g) - \tfrac{1}{2}\mathrm{gR(g)} = 8\pi\kappa T$$

where Ricci($g$) is the Ricci tensor of the spacetime metric $g$ and $R(g)$ its scalar curvature. The symmetric 2-tensor $S(g)$ is called the Einstein tensor. The

Bianchi identities, due to the invariance of curvature by isometries of $g$, imply that the divergence of the Einstein tensor is identically zero: the Einstein equations imply therefore the vanishing of the divergence of the source tensor $T$. The equations so obtained generalize in a relativistic context the conservation laws of Newtonian mechanics. In local spacetime coordinates $x^\alpha$, the Einstein equations and conservation laws read

$$S_{\alpha\beta} \equiv R_{\alpha\beta} - \tfrac{1}{2}g_{\alpha\beta}R = 8\pi\kappa T_{\alpha\beta}, \qquad \nabla_\alpha T^{\alpha\beta} \equiv 0$$

where $\nabla$ denotes the covariant derivative in the metric $g$.

The gravitational constant $\kappa$ is inspired by the Newtonian equation relating the potential $U$ with the density of matter. This equation can be obtained as an approximation of Einstein's equations with matter in the case of low velocities of matter and weak gravitational fields. The Newton's equation of motion of test particles is also an approximation of Einstein's geodesic motion of such particles which can be deduced from Einstein's equations themselves. However, if one wants to remain in the framework of the general relativity theory, it is these Einstein's equations which define the mass of a body, there is no comparison possible with some fixed given mass. As length had the dimension of time already in special relativity, now mass is found to have dimension of length. We write the equations in geometrical units, where $8\pi\kappa = 1$, keeping in mind the corresponding change to usual laboratory units only in specific applications. In geometrical units the mass of the Earth is of the order of the centimeter. The most precise measures of $\kappa$ are still made using Newton type experiments, giving $\kappa = 6.67259 \times 10^{-11}\,\mathrm{m^3\,kg^{-1}\,s^{-2}}$.

In the case of electromagnetic (or classical Yang–Mills) field sources, the stress energy tensor in special relativity is the well-known Maxwell tensor $\tau$ (or its generalizations), whose divergence vanishes when the field satisfies the Maxwell (or Yang–Mills) equations in vacuum. The expression of this tensor in a curved spacetime can be trivially deduced from its Minkowskian form. Its expression can also be deduced from the Lagrangian, and the vanishing of its divergence results from the invariance of this Lagrangian under isometries of the metric. It is the natural source of Einstein equations coupled with these fields. In the case of matter, the construction of a stress energy tensor is already delicate even in special relativity.

The simplest models of sources with well-understood properties – kinetic matter and perfect fluids – are reviewed in this article. Physical situations difficult to model, even in special relativity, dissipative fluids and elasticity, are mentioned. The extension to electrically, or classical Yang–Mills–Higgs, charged matter, offers no conceptual difficulty, but interesting new situations.

## Fluid Sources

A fluid source in a domain of a spacetime $(V, g)$ is such that there exists, in this domain, a unit timelike vector field $u$, satisfying $g(u,u) \equiv g_{\alpha\beta}u^\alpha u^\beta = -1$, whose trajectories are the flow lines of matter. A moving Lorentzian orthonormal frame is called a proper frame if its timelike vector is $u$. Since the Einstein gravitational potentials reduce at a point in a Lorentzian orthonormal frame to Minkowskian values, one admits that the spacetime symmetric 2-tensor $T$, which embodies the density of stress, energy, and momentum of a given type of matter, in a proper frame takes the expression it would have in special relativity and inertial coordinates. The expression of $T$ in a general frame results from its tensorial character and the equivalence principle. The problem is to find a good expression of $T$ in special relativity.

### Case of Dust (Incoherent Matter)

In a proper frame there is neither momentum nor stresses. Therefore, the stress energy tensor reads in a general frame, with $r$ a scalar function representing the matter density:

$$T = ru \otimes u, \quad \text{i.e., } T_{\alpha\beta} = ru_\alpha u_\beta$$

Using the property $g(u,u) = -1$, the conservation laws imply the vanishing of the divergence of the matter flow $ru$, that is, the continuity equation (conservation of matter)

$$\nabla_\alpha(ru^\alpha) = 0$$

and the motion of the particles along geodesics of the metric:

$$u^\alpha \nabla_\alpha u^\beta = 0$$

Similar equations are obtained for a null dust model where $g(u,u) = 0$.

### Perfect Fluid

**Euler equations** In Newtonian mechanics, a continuous matter flow is characterized by its mass density and flow velocity. The equations are a continuity equation (conservation of matter) and equations of motion resulting from Newton's law, which link the acceleration vector and the space

divergence of the stress symmetric 2-tensor whose contraction with the normal to a small 2-surface gives the force applied to it. A fluid is called perfect if the pressure it applies to a small surface element with normal $n$ is independent of $n$. Its stress tensor $t$, symmetric 2-tensor on Euclidean space, is then invariant by rotations. By generalization, a relativistic fluid is called perfect if its stress energy tensor has the following form:

$$T_{\alpha\beta} = \mu u_\alpha u_\beta + p(g_{\alpha\beta} + u_\alpha u_\beta)$$

Then in a proper frame, where $g$ takes the Minkowskian values and the only nonvanishing component of $u$ is along the time axis and equal to 1, the projection of $T$ on space is the Newtonian stress tensor with pressure $p$, while $\mu$, the projection of $T$ on the time axis, is the fluid energy density. There is no momentum density in the proper frame. The conservation laws, also called Euler equations, are shown to split, as in the case of dust, into a continuity equation

$$\nabla_\alpha[(\mu + p)u^\alpha] - u^\alpha \partial_\alpha p = 0$$

and equations of motion

$$(\mu + p)u^\alpha \nabla_\alpha u^\beta + (g^{\alpha\beta} + u^\alpha u^\beta)\partial_\alpha p = 0$$

In relativity, where mass and energy are equivalent, the continuity equation is no more a conservation law.

**Equations of state** As in Newtonian mechanics, the Euler equations must be completed by a relation, called equation of state, depending on the physical properties of the fluid. In general in addition to mechanics, thermodynamic properties must be considered. In relativity, they are borrowed from classical thermodynamics formulated in a spacetime context.

In the simplest cases one introduces a conserved rest mass density $r$ (or particle number density for particles with rest mass zero), satisfying the equation

$$\nabla_\alpha P^\alpha = 0 \quad \text{with} \quad P^\alpha \equiv r u^\alpha$$

This $r$ differs from the density of energy $\mu$. One sets $\mu = r(1 + \varepsilon)$ and calls $\varepsilon$ the internal specific energy. The first law of (reversible) thermodynamics is extended to relativistic perfect fluids by the identity

$$\Theta \, \mathrm{d}S \equiv \mathrm{d}\varepsilon + p\mathrm{d}(r^{-1})$$

which defines both the absolute temperature $\Theta$ and the differential of the specific entropy $S$. Modulo the continuity equation and the thermodynamic identity, the matter conservation is equivalent to the conservation of entropy along the flow lines:

$$\nabla_\alpha(rSu^\alpha) = 0 \quad \text{hence} \quad u^\alpha \partial_\alpha S = 0$$

The scalars $p$, $\mu$,$S$, $r$ are not independent. Simple situations can be modeled by an "equation of state" linking these quantities. In astrophysics, one is inspired by what is known from classical fluids, with additional relativistic considerations. General relativity plays a role in the case of strong gravitational field.

Very cold matter and nuclear matter are barotropic fluids; they obey an equation of state of the form $p = p(\mu)$.

When the energy $\mu$ is largely dominated by the radiation energy, the fluid is called ultrarelativistic. The Stefan–Boltzmann laws give $\mu = KT^4$ and $p = (1/3)KT^4$, hence $p = (1/3)\mu$; the stress energy tensor is traceless.

In white dwarves, the fluid is considered as polytropic: it obeys an equation of state of the form $p = f(S)r^\gamma$. If only the internal energy $\varepsilon$ and pressure $p$ are dominated by radiation, then $\varepsilon = Kr^{-1}T^4$ and $p = (1/3)KT^4$, hence $p = (1/3)r\varepsilon$. The use of the thermodynamic identity leads to $\gamma = 4/3$, $p = (K/3)(3S/4K)^{4/3}r^{4/3}$, with $\mu = 3p + r$.

For most other stars, the physical situation is too complex to be modeled by a simple equation; only tables of numerical values may be available.

In cosmology, there is little physical information about the fluid which is to represent the energy content of the universe. It is assumed that in the early universe of the big-bang models, at very high temperature, the fluid was ultrarelativistic. At later times, it is generally assumed, for simplicity, that there is an equation of state linear and independent of entropy, $p = (\gamma - 1)\mu$. In order that the speed of sound waves be not greater than the speed of light, one assumes that $1 \leq \gamma \leq 2$; $\gamma = 1$ corresponds to dust, $\gamma = 2$ to a stiff (see below) fluid.

Recent confrontations of theory and observations seem to imply the existence of a new, not directly seen, type of matter, called "dark matter."

**Wave fronts and propagation speeds** The wave fronts of a differential system are the submanifolds of spacetime whose normals $n$ annul the characteristic determinant. Discontinuities propagate along wave fronts. For a hyperbolic system, the wave fronts determine the domain of dependence of a solution. For a perfect fluid, they are found to be

1. the matter wave fronts, generated by the flow lines, such that $u^\alpha n_\alpha = 0$ and

2. the sound wave fronts, whose normals satisfy the equation

$$D \equiv (p'_\mu - 1)(u^\alpha n_\alpha)^2 + p'_\mu n^\alpha n_\alpha = 0$$

in a proper frame at a point of spacetime $u^\alpha = \delta_0^\alpha$, $g_{\alpha\beta} = \eta_{\alpha\beta}$; this equation states that the slope of the spacetime normal to the wave front can be written as

$$\left(\frac{\Sigma(n_i)^2}{n_0^2}\right)^{1/2} = \frac{1}{\sqrt{p'_\mu}}$$

The sound propagation speed is the inverse of this slope, that is, $v = \sqrt{p'_\mu}$. It is less than the speed of light, as expected from a relativistic theory, if $p'_\mu \leq 1$. The limiting case where these speeds are equal is called incompressible or stiff fluid.

**Hyperbolicity, existence, and uniqueness theorem** The characteristics of the perfect fluid equations are real, but the apparent multiplicity of the matter wave fronts poses a problem for the hyperbolicity of the relativistic Euler equations, even in a given background metric. However, Choquet-Bruhat has proven that this system is a hyperbolic Leray system as well as its coupling with the Einstein equations, for instance, in wave gauge. The following theorem can then be proved using the general theorem on hyperbolic systems and an extension of the method used for Einstein's equations in vacuum.

**Theorem** *Let $(M,\bar{g},K)$ be an initial data set for the Einstein equations and $(\bar{u},\bar{\mu},\bar{S})$ be Cauchy data in a local Sobolev space $H_s^{\text{loc}}$, $s \geq 3$, on the 3-manifold M for a perfect fluid with a smooth equation of state. Suppose $\bar{\mu} > 0$ and $p'_{\bar{\mu}} \leq 1$. There exists a globally hyperbolic spacetime of maximal extension solution of the Einstein equations with source such as perfect fluid taking these Cauchy data. Such a spacetime and fluid flow are smooth for smooth initial data. They are unique, up to spacetime isometries.*

The Euler equations have also been written as a first-order symmetric hyperbolic system by Boillat, Ruggeri, and Strumia using general methods relying on the existence of a convex functional, and directly by Rendall, who pointed out the difficulty of modeling the general motion of isolated fluid bodies, because of the assumption $\bar{\mu} > 0$. He constructed some solutions without this assumption where the boundaries are freely falling. The general problem of determining the evolution of boundaries appears everywhere in general relativity, and in classical mechanics.

**Global problems** The spacetimes obtained above are, in general, incomplete: even in Minkowski spacetime, the Euler equations do not in general have solutions that are global in time. Shocks appear in relativistic perfect fluids as in classical ones. Global existence results have been obtained for four-dimensional ultrarelativistic fluids (limited data), and in the case of 1-space dimension. A detailed study of the global behavior of spherically symmetric solutions of the Einstein–Euler equations with equation of state admitting a phase transition from zero pressure to stiff fluid has been done by Christodoulou.

### Dissipative Fluids

A general fluid stress energy tensor is with $u$, a unit vector whose trajectories are the flow lines:

$$T^{\alpha\beta} = \mu u^\alpha u^\beta + q^\alpha u^\beta + q^\beta u^\alpha + Q^{\alpha\beta}$$
$$\text{with } q^\alpha u_\alpha = 0, \quad Q^{\alpha\beta} u_\alpha = 0$$

$\mu = T^{\alpha\beta} u_\alpha u_\beta$ is the energy density, which must satisfy $\mu \geq 0$, $Q$ is a space tensor representing the stresses, orthogonal to $u$ and $q$ is a space vector considered as a heat flow. The fundamental equations are still $\nabla_\alpha T^{\alpha\beta} = 0$, but they must be implemented by constitutive equations for $q$ and $Q$ which do not have simple satisfactory answer in a relativistic context. The transfer of results from classical mechanics on viscous fluids or on heat transfer leads to propagation speeds greater than the speed of light. It should be remarked that these classical equations are obtained as governing asymptotic states; thus, the parabolic character of their relativistic version does not contradict relativistic causality. However, it would be interesting to obtain, for dissipative relativistic fluids, hyperbolic dissipative equations. Various systems have been proposed, in particular, by Marle by using an approximation near equilibrium of a solution of the relativistic Boltzmann equation. A promising system, also inspired from kinetic theory, is the "extended thermodynamics" of Müller and Ruggeri which takes as 14 fundamental unknowns, the vector $P = ru$ and the tensor $T$, satisfying the conservation laws. These equations are supplemented by equations linking a totally symmetric 3-tensor $A$ with a symmetric 2-tensor $I$ by equations of the form

$$\nabla_\alpha A^{\alpha\beta\gamma} = I^{\beta\gamma} \qquad [1]$$

$A$ and $I$ are functions of $P$ and $T$ depending on the model and called constitutive equations. The system is shown to be symmetric hyperbolic under the existence of a convex entropy function, property which holds under appropriate physical assumptions.

Reasonable equations have been proposed and studied for several constituent fluids and superfluids.

### Charged Fluids

The stress energy tensor of a charged fluid with electric (or Yang–Mills) charge is generally the sum of the stress energy tensor of the fluid and of the Maxwell (or Yang–Mills) field. This tensor is conserved modulo the Maxwell (or Yang–Mills) equations with source the electric current, and the Euler equations completed by the Lorentz force. The corresponding Einstein–Maxwell perfect fluid system is well posed in the case of zero or infinite conductivity (magnetohydrodynamics). A subtlety appears in the case of finite conductivity: the system is still well posed, but for a restricted (Gevrey) class of $C^\infty$ fields.

## Kinetic Models

### Distribution Function and Moments

A general relativistic kinetic theory can be formulated without appeal to classical mechanics or special relativity. The matter is composed of particles whose size is negligible in the considered scale: rarefied gases in the laboratory, galaxies or even clusters of galaxies at the cosmological scale. The number of particles is so great and their motion so chaotic that the state of the matter can be described by a "one-particle distribution function," a positive scalar function on the tangent bundle to the spacetime $(x,p) \mapsto f(x,p)$, which gives the mean number of particles with momentum $p$ present at the point $x$ of spacetime.

The first moment of $f$ is a causal vector field $P$ defined by the integral over the space $\mathcal{P}_x$ of momenta at $x$, with $\omega_p$ a volume element in that space:

$$P(x) =: \int_{\mathcal{P}_x} pf(x,p)\omega_p$$

Out of the first moment, one extracts a scalar $r \geq 0$, interpreted as the square of a proper mass density given by $r^2 =: -g(P, P)$ and, if $r > 0$, a unit vector $u = r^{-1}P$ interpreted as the macroscopic flow velocity.

The second moment of the distribution function $f$ is the symmetric 2-tensor on spacetime given by

$$T(x) =: \int_{\mathcal{P}_x} f(x,p)p \otimes p\omega_p$$

It is interpreted as the stress energy tensor of the distribution $f$. Higher moments are defined similarly.

### Liouville–Vlasov Equation

When the gas is so rarefied that the particle trajectories do not cross, then in the absence of nongravitational forces, these trajectories are geodesics of $g$, orbits in $TV$ of the vector field $X = (p^\alpha,\ Q^\alpha \equiv -\Gamma^\alpha_{\lambda\mu} p^\lambda p^m)$ with $\Gamma^\alpha_{\lambda\mu}$, the Christoffel symbols of $g$.

In a collisionless model, the physical law of conservation of particles imposes the conservation of $f$ along the trajectories of $X$, that is, the Liouville–Vlasov equation

$$\mathcal{L}_X f \equiv p^\alpha \frac{\partial f}{\partial x^\alpha} + Q^\alpha \frac{\partial f}{\partial p^\alpha} = 0$$

**Conservation laws** If $f$ satisfies the Vlasov equation, then all moments satisfy a conservation law, in particular,

$$\nabla_\alpha P^\alpha = 0 \text{ and } \nabla_\alpha T^{\alpha\beta} = 0$$

equations which make the Einstein–Vlasov system consistent.

The theory extends without problem to particles having the same rest mass $m$, because the scalar $g(p, p) = -m^2$ is constant on a geodesic.

**Cauchy problem** The Einstein–Vlasov system is an integro-differential system for $g$ and $f$ on a manifold $V = M \times R$. The Cauchy data for the spacetime metric $g$ on $M_0 = M \times \{0\}$ is, as usual, a pair $(\bar{g}, K)$, implemented with gauge initial data which complete the definition of Cauchy data for a well-posed hyperbolic system in the chosen gauge. The Cauchy data for $f$ are a function $\bar{f}$ on the bundle $P_{M_0}$. It has been proved long ago that there exists a solution, geometrically unique, in a neighborhood of $M_0$ if the data are in Sobolev spaces, weighted by a power of $p^0$ in the case of $\bar{f}$.

Since the Vlasov matter model, solution of a linear equation for given $g$, has no singularity by itself, the Einstein–Vlasov system is a good candidate for solutions that are global in time. This global existence has been proved by Rein and Rendall in the case of small data, asymptotically flat with spherical symmetry or plane symmetry, or with hyperbolic symmetry and compact space. Global existence without these symmetries is an open problem.

### Boltzmann Equation

When the particles undergo collisions, their trajectories in phase space are no more connected integral curves of the vector field $X$, that is, their moment

undergoes a jump with the crossing of another trajectory. In the Boltzmann model, the derivative $\mathcal{L}_X f$ is equal to the so-called collision operator, $\mathcal{I}f$:

$$(\mathcal{L}_X f)(x,p) = (\mathcal{I}f)(x,p)$$

where $\mathcal{I}f$ is an integral operator linked with the probability that two particles of momentum, respectively, $p'$ and $q'$, collide at $x$ and give, after the shock, two particles of momentum $p$ and $q$. For "elastic" shocks, the total momentum is conserved, that is, $p'$ and $q'$ lie in the submanifold $\Sigma_{pq} =: \{p' + q' = p + q\}$, with volume element $\xi'$ and

$$(\mathcal{I}f)(x,p) \equiv \int_{\mathcal{P}_x}\int_{\Sigma_{pq}} [f(x,p')f(x,q') - f(x,p)f(x,q)]A(x,p,q,p',q')\xi' \wedge \omega_q$$

The function $A(x, p, q, p', q')$ is called the shock cross section; it is a phenomenological quantity. No explicit expression is known for it in relativity. A generally admitted property is the reversibility of elastic shocks, $A(x, p, q, p', q') = A(x, p', q', p, q)$. It can be proved that under this hypothesis, the first and second moment of $f$ are conserved as in the collisionless case, making the Einstein–Boltzmann system consistent. Existence of solutions (that are local in time) of the Cauchy problem for this system has long been known. No global existence for the coupled system is known yet.

One defines, in a relativistic context, an entropy flux vector $H$ which is proved to satisfy an $H$-theorem, that is, $\nabla_\alpha H^\alpha \geq 0$. In an expanding universe, for instance, Robertson Walker, where $H$ depends only on time and an entropy density is defined by $H^0$, one finds that a decrease in entropy is linked with the expansion of the universe, thus permitting its ever-increasing organization from an initial anisotropy of $f$ in momentum space.

## Other Matter Sources

### Elastic Media

There are no solids in general relativity; in special relativity rigid motions are already very restricted. A theory of elastic deformations can only be defined relatively to some *a priori* given state of matter whose perturbations will satisfy laws analogous to the classical laws. Various such theories have been proposed through geometric considerations, extending methods of classical elasticity; they have been used to predict the possible signals from bar detectors of gravitational waves, or the motions in the crust of neutron stars. A general theory constructed by Lagrangian formalism has recently been developed.

### Spinor Sources

A symmetric stress energy tensor can be associated to classical spinors of spin 1/2, leading to a well-posed Einstein–Dirac system. The theories of supergravity couple the Einstein–Cartan equations with anticommuting spin 3/2 sources.

# Electric–Magnetic Duality

**Tsou Sheung Tsun**, University of Oxford, Oxford, UK

## Introduction

Classical electromagnetism is described by Maxwell's equations, which, in 3-vector notation and corresponding respectively to the laws of Coulomb, Ampère, Gauss, and Faraday, are given by eqns [1a]–[1d]:

$$\operatorname{div} \boldsymbol{E} = \rho \tag{1a}$$

$$\operatorname{curl} \boldsymbol{B} - \frac{\partial \boldsymbol{E}}{\partial t} = \boldsymbol{J} \tag{1b}$$

$$\operatorname{div} \boldsymbol{B} = 0 \tag{1c}$$

$$\operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0 \tag{1d}$$

Equivalently, in covariant 4-vector notation, these correspond to eqns [2a] and [2b]:

$$\partial_\nu F^{\mu\nu} = -j^\mu \tag{2a}$$

$$\partial^*{}_\nu F^{\mu\nu} = 0 \tag{2b}$$

In eqns [1], $\boldsymbol{E}$ and $\boldsymbol{B}$ are the electric and magnetic fields, respectively, $\rho$ is the electric charge density, and $\boldsymbol{J}$ is the electric current. In eqns [2], $F_{\mu\nu}$ is the field tensor, ${}^*F_{\mu\nu}$ the dual field tensor, and $j^\mu$ is the 4-current, related to the previous vector quantities by the following relations:

$$F_{\mu\nu} = \begin{pmatrix} 0 & E_1 & E_2 & E_3 \\ -E_1 & 0 & -B_3 & B_2 \\ -E_2 & B_3 & 0 & -B_1 \\ -E_3 & -B_2 & B_1 & 0 \end{pmatrix}$$

$${}^*F_{\mu\nu} = \begin{pmatrix} 0 & B_1 & B_2 & B_3 \\ -B_1 & 0 & E_3 & -E_2 \\ -B_2 & -E_3 & 0 & E_1 \\ -B_3 & E_2 & -E_1 & 0 \end{pmatrix}$$

$$j^\mu = (\rho, \boldsymbol{J})$$

Throughout this article, we shall denote the three spatial indices by lower-case Latin letters such as $i$, $j$, while Greek indices such as $\mu$, $\nu$ denote spacetime indices running through $0, 1, 2, 3$. The Einstein summation convention is used, whereby repeated indices are summed. Spacetime indices are raised and lowered by the (flat) Minkowski metric $g_{\mu\nu} = \operatorname{diag}(1, -1, -1, -1)$. We also use units conventional in particle physics, in which the reduced Planck constant $\hbar$ and the speed of light $c$ are both set to 1.

In terms of the totally skew symmetric symbol $\varepsilon_{\mu\nu\rho\sigma}$ (with $\varepsilon_{0123} = 1$), the two field tensors are related by eqn [3]:

$${}^*F_{\mu\nu} = -\tfrac{1}{2}\varepsilon_{\mu\nu\rho\sigma}F^{\rho\sigma} \tag{3}$$

We say that ${}^*F_{\mu\nu}$ is the dual of $F_{\mu\nu}$, and eqn [3] is indeed a duality relation because eqn [4] holds, which means that up to a sign, $F_{\mu\nu}$ and ${}^*F_{\mu\nu}$ are duals of each other:

$${}^*({}^*F) = -F \tag{4}$$

This duality is in fact the Hodge duality between $p$-forms and $(n-p)$-forms in an $n$-dimensional space. In our particular case, $p = 2$ and $n = 4$, so that both $F$ and its dual are 2-forms. The minus sign in eqn [4] comes about because of the Lorentzian (or pseudo-Riemannian) signature of Minkowski spacetime.

The physical significance of this duality is that such a symmetry interchanges electric and magnetic fields (again up to sign) (eqn [5]), as can be seen from the matrix representation of $F_{\mu\nu}$ and ${}^*F_{\mu\nu}$ above:

$${}^*\!: \boldsymbol{E} \mapsto \boldsymbol{B},\ \boldsymbol{B} \mapsto -\boldsymbol{E} \tag{5}$$

Now in the absence of electric charges and currents, one sees immediately that Maxwell's equations [1] or [2] are dual symmetric. This means that, *in vacuo*, whether we call an electromagnetic field electric or magnetic is a matter of convention. As far as the dynamics is concerned, there is no distinction.

On the other hand, eqns [1] and [2] as presented, that is, in the presence of matter, are manifestly not dual symmetric. The underlying reason for this asymmetry has been much studied both in physics and in mathematics. One of the two questions that this article addresses is precisely this. Following on this, we shall see what happens if we try somehow to restore this dual symmetry even in the presence of matter.

The second question that we wish to discuss is a generalization of this duality. Electromagnetism is a gauge theory, in which the gauge group is the abelian circle group U(1), representing the phase of wave-functions in quantum mechanics. A physically relevant generalization, in which the abelian U(1) is replaced by a nonabelian group (e.g., SU(2), SU(3))

is called Yang–Mills theory (Yang and Mills 1954), which is the theoretical basis of all modern particle physics. We shall show in this article how the concept of electric–magnetic duality can be generalized in the context of Yang–Mills theory.

## Gauge Invariance, Sources, and Monopoles

Electric–magnetic duality, whether in the well-known abelian case or in the still somewhat open nonabelian case, is intimately connected with gauge invariance, sources, and monopoles, and also the dynamics as embodied in the gauge action. These questions in turn find their natural setting in differential geometry, particularly the geometry of fibre bundles.

Although classical electrodynamics can be fully described by the field tensor $F_{\mu\nu}$, one needs to introduce the electromagnetic (or gauge) potential $A_\mu$ if one considers quantum mechanics, as has been beautifully demonstrated by the Bohm–Aharonov experiment. The two quantities are related by eqn [6]:

$$F_{\mu\nu}(x) = \partial_\nu A_\mu(x) - \partial_\mu A_\nu(x) \qquad [6]$$

The fact that the phase of a wave function $\psi(x)$ (e.g., of the electron) is not a measurable quantity (although relative phases of course are) implies that we are free to make the following transformation:

$$\psi(x) \mapsto \mathrm{e}^{\mathrm{i}e\Lambda(x)}\psi(x) \qquad [7]$$

This in turn implies an unobservable transformation [8] on the gauge potential, where $\Lambda(x)$ is a real-valued function on spacetime:

$$A_\mu(x) \mapsto A_\mu(x) + \partial_\mu\Lambda(x) \qquad [8]$$

This invariance is called gauge invariance. Since in this abelian case $F_{\mu\nu}$ is gauge invariant, so are the Maxwell equations, for which we shall take from now on the covariant form [2]. Inasmuch as the Maxwell equations dictate the dynamics of electromagnetism, gauge invariance is an intrinsic ingredient even in the classical theory.

In Yang–Mills theory, the U(1) phase $\mathrm{e}^{\mathrm{i}e\Lambda(x)}$ is replaced by an element $S(x)$ of a nonabelian group $G$, so that eqns [7], [8], and [6] become, respectively, eqns [9], [10], and [11]:

$$\psi(x) \mapsto S(x)\psi(x) \qquad [9]$$

$$A_\mu(x) \mapsto S(x)A_\mu(x)S^{-1}(x) - \left(\frac{i}{g}\right)\partial_\mu S(x)S^{-1}(x) \qquad [10]$$

$$F_{\mu\nu}(x) = \partial_\nu A_\mu(x) - \partial_\mu A_\nu(x) + \mathrm{i}g[A_\mu(x), A_\nu(x)] \qquad [11]$$

Here the electric coupling $e$ is replaced by a general gauge coupling $g$. The quantities $A_\mu$ and $F_{\mu\nu}$ now take values in the Lie algebra of the Lie group $G$ and the bracket is the Lie bracket. The wave function $\psi(x)$ takes values in a vector space on which an appropriate representation of $G$ acts. Notice that now the field tensor $F_{\mu\nu}$ is no longer invariant, but only covariant:

$$F_{\mu\nu}(x) \mapsto S(x)F_{\mu\nu}(x)S^{-1}(x) \qquad [12]$$

Next we consider the charges of gauge theory. For the moment, we wish to distinguish between two types of charges: sources and monopoles. These are defined with respect to the gauge field, which in turn is derivable from the gauge potential.

Source charges are those charges that give rise to a nonvanishing divergence of the field. For example, the electric current $j$ due to the presence of the electric charge $e$ occurs on the right-hand side of the first Maxwell equation, and is given in the quantum case by eqn [13], where $\gamma^\mu$ is a Dirac gamma matrix, identifiable as a basis element of the Clifford algebra over spacetime:

$$j^\mu = e\bar{\psi}\gamma^\mu\psi \qquad [13]$$

In the Yang–Mills case, the first Maxwell equation is replaced by the Yang–Mills equation

$$D_\nu F^{\mu\nu} = -j^\mu, \qquad j^\mu = g\bar{\psi}\gamma^\mu\psi \qquad [14]$$

We define the covariant derivative $D$ as in

$$D_\mu F^{\mu\nu} = \partial_\mu F^{\mu\nu} - \mathrm{i}g[A_\mu, F^{\mu\nu}] \qquad [15]$$

Monopole charges, on the other hand, are topological obstructions specified geometrically by nontrivial $G$-bundles over every 2-sphere $S^2$ surrounding the charge. They are classified by elements of $\pi_1(G)$, the fundamental group of $G$. They are typified by the (abelian) magnetic monopole as first discussed by Dirac in 1931.

Let us go into a little more detail about the Dirac magnetic monopole. If the field tensor $F_{\mu\nu}$ does come from a gauge potential $A_\mu$ as in eqn [6], then simple algebra will tell us that this implies $\partial_\nu {}^*F^{\mu\nu} = 0$ as in eqn [2]. Hence, we conclude the following:

$$\exists \text{ monopole} \implies A_\mu \text{ cannot be well defined everywhere}$$

The result is actually stronger. Suppose there exists a magnetic monopole at a certain point in spacetime, and, without loss of generality, we shall consider a static monopole. If we surround this point by a (spatial) 2-sphere $\Sigma$, then the magnetic flux out of the sphere is given by

$$\iint_\Sigma \boldsymbol{B}\cdot\mathrm{d}\boldsymbol{\sigma} = \iint_{\Sigma^\mathrm{N}} \boldsymbol{B}\cdot\mathrm{d}\boldsymbol{\sigma} + \iint_{\Sigma^\mathrm{S}} \boldsymbol{B}\cdot\mathrm{d}\boldsymbol{\sigma} \qquad [16]$$

Here $\Sigma^{\mathrm{N}}$ and $\Sigma^{\mathrm{S}}$ are the northern and southern hemispheres overlapping on the equator $S$. By Stokes' theorem, since $F_{\mu\nu}$ has no components $F_{0i} = E_i$, we have

$$\iint_{\Sigma^{\mathrm{N}}} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{\sigma} = \oint_S \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{s} \qquad [17a]$$

$$\iint_{\Sigma^{\mathrm{S}}} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{\sigma} = \oint_{-S} \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{s} \qquad [17b]$$

In eqn [17b], $-S$ means the equator with the opposite orientation. Hence, $\oint_S + \oint_{-S} = 0$. But this contradicts the assumption that there exists a magnetic monopole at the center of the sphere. Hence, we see that if a monopole exists, then $A_\mu$ will have at least a string of singularities leading out of it. This is the famous Dirac string.

The more mathematically elegant way to describe this is that the principal bundle corresponding to electromagnetism with a magnetic monopole is nontrivial, so that the gauge potential $A_\mu$ has to be patched (i.e., related by transition functions in the overlap). Consider the example of a static monopole of magnetic charge $\tilde{e}$. For any (spatial) sphere $S_r$ of radius $r$ surrounding the monopole, we cover it with two patches N, S as follows:

$$\begin{aligned} (\mathrm{N}){:}\quad & 0 \le \theta < \pi,\ 0 \le \phi \le 2\pi \\ (\mathrm{S}){:}\quad & 0 < \theta \le \pi,\ 0 \le \phi \le 2\pi \end{aligned}$$

In each patch we define the following:

$$\begin{aligned} A_1^{(\mathrm{N})} &= \frac{\tilde{e}y}{4\pi r(r+z)} \\ A_2^{(\mathrm{N})} &= -\frac{\tilde{e}x}{4\pi r(r+z)} \\ A_3^{(\mathrm{N})} &= 0 \\ A_1^{(\mathrm{S})} &= -\frac{\tilde{e}y}{4\pi r(r-z)} \\ A_2^{(\mathrm{S})} &= \frac{\tilde{e}x}{4\pi r(r-z)} \\ A_3^{(\mathrm{S})} &= 0 \end{aligned}$$

In the overlap (containing the equator), $A^{(\mathrm{N})}$ and $A^{(\mathrm{S})}$ are related by a gauge transformation:

$$\begin{aligned} A_i^{(\mathrm{N})} - A_i^{(\mathrm{S})} &= \partial_i \Lambda \\ \Lambda &= \left(\frac{\tilde{e}}{2\pi}\right) \tan^{-1}\left(\frac{y}{x}\right) = \frac{\tilde{e}\phi}{2\pi} \end{aligned} \qquad [18]$$

Notice that $A_i^{(\mathrm{N})}$ has a line of singularity along the negative $z$-axis (which is the Dirac string in this case); similarly for $A_i^{(\mathrm{S})}$ along the positive $z$-axis.

Furthermore, the corresponding field strength is given by

$$\boldsymbol{E} = 0 \qquad [19a]$$

$$\boldsymbol{B} = \frac{\tilde{e}\boldsymbol{r}}{4\pi r^3} \qquad [19b]$$

If we now evaluate the "magnetic flux" out of $S_r$, we have

$$\iint_{S_r} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{\sigma} = \oint_{\text{Equator}} \left(A_\mu^{(\mathrm{N})} - A_\mu^{(\mathrm{S})}\right) \mathrm{d}x^\mu = \tilde{e} \qquad [20]$$

In other words, in the presence of a magnetic monopole, the second half of Maxwell's equations is modified according to eqn [21], with $\tilde{j}^\mu$ given by eqn [22].

$$\left.\begin{aligned} \operatorname{div} \boldsymbol{B} &= \tilde{\rho} \\ \operatorname{curl} \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} &= \tilde{\boldsymbol{J}} \end{aligned}\right\}, \qquad \partial_\nu {}^*F^{\mu\nu} = -\tilde{j}^\mu \qquad [21]$$

$$\tilde{j}^\mu = \tilde{e}\bar{\psi}\gamma^\mu\psi \qquad [22]$$

Furthermore, the form of eqn [21] tells us that a monopole of the $F_{\mu\nu}$ field can also be considered as a source of the ${}^*F_{\mu\nu}$ field. The two descriptions are equivalent.

How are the charges $e$ and $\tilde{e}$ related? The gauge transformation $S = \mathrm{e}^{\mathrm{i}e\Lambda}$ relating $A_\mu^{(\mathrm{N})}$ and $A_\mu^{(\mathrm{S})}$ must be well defined; that is, if one goes round the equator once, $\phi = 0 \to 2\pi$, one should get the same $S$. This gives

$$e\tilde{e} = 2\pi n, \qquad n \in \mathbb{Z} \qquad [23]$$

In particular, the unit electric and magnetic charges are related by eqn [24], which is Dirac's quantization condition,

$$e\tilde{e} = 2\pi \qquad [24]$$

So, in principle, just as in the electric case, where we could have charges $e, 2e, \ldots,$ here we could also have magnetic charges of $\tilde{e}, 2\tilde{e}, \ldots$ . In other words, both charges are quantized.

Another way to look at this is to consider the classification of principal bundles over $S^2$. The reason for these topological 2-spheres is that we are interested in enclosing a point charge. For a nontrivial bundle, the patching is given by a function $S$ defined in the overlap (the equator), in other words, a map $S^1 \to \mathrm{U}(1)$. What this amounts to is a closed curve in the circle group U(1). Now, curves that can be continuously deformed into one another cannot give

distinct fibre bundles, so that one sees easily that there exists a one-to-one correspondence:

$$\{\text{principal U(1) bundles over } S^2\}$$
$$\updownarrow$$
$$\{\text{homotopy classes of closed curves in U(1)}\}$$

This last is $\pi_1(\text{U}(1)) \cong \mathbb{Z}$. Hence, we recover Dirac's quantization condition.

So, for electromagnetism, there are two equivalent ways of defining the magnetic charge, as a source or as a monopole:

1. $\partial_\nu {}^*F^{\mu\nu} = -\tilde{j}^\mu \propto n\tilde{e} \neq 0$.
2. An element of $\pi_1(\text{U}(1)) \cong \mathbb{Z}$.

The same goes for the electric charge. We also note that both definitions give us the fact that these charges are discrete (quantized) and conserved (invariant under continuous deformations).

We now want to apply similar considerations to the magnetic charges in the nonabelian case. For several (subtle) reasons the obvious expression $D_\nu {}^*F^{\mu\nu} \stackrel{?}{=} -\tilde{j}^\mu$ as a source (see **Table 1**) does not work. The quickest way to say this is that ${}^*F^{\mu\nu}$ in general has no corresponding potential $\tilde{A}_\mu$ and so is not a gauge field. Moreover, in contrast to the abelian case, the field tensor does not fully specify the physical field configuration, as demonstrated by Wu and Yang. We shall come back to this later.

But we have just seen that in the abelian case there is another equivalent definition, which is that a magnetic monopole is given by the gauge configuration corresponding to a nontrivial U(1) bundle over $S^2$. This can be generalized to the nonabelian case without any problem. Moreover, this definition automatically guarantees that a nonabelian monopole charge is quantized and conserved. This is the way monopoles are defined above.

Arguments similar to the abelian case easily yield the nonabelian analog of the Dirac quantization condition, eqn [25], the difference between the two cases being only a matter of conventional normalization.

$$g\tilde{g} = 4\pi \qquad [25]$$

**Table 1** Definitions of charges

| | *Sources* | *Monopoles* |
|---|---|---|
| Abelian | $\partial_\nu F^{\mu\nu} = -j^\mu$ | $\partial_\nu {}^*F^{\mu\nu} = -\tilde{j}^\mu$ |
| Nonabelian | $D_\nu F^{\mu\nu} = -j^\mu$ | ? |

## Abelian Duality and the Wu–Yang Criterion

We saw above the well-known fact that classical Maxwell theory is invariant under the duality operator. By this we mean that at any point in spacetime free of electric and magnetic charges we have the two dual symmetric Maxwell equations:

$$\partial_\nu {}^*F^{\mu\nu} = 0 \quad [\text{d}F = 0] \qquad [26]$$

$$\partial_\nu F^{\mu\nu} = 0 \quad [\text{d}^*F = 0] \qquad [27]$$

Displayed in square brackets are the equivalent equations in the language of differential forms. Then by the Poincaré lemma we deduce immediately the existence of potentials $A$ and $\tilde{A}$ such that eqns [28] and [29] hold:

$$F_{\mu\nu}(x) = \partial_\nu A_\mu(x) - \partial_\mu A_\nu(x) \qquad [F = \text{d}A] \qquad [28]$$

$${}^*F_{\mu\nu}(x) = \partial_\nu \tilde{A}_\mu(x) - \partial_\mu \tilde{A}_\nu(x) \qquad [{}^*F = \text{d}\tilde{A}] \qquad [29]$$

The two potentials transform independently under independent gauge transformations $\Lambda$ and $\tilde{\Lambda}$:

$$A_\mu(x) \mapsto A_\mu(x) + \partial_\mu \Lambda(x) \qquad [30]$$

$$\tilde{A}_\mu(x) \mapsto \tilde{A}_\mu(x) + \partial_\mu \tilde{\Lambda}(x) \qquad [31]$$

This means that the full symmetry of this theory is doubled to $\text{U}(1) \times \tilde{\text{U}}(1)$, where the tilde on the second circle group indicates that it is the symmetry of the dual potential $\tilde{A}$. It is important to note that the physical degrees of freedom remain the same. This is clear because $F$ and ${}^*F$ are related by an algebraic equation [3]. As a consequence, the physical theory is the same: the doubled gauge symmetry is there all the time but is just not so readily detected.

As mentioned in the Introduction, this dual symmetry means that what we call "electric" or "magnetic" is entirely a matter of choice.

In the presence of electric charges, the Maxwell equations usually appear as

$$\partial_\nu {}^*F^{\mu\nu} = 0 \qquad [32]$$

$$\partial_\nu F^{\mu\nu} = -j^\mu \qquad [33]$$

The apparent asymmetry in these equations comes from the experimental fact that there is only one type of charges observed in nature, which we choose to regard as a source of the field $F$ (or, equivalently but unconventionally, as a monopole of the field ${}^*F$). But as we see by dualizing eqns [32] and [33], that is, by interchanging the role of electricity and magnetism in relation to $F$, we could equally have thought of these instead as source charges of

the field $^*F$ (or, similarly to the above, as monopoles of $F$):

$$\partial_\nu {}^*F^{\mu\nu} = -\tilde{j}^\mu \qquad [34]$$

$$\partial_\nu F^{\mu\nu} = 0 \qquad [35]$$

If both electric and magnetic charges existed in nature, then we would have the dual symmetric pair:

$$\partial_\nu {}^*F^{\mu\nu} = -\tilde{j}^\mu \qquad [36]$$

$$\partial_\nu F^{\mu\nu} = -j^\mu \qquad [37]$$

This duality in fact goes much deeper, as can be seen if we use the Wu–Yang criterion to derive the Maxwell equations, although we should note that what we present here is not the textbook derivation of the Maxwell equations from an action, but we conisder this method to be much more intrinsic and geometric. Consider first pure electromagnetism. The free Maxwell action is given by

$$\mathcal{A}_F^0 = -\frac{1}{4}\int F_{\mu\nu}F^{\mu\nu} \qquad [38]$$

The true variables of the (quantum) theory are the $A_\mu$, so in eqn [38] we should put in a constraint to say that $F_{\mu\nu}$ is the curl of $A_\mu$ [28]. This can be viewed as a topological constraint, because it is precisely equivalent to [26]. Using the method of Lagrange multipliers, we form the constrained action

$$\mathcal{A} = \mathcal{A}_F^0 + \int \lambda_\mu(\partial_\nu {}^*F^{\mu\nu}) \qquad [39]$$

We can now vary this with respect to $F_{\mu\nu}$, obtaining eqn [40], which implies [27]:

$$F^{\mu\nu} = 2\varepsilon^{\mu\nu\rho\sigma}\partial_\rho\lambda_\sigma \qquad [40]$$

Moreover, the Lagrange multiplier $\lambda$ is exactly the dual potential $\tilde{A}$.

This derivation is entirely dual symmetric, since we can equally well use [27] as constraint for the action $\mathcal{A}_F^0$, now considered as a functional of $^*F^{\mu\nu}$ (eqn [41]), and obtain [26] as the equation of motion:

$$\mathcal{A}_F^0 = \frac{1}{4}\int {}^*F_{\mu\nu}{}^*F^{\mu\nu} \qquad [41]$$

This method applies to the interaction of charges and fields as well. In this case we start with the free field plus free particle action (eqn [42]), where we assume the free particle $m$ to satisfy the Dirac equation,

$$\mathcal{A}^0 = \mathcal{A}_F^0 + \int \bar{\psi}(\mathrm{i}\partial_\mu\gamma^\mu - m)\psi \qquad [42]$$

To fix ideas, let us regard this particle carrying an electric charge $e$ as a monopole of the potential $\tilde{A}_\mu$. Then the constraint we put in is [33], giving

$$\mathcal{A}' = \mathcal{A}^0 + \int \tilde{\lambda}_\mu(\partial_\nu F^{\mu\nu} + j^\mu) \qquad [43]$$

Variation with respect to $^*F$ gives eqn [32], and varying with respect to $\bar{\psi}$ gives

$$(\mathrm{i}\partial_\mu\gamma^\mu - m)\psi = -eA_\mu\gamma^\mu\psi \qquad [44]$$

So, the complete set of equations for a Dirac particle carrying an electric charge $e$ in an electromagnetic field is [32], [33], and [44]. The duals of these equations will describe the dynamics of a Dirac magnetic monopole in an electromagnetic field.

We see from this that the Wu–Yang criterion actually gives us an intuitively clear picture of interactions. The assertion that there is a monopole at a certain spacetime point $x$ means that the gauge field on a 2-sphere surrounding $x$ has to have a certain topological configuration (e.g., giving a nontrivial bundle of a particular class), and if the monopole moves to another point then the gauge field will have to rearrange itself so as to maintain the same topological configuration around the new point. There is thus naturally a coupling between the gauge field and the position of the monopole, or, in physical language, a topologically induced interaction between the field and the charge (Wu and Yang, 1976). Furthermore, this treatment of interaction between field and matter is entirely dual symmetric.

As a side remark, consider that although the action $\mathcal{A}_F^0$ is not immediately identifiable as geometric in nature, the Wu–Yang criterion, by putting the topological constraint and the equation of motion on equal (or dual) footing, suggests that in fact it is geometric in a subtle manner not yet fully understood. Moreover, as pointed out, eqn [40] says that the dual potential is given by the Lagrange multiplier of the constrained action.

## Nonabelian Duality Using Loop Variables

The next natural step is to generalize this duality to the nonabelian Yang–Mills case. Although there is no difficulty in defining $^*F^{\mu\nu}$, which is again given by [3], we immediately come to difficulties in the relation between field and potential; for example, as in eqn [11],

$$F_{\mu\nu}(x) = \partial_\nu A_\mu(x) - \partial_\mu A_\nu(x) + \mathrm{i}g[A_\mu(x), A_\nu(x)]$$

First of all, despite appearances the Yang–Mills equation [45] (in the free-field case) and the Bianchi

identity [46] are not dual-symmetric, because the correct dual of the Yang–Mills equation ought to be given by eqn [47], where $\tilde{D}_\nu$ is the covariant derivative corresponding to a dual potential:

$$D_\nu F^{\mu\nu} = 0 \qquad [45]$$

$$D_\nu {}^*F^{\mu\nu} = 0 \qquad [46]$$

$$\tilde{D}_\nu {}^*F^{\mu\nu} = 0 \qquad [47]$$

Secondly, the Yang–Mills equation, unlike its abelian counterpart [27], says nothing about whether the 2-form ${}^*F$ is closed or not. Nor is the relation [11] about exactness at all. In other words, the Yang–Mills equation does not guarantee the existence of a dual potential, in contrast to the Maxwell case. In fact, Gu and Yang have constructed a counterexample. Because the true variables of a gauge theory are the potentials and not the fields, this means that Yang–Mills theory is not symmetric under the Hodge star operation [3].

Nevertheless, electric–magnetic duality is a very useful physical concept, so one may wish to seek a more general duality transform ($\tilde{\ }$), satisfying the following properties:

1. $(\quad)^{\tilde{}\tilde{}} = \pm(\quad)$.
2. Electric field $F_{\mu\nu} \overset{\sim}{\longleftrightarrow}$ magnetic field $\tilde{F}_{\mu\nu}$.
3. Both $A_\mu$ and $\tilde{A}_\mu$ exist as potentials (away from charges).
4. Magnetic charges are monopoles of $A_\mu$, and electric charges are monopoles of $\tilde{A}_\mu$.
5. $\tilde{\ }$ reduces to $^*$ in the abelian case.

One way to do this is to study the Wu–Yang criterion more closely. This reveals the concept of charges as topological constraints to be crucial even in the pure field case, as can be seen in **Figure 1**. The point to stress is that, in the above abelian case, the condition for the absence of a topological charge (a monopole) exactly removes the redundancy of the variables $F_{\mu\nu}$, and hence recovers the potential $A_\mu$.

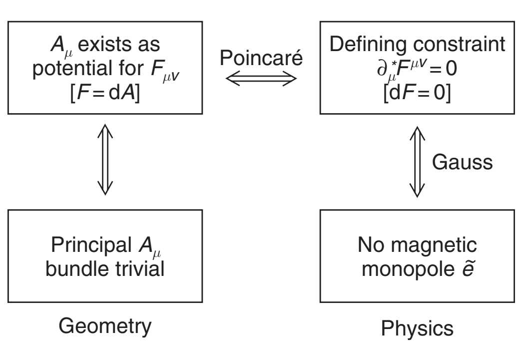

**Figure 1**

Now the nonabelian monopole charge was defined topologically as an element of $\pi_1(G)$, and this definition also holds in the abelian case of U(1), with $\pi_1(\text{U}(1)) = \mathbb{Z}$. So the first task is to write down a condition for the absence of a nonabelian monopole.

To fix ideas, let us consider the group SO(3), whose monopole charges are elements of $\mathbb{Z}_2$, which can be denoted by a sign $\pm$. The vacuum, charge $(+)$ (that is, no monopole) is represented by a closed curve in the group manifold of even winding number, and the monopole charge $(-)$ by a closed curve of odd winding number. It is more convenient, however, to work in SU(2), which is the double cover of SO(3) and which has the topology of $S^3$, as sometimes it is useful to identify the fundamental group of SO(3) with the center of SU(2) and hence consider the monopole charge as an element of this center. There the charge $(+)$ is represented by a closed curve, and the charge $(-)$ by a curve that winds an odd number of "half-times" round the sphere $S^3$. Since these charges are defined by closed curves, it is reasonable to try to write the constraint in terms of loop variables. The treatment presented below is not as rigorous as some others, but the latter are not so well adapted to the problem in hand. Furthermore, it is important to emphasize that this approach aims to generalize electric–magnetic duality to Yang–Mills theory in direct and close analogy to duality in electromagnetism, without any further symmetries with which it may be expedient to enrich the theory. Other approaches are referred to in the next section.

Consider the gauge-invariant Dirac phase factor (or holonomy) $\Phi(C)$ of a loop $C$, which can be written symbollically as a path-ordered exponential:

$$\Phi[\xi] = P_s \exp ig \int_0^{2\pi} ds\, A_\mu(\xi(s))\dot{\xi}^\mu(s) \qquad [48]$$

In eqn [48], we parametrize the loop $C$ as is eqn [49] and a dot denotes differentiation with respect to the parameter $s$.

$$C: \quad \{\xi^\mu(s):\ s = 0 \to 2\pi, \xi(0) = \xi(2\pi) = \xi_0\} \qquad [49]$$

We thus regard loop variables in general as functionals of continuous piecewise smooth functions $\xi$ of $s$. In this way, loop derivatives and loop integrals are just functional derivatives and functional integrals. This means that loop derivatives $\delta_\mu(s)$ are defined by a regularization procedure approximating delta functions with finite bump functions and then taking limits in a definite order. For functional integrals, there exist various regularization procedures, which are treated elsewhere in this Encyclopedia.

Polyakov (1980) introduces the logarithmic loop derivative of $\Phi[\xi]$:

$$F_\mu[\xi|s] = \frac{i}{g}\Phi^{-1}[\xi]\delta_\mu(s)\Phi[\xi] \qquad [50]$$

This acts as a kind of "connection" in loop space since it tells us how the phase of $\Phi[\xi]$ changes from one loop to a neighbouring loop. One can go a step further and define its "curvature" in direct analogy with $F_{\mu\nu}(x)$ by

$$G_{\mu\nu}[\xi|s] = \delta_\nu(s)F_\mu[\xi|s] - \delta_\mu(s)F_\nu[\xi|s] + ig[F_\mu[\xi|s], F_\nu[\xi|s]] \qquad [51]$$

It can be shown that by using the $F_\mu[\xi|s]$ we can rewrite the Yang–Mills action as eqn [52], where the normalization factor $\bar{N}$ is an infinite constant:

$$\mathcal{A}_F^0 = -\frac{1}{4\pi\bar{N}}\int \delta\xi \int_0^{2\pi} \mathrm{d}s\, \mathrm{tr}\{F_\mu[\xi|s]F^\mu[\xi|s]\}|\dot{\xi}(s)|^{-2} \qquad [52]$$

However, the true variables of the theory are still the $A_\mu$. They represent 4 functions of a real variable, whereas the loop connections represent 4 functionals of the real function $\xi(s)$. Just as in the case of the $F_{\mu\nu}$, these $F_\mu[\xi|s]$ have to be constrained so as to recover $A_\mu$, but this time much more severely.

It turns out that, in pure Yang–Mills theory, the constraint that says there are no monopoles ([53]) also removes the redundancy of the loop variables, exactly as in the abelian case,

$$G_{\mu\nu}[\xi|s] = 0 \qquad [53]$$

That this condition is necessary is easy to see by simple algebra. The proof of the converse of this "extended Poincaré lemma" is fairly lengthy. Granted this, we can now apply the Wu–Yang criterion to the action [52] and derive the Polyakov equation [54], which is the loop version of the Yang–Mills equation:

$$\delta_\mu(s)F^\mu[\xi|s] = 0 \qquad [54]$$

In the presence of a monopole charge (–), the constraint [53] will have a nonzero right-hand side,

$$G_{\mu\nu}[\xi|s] = -J_{\mu\nu}[\xi|s] \qquad [55]$$

The loop current $J_{\mu\nu}[\xi|s]$ can be written down explicitly. However, its global form is much easier to understand. Recall that $F^\mu[\xi|s]$ can be thought of as a loop connection, for which we can form its "holonomy." This is defined for a closed (spatial) surface $\Sigma$ (enclosing the monopole), parametrized by a family of closed curves $\xi_t(s), t = 0 \to 2\pi$. The "holonomy" $\Theta_\Sigma$ is then the total change in phase of $\Phi[\xi_t]$ as $t \to 2\pi$, and thus equals the charge (–).

To formulate an electric–magnetic duality that is applicable to nonabelian theory, one defines yet another set of loop variables. Instead of the Dirac phase factor $\Phi[\xi]$ for a complete curve [48], we consider the parallel phase transport for part of a curve from $s_1$ to $s_2$:

$$\Phi_\xi(s_2, s_1) = P_s \exp ig\int_{s_1}^{s_2} \mathrm{d}s A_\mu(\xi(s))\dot{\xi}^\mu(s) \qquad [56]$$

Then the new variables are defined by [57].

$$E_\mu[\xi|s] = \Phi_\xi(s,0)F_\mu[\xi|s]\Phi_\xi^{-1}(s,0) \qquad [57]$$

These are not gauge invariant like $F_\mu[\xi|s]$ and may not be as useful in general, but seem more convenient for dealing with duality.

Using these variables, we now define their dual $\tilde{E}_\mu[\eta|t]$ according to

$$\omega^{-1}(\eta(t))\tilde{E}_\mu[\eta|t]\omega(\eta(t)) = -\frac{2}{\bar{N}}\varepsilon_{\mu\nu\rho\sigma}\dot{\eta}^\nu(t)\int \delta\xi\, \mathrm{d}s E^\rho[\xi|s]\dot{\xi}^\sigma(s)\dot{\xi}^{-2}(s) \times \delta(\xi(s) - \eta(t)) \qquad [58]$$

In eqn [58], $\omega(x)$ is a (local) rotation matrix transforming from the frame in which the orientation in internal symmetry space of the fields $E_\mu[\xi|s]$ are measured to the frame in which the dual fields $\tilde{E}_\nu[\eta|t]$ are measured. It can be shown that this dual transform satisfies all five of the required conditions listed earlier.

Electric–magnetic duality in Yang–Mills theory is now fully reestablished using this generalized duality. We have the dual pairs of equations [59]–[60] and [61]–[62]:

$$\delta_\nu E_\mu - \delta_\mu E_\nu = 0 \qquad [59]$$

$$\delta^\mu E_\mu = 0 \qquad [60]$$

$$\delta^\mu \tilde{E}_\mu = 0 \qquad [61]$$

$$\delta_\nu \tilde{E}_\mu - \delta_\mu \tilde{E}_\nu = 0 \qquad [62]$$

Equation [59] guarantees that the potential $A$ exists, and so is equivalent to [53], and hence is the nonabelian analog of [26]; while equation [60] is equivalent to the Polyakov version of Yang–Mills equation [54], and hence is the nonabelian analog of [27]. Equation [61] is equivalent by duality to [59] and is the dual Yang–Mills equation. Similarly equation [62] is equivalent to [60], and guarantees the existence of the dual potential $\tilde{A}$.

The treatment of charges using the Wu–Yang criterion also follows the abelian case, and will not be further elaborated here. For this and further details, the reader is referred to the orginal papers (Chan and Tsou 1993, 1999).

Also, just as in the abelian case, the gauge symmetry is doubled: from the group $G$ we deduce that the full gauge symmetry is in fact $G \times \tilde{G}$, but that the physical degrees of freedom remain the same.

The above exposition establishes electric–magnetic duality in Yang–Mills theory only for classical fields. A hint that this duality persists at the quantum level comes from the work of 't Hooft (1978) on confinement. There he introduces two loop quantities $A(C)$ and $B(C)$ that are operators in the Hilbert space of quantum states satisfying the commutation relation [63] for an SU($N$) gauge theory, where $n$ is the linking number between the two (spatial) loops $C$ and $C'$:

$$A(C)B(C') = B(C')A(C)\exp(2\pi i n/N) \qquad [63]$$

The order or Wilson operator is given explicitly by $A(C) = \operatorname{tr}\Phi(C)$. These two operators play dual roles in the sense of electric–magnetic duality:

- $A(C)$ measures the magnetic flux through $C$ and creates electric flux along $C$.
- $B(C)$ measures the electric flux through $C$ and creates magnetic flux along $C$.

By defining the disorder operator $B(C)$ as the Wilson operator corresponding to the dual potential $\tilde{A}$ obtained above, one can prove the commutation relation [63], thus showing that these classical fields, when promoted to operators, retain their duality relation. Furthermore, there is a remarkable relation between the two (abstractly identical) gauge groups, in that if one is confined then the dual must be broken (that is, in the Higgs phase). This result is known as 't Hooft's theorem.

The doubling of gauge symmetry, together with 't Hooft's theorem, has been applied to the confined colour group SU(3) of quantum chromodynamics (QCD), in the Dualized Standard Model, to solve the puzzle of the existence of exactly three generations of fermions, with good observational support, by identifying the (necessarily broken) dual SU(3) with the generation symmetry (Chan and Tsou, 2002).

## Other Treatments of Nonabelian Duality

Since Yang–Mills theory is not symmetric under the Hodge $^*$-operation, there are several routes one can take to generalize the concept of electric–magnetic duality to the nonabelian case. What was presented in the last section is a modification of the $^*$-operation so as to restore this symmetry for Yang–Mills theory, keeping to the original gauge structure as much as possible. However, Yang–Mills theory as used today in particle and field theories are usually embedded in theories with more structures. In the simplest case we have the Standard Model of Particle Physics, which describes all of particle interactions (except gravity) and which has the gauge group usually written as $SU(3) \times SU(2) \times U(1)$, corresponding to the SU(3) of strong interaction and $SU(2) \times U(1)$ of electroweak interaction. [Strictly speaking, it is $(SU(3) \times SU(2) \times U(1))/\mathbb{Z}_6$, if we have the standard particle spectrum.] However, the former group is confined and the latter broken. The breaking is usually effected by introducing scalar fields called Higgs fields into the theory.

Besides the experimentally well-tested Standard Model, there are many theoretically popular models of gauge theory in which supersymmetry is postulated, thereby introducing extra symmetries into the theory. Many of these are remnants of string theory, and are usually envisaged as gauge theories in a spacetime dimension higher than 4.

Because of the extra structures and increased symmetries in these theories, there is quite a proliferation of concepts of duality, which could all be thought of as generalizations of abelian electric–magnetic duality (Schwarz, 1997). They come under the names of Seiberg–Witten duality, S-duality, T-duality, mirror symmetry, and so on. All these other aspects of duality have their own entries in this Encyclopedia.

# Electroweak Theory

**K Konishi**, Università di Pisa, Pisa, Italy

## Introduction

The discovery of the electroweak theory crowned long years of investigation on weak interactions. The key earlier developments included Fermi's phenomenological four-fermion interactions for the $\beta$-decay, discovery of parity violation and establishment of $V - A$ structure of the weak currents, the Feynman–Gell–Mann conserved vector current (CVC) hypothesis, current algebra and its beautiful applications in the 1960s, Cabibbo mixing and lepton–hadron universality, and finally, the proposal of intermediate vector bosons (IVBs) to mitigate the high-energy behavior of the pointlike Fermi's interaction theory.

It turned out that the scattering amplitudes in IVB theory still generally violated unitarity, due to the massive vector boson propagator,

$$\frac{-g^{\mu\nu} + q^{\mu}q^{\nu}/M^2}{q^2 - M^2 + \mathrm{i}\epsilon}$$

The electroweak theory, known as Glashow–Weinberg–Salam (GWS) theory (Weinberg 1967, Salam 1968, Taylor 1976), was born through the attempts to make the hypothesis of IVBs for the weak interactions such that it is consistent with unitarity.

The GWS theory contains, and is in a sense a generalization of, quantum electrodynamics (QED) which was earlier successfully established as the quantum theory of electromagnetism in interaction with matter. GWS theory describes the weak and electromagnetic interactions in a single, unified gauge theory with gauge group

$$\mathrm{SU_L}(2) \times \mathrm{U}(1) \qquad [1]$$

Part of this gauge symmetry is realized in the so-called "spontaneously broken" mode; only a $\mathrm{U_{EM}}(1) \subset \mathrm{SU_L}(2) \times \mathrm{U}(1)$ subgroup, corresponding to the usual local gauge symmetry of the electromagnetism, remains manifest at low energies, with a massless gauge boson (photon). The other three gauge bosons $W^{\pm}, Z$, are massive, with masses $\sim$80.4 and 91.2 GeV, respectively.

The theory is renormalizable, as conjectured by S Weinberg and by A Salam, and subsequently proved by G 't Hooft (1971), and makes well-defined predictions order by order in perturbation theory.

Since the experimental observation of neutral currents (a characteristic feature of the Weinberg–Salam theory which predicts an extra, neutral massive vector boson, $Z$, as compared to the naive IVB hypothesis) at Gargamelle bubble chamber at CERN (1973), the theory has passed a large number of experimental tests. The first basic confirmation also included the discovery of various new particles required by the theory: the charm quark (SLAC, BNL, 1974), the bottom quark (Fermilab, 1977), and the tau ($\tau$) lepton (SLAC, 1975). The heaviest top quark, having mass about two hundred times that of the proton, was found later (Fermilab, 1995). The direct observation of W and Z vector bosons was first made by UA1 and UA2 experiments at CERN (1983).

The GWS theory is today one of the most precise and successful theories in physics. Even more important, perhaps, together with quantum chromodynamics (QCD), which is a SU(3) (color) gauge theory describing the strong interactions (which bind quarks into protons and neutrons, and the latter two into atomic nuclei), it describes correctly – within the present experimental and theoretical uncertainties – all the presently known fundamental forces in Nature, except gravity. The $\mathrm{SU}(3)_{\mathrm{QCD}} \times (\mathrm{SU_L}(2) \times \mathrm{U}(1))_{\mathrm{GWS}}$ theory is known as the standard model (SM).

Both the electroweak (GSW) theory and QCD are gauge theories with a nonabelian (noncommutative) gauge group. This type of theories, known as Yang–Mills theories, can be constructed by generalizing the well-known gauge principle of QED to more general group transformations. It is a truly remarkable fact that all of the fundamental forces known today (apart from gravity) are described by Yang–Mills theories, and in this sense a very nontrivial unification can be said to underlie the basic laws of Nature (G 't Hooft).

There are further deep and remarkable conditions (anomaly cancellations), satisfied by the structure of the theory and by the charges of experimentally known spin-1/2 elementary particles (see Tables 1 and 2), which guarantees the consistency of the theory as a quantum theory.

It should be mentioned, however, that the recent discovery of neutrino oscillations (SuperKamiokande (1998), SNO, KamLAND, K2K experiments), which proved the neutrinos to possess nonvanishing masses, clearly indicates that the standard GWS theory must be extended, in an as yet unknown way.

**Table 1** Quarks and their charges

| *Quarks* | $SU_L(2)$ | $U_Y(1)$ | $U_{EM}(1)$ |
|---|---|---|---|
| $\begin{pmatrix} u_L \\ d'_L \end{pmatrix}, \begin{pmatrix} c_L \\ s'_L \end{pmatrix}, \begin{pmatrix} t_L \\ b'_L \end{pmatrix}$ | $\underline{2}$ | $\frac{1}{3}$ | $\begin{pmatrix} \frac{2}{3} \\ -\frac{1}{3} \end{pmatrix}$ |
| $u_R, c_R, t_R$ | $\underline{1}$ | $\frac{4}{3}$ | $\frac{2}{3}$ |
| $d_R, s_R, b_R$ | $\underline{1}$ | $-\frac{2}{3}$ | $-\frac{1}{3}$ |

The primes indicate that the mass eigenstates are different from the states transforming as multiplets of $SU_L(2) \times U_Y(1)$. They are linearly related by CKM mixing matrix.

**Table 2** Leptons and their charges

| *Leptons* | $SU_L(2)$ | $U_Y(1)$ | $U_{EM}(1)$ |
|---|---|---|---|
| $\begin{pmatrix} \nu'_{eL} \\ e_L \end{pmatrix}, \begin{pmatrix} \nu'_{\mu L} \\ \mu_L \end{pmatrix}, \begin{pmatrix} \nu'_{\tau L} \\ \tau_L \end{pmatrix}$ | $\underline{2}$ | $-1$ | $\begin{pmatrix} 0 \\ -1 \end{pmatrix}$ |
| $e_R, \mu_R, \tau_R$ | $\underline{1}$ | $-2$ | $-1$ |

The primes indicate again that the mass eigenstates are in different from the states transforming as multiplets of $SU_L(2) \times U_Y(1)$, as required by the observed neutrino oscillations.

The following is a brief summary of the GWS theory, its characteristic features, its implications to the symmetries of Nature, the status of the precision tests, and its possible extensions.

## GWS Theory

All the presently known elementary particles (except for the gauge bosons $W^{\pm}, Z, \gamma$, the gluons, the graviton, possibly right-handed neutrinos) are listed in Tables 1–3 together with their charges with respect to the $SU_L(2) \times U(1)$ gauge group.

A doublet of Higgs scalar particles is included even though the physical component (which should appear as an ordinary scalar particle) has not yet been experimentally observed.

The Lagrangian is given by

$$\mathcal{L} = \mathcal{L}_{\text{gauge}} + \mathcal{L}_{\text{quarks}} + \mathcal{L}_{\text{leptons}} + \mathcal{L}_{\text{Higgs}} + \mathcal{L}_{\text{Yukawa}} + \mathcal{L}_{\text{g.f.}} + \mathcal{L}_{\text{ghosts}}$$

The gauge kinetic terms are

$$\mathcal{L}_{\text{gauge}} = -\frac{1}{4}\sum_{a=1}^{3} F^a_{\mu\nu}F^{a\mu\nu} - \frac{1}{4}G_{\mu\nu}G^{\mu\nu}$$

**Table 3** Higgs doublet scalars and their charges

| *Higgs doublet* | $SU_L(2)$ | $U_Y(1)$ | $U_{EM}(1)$ |
|---|---|---|---|
| $\begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix}$ | $\underline{2}$ | 1 | $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ |

where

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g\epsilon^{abc}A^b_\mu A^c_\nu$$
$$G_{\mu\nu} = \partial_\mu B_\nu - \partial_\nu B_\mu$$

are $SU_L(2) \times U(1)$ gauge field tensors; $\mathcal{L}_{\text{g.f.}}$ and $\mathcal{L}_{\text{FP}}$ are the so-called gauge-fixing term and Faddeev–Popov ghost term, needed to define the gauge-boson propagators appropriately and to eliminate certain unphysical contributions. The gauge invariance of the theory is ensured by a set of identities (A Slavnov, J C Taylor). The quark kinetic terms have the form

$$\mathcal{L}_{\text{quarks}} = \sum_{\text{quarks}} \bar{\psi} i\gamma^\mu \mathcal{D}_\mu \psi$$

where $\mathcal{D}_\mu$ are appropriate covariant derivatives,

$$\mathcal{D}_\mu q_L = \left(\partial_\mu - \frac{ig}{2}\tau \cdot A_\mu - \frac{ig'}{6}B_\mu\right)q_L$$

for the left-handed quark doublets,

$$\mathcal{D}_\mu u_R = \left(\partial_\mu - \frac{2ig'}{3}B_\mu\right)u_R$$
$$\mathcal{D}_\mu d_R = \left(\partial_\mu + \frac{ig'}{3}B_\mu\right)d_R$$

and similarly for other "up" quarks $c_R$ (charm) and $t_R$ (top), and "down" quarks, $s_R$ (strange), and $b_R$ (bottom). Analogously, the lepton kinetic terms are given by

$$\mathcal{L}_{\text{leptons}} = \sum_{i=1}^{3} \bar{\psi}^i i\gamma^\mu \mathcal{D}_\mu \psi^i = \sum_{i=1}^{3} \bar{\psi}^i_L i\gamma^\mu \left(\partial_\mu - ig\frac{\tau^a A^a_\mu}{2} + \frac{ig'}{2}B_\mu\right)\psi^i_L + \sum_{i=1}^{3} \bar{\psi}^i_R i\gamma^\mu (\partial_\mu + ig' B_\mu)\psi^i_R$$

where $\psi^i (i = 1, 2, 3)$ indicate the $e, \mu, \tau$ lepton families; finally, the parts involving the Higgs fields are

$$\mathcal{L}_{\text{Higgs}} = \mathcal{D}_\mu \phi * \mathcal{D}^\mu \phi + V(\phi, \phi^\dagger)$$
$$V(\phi, \phi^\dagger) = -\mu^2 \phi^\dagger \phi - \lambda(\phi^\dagger \phi)^2$$

and

$$\mathcal{L}_{\text{Yukawa}} = \sum_{i,j=1}^{3}\left[g^{ij}_d \bar{q}^i_L \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} d^j_R + g^{ij}_u \bar{q}^i_L \begin{pmatrix} \phi^{0*} \\ -\phi^- \end{pmatrix} u^j_R\right] + \text{h.c.} + \sum_{i,j=1}^{3}\left[g^i_e \bar{\psi}^i_L \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \psi^i_R\right] + \text{h.c.} \quad [2]$$

For $\mu^2 < 0$, the Higgs potential has a minimum at

$$\langle \phi^\dagger \phi \rangle = \langle |\phi^+|^2 + |\phi^0|^2 \rangle = -\frac{\mu^2}{2\lambda} \equiv \frac{v^2}{2} \neq 0$$

By choosing conveniently the direction of the Higgs field, its vacuum expectation value (VEV) is expressed as

$$\left\langle \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \right\rangle = \begin{pmatrix} 0 \\ v/\sqrt{2} \end{pmatrix}, \quad v \equiv \sqrt{-\frac{\mu^2}{\lambda}} \qquad [3]$$

The physical properties of Higgs and gauge bosons are best seen by choosing the so-called unitary gauge,

$$\Phi(x) = \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} = e^{i\zeta^a(x)\tau^a/v} \begin{pmatrix} 0 \\ (v + \eta(x))/\sqrt{2} \end{pmatrix} \equiv U(\zeta)\Phi'(x)$$

$$\psi_L = U(\zeta)\psi'_L, \qquad \psi_R = \psi'_R$$

$$A_\mu = U(\zeta)\left(A'_\mu + \frac{i}{g}\partial_\mu\right)U^{-1}(\zeta), \qquad A_\mu \equiv \frac{\tau^a A^a_\mu}{2}$$

and expressing everything in terms of primed variables. It is easy to see that

1. There is one physical scalar (Higgs) particle with mass,

$$m_\eta = \sqrt{-2\mu^2} \qquad [4]$$

2. The Higgs kinetic term $(\mathcal{D}\phi'^\dagger)(\mathcal{D}\phi')$ produces the gauge-boson masses

$$M^2_{W^\pm} = \frac{g^2 v^2}{4}, \qquad M^2_Z = \frac{v^2}{4}(g^2 + g'^2) \qquad [5]$$

3. The physical gauge bosons are the charged $W^\pm$, and two neutral vector bosons described by the fields

$$Z_\mu = \cos\theta_W A_{3\mu} - \sin\theta_W B_\mu,$$
$$A_\mu = \sin\theta_W A_{3\mu} + \cos\theta_W B_\mu$$

where the mixing angle

$$\theta_W = \tan^{-1}\frac{g'}{g} \quad \left(\sin\theta_W = \frac{g'}{\sqrt{g^2 + g'^2}}\right)$$

is known as the Weinberg angle. The massless $A_\mu$ field describes the photon.

## Fermi Interactions and Neutral Currents

The fermions interact with gauge bosons through the charge and neutral currents

$$\mathcal{L} = \frac{g}{2}(J_{-\mu}W^\mu_+ + J_{+\mu}W^\mu_-) + \mathcal{L}^{\text{n.c.}} \qquad [6]$$

$$\mathcal{L}^{\text{n.c.}} = gJ^3_\mu A^{3\mu} + \frac{g'}{2}J^Y_\mu B^\mu$$
$$= eJ^\mu_{\text{em}}A_\mu + \frac{g}{\cos\theta_W}J^0_\mu Z^\mu \qquad [7]$$

where

$$J_{+\mu} = \sum \bar{\psi}_L \gamma_\mu \tau^+ \psi_L$$
$$= \frac{1}{2}\sum \bar{\psi}\gamma_\mu \tau^+(1 - \gamma_5)\psi$$
$$\equiv \frac{1}{2}J^{V-A}_{+\mu} \qquad [8]$$

corresponds to the standard charged current, and

$$J^0_\mu = J^3_\mu - \sin^2\theta_W J^{\text{em}}_\mu \qquad [9]$$

is the neutral current to which the $Z$ boson is coupled ($J^3_\mu = (1/2)\sum \bar{\psi}_L\gamma_\mu\tau^3\psi_L$ and $J^{\text{em}}_\mu$ is the electromagnetic current). The model thus predicts the existence of neutral current processes, mediated by the $Z$ boson, such as $\nu_\mu e \to \nu_\mu e$ or $\bar{\nu}_\mu e \to \bar{\nu}_\mu e$, with cross section of the same order of that for the charged current process, $\bar{\nu}_e e \to \bar{\nu}_e e$, but with a characteristic L–R asymmetric couplings depending on the Weinberg angle. By eqn [9] appropriate ratios of cross sections, such as $\sigma(\nu_\mu e \to \nu_\mu e)/\sigma(\bar{\nu}_\mu e \to \bar{\nu}_\mu e)$, can be used to measure $\sin^2\theta_W$.

The exchange of heavy $W$ bosons generates an effective current–current interaction at low energies:

$$\mathcal{L}^{\text{c.c}}_{\text{eff}} = -\frac{g^2}{2M^2_W}J_{-\mu}J^\mu_+$$

the well-known Fermi–Feynman–Gell-Mann Lagrangian $-\frac{G_F}{\sqrt{2}}J^\dagger_{V-A\mu}J^\mu_{V-A}$, with

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8M^2_W}$$

This means that the Higgs VEV must be taken to be

$$v = 2^{-1/4}G_F^{-1/2} \simeq 246\ \text{GeV} \qquad [10]$$

## Masses

It is remarkable that "all" known masses of the elementary particles – except perhaps those of the neutrino masses – are generated in GWS theory through the spontaneous breakdown of $SU_L(2) \times U(1)$ symmetry, through the Higgs VEV (eqns [3] and [10]). The boson masses are given by [4] and [5]. Note that the relation

$$\rho = \frac{M^2_W}{M^2_Z\cos^2\theta_W} = 1 + O(\alpha)$$

reflects an accidental SO(3) symmetry present (note the SO(4) symmetry of the Higgs potential in the limit $\alpha \to 0$, before the spontaneous breaking) in the model, called custodial symmetry. This is a characteristic, model-dependent feature of the minimal model, not

necessarily required by the gauge symmetry. This relation is well met experimentally, although a quantitative discussion requires the choice of the renormalization scheme (including the definition of $\sin\theta_W$ itself) and check of consistency with various other data.

The fermions get mass through the Yukawa interactions (eqn [2]); the fermion masses are arbitrary parameters of the model and cannot be predicted within the GWS theory. An important feature of this mechanism is that the coupling of the physical Higgs particle to each fermion is proportional to the mass of the latter. This should give a clear, unambiguous experimental signature for the Higgs scalar of the minimal GWS model.

The recent discovery of nonvanishing neutrino masses requires the theory to be extended. Actually, there is a natural way to incorporate such masses in the standard GWS model, by a minimal extension. As the right-handed neutrinos, if they exist, are entirely neutral with respect to the $SU_L(2)\times U(1)$ gauge symmetry, they do not need its breaking to have mass. In other words, $\nu_R$ may get Majorana masses, $\sim M_R\nu_R\nu_R$, by some yet unknown mechanism, much larger than those of other fermions (such a mechanism is quite naturally present in some grand unified models). If now the Yukawa couplings are introduced as for the quarks and for the down leptons, then the Dirac mass terms result upon condensation of the Higgs field, and the neutrino mass matrix would take the form, for one flavor (in the space of $(\nu_L,\bar{\nu}_R)$):

$$\begin{pmatrix} 0 & m_D \\ m_D & M_R \end{pmatrix} \qquad [11]$$

**Table 4** Quark masses

| $u$ (MeV) | $c$ (GeV) | $t$ (GeV) | $d$ (MeV) | $s$ (MeV) | $b$ (GeV) |
|---|---|---|---|---|---|
| 1.5–4 | 1.15–1.35 | $174.3\pm5.1$ | 4–8 | 80–130 | 4.1–4.4 |

**Table 5** Leptons masses

| $\nu_e$(eV) | $\nu_\mu$(MeV) | $\nu_\tau$(MeV) |
|---|---|---|
| $<3$ | $<0.19$ | $<18.2$ |
| $e$ (MeV) | $\mu$ (MeV) | $\tau$ (MeV) |
| $0.510\,998\,92\pm4\times10^{-8}$ | $105.658369\pm9\times10^{-6}$ | $1776.99\pm0.26$ |

**Table 6** Gauge-boson masses

| *Photon* | *Gluons* | $W^\pm$(GeV) | $Z$ (GeV) |
|---|---|---|---|
| 0 | 0 | $80.425\pm0.038$ | $91.1876\pm0.0021$ |

If the Dirac masses are assumed to be of the same order of those of the quarks and if the right-handed Majorana masses $M_R$ are far larger, for example, of the order of the grand unified scale, $O(10^{16}\,\text{GeV})$, then diagonalization of the mass matrix would give, for the physical masses of the left-handed neutrinos, $\sim m_D^2/M_R \ll m_D$, much smaller than other fermion masses, quite naturally ("see-saw" mechanism).

**CKM Quark Mixing** As there is *a priori* no reason why the weak-interaction eigenstates should be equal to the mass eigenstates, the Yukawa couplings in eqn [2] are in general nondiagonal matrices in the flavor. Suppose that the the weak base for the quarks is given in terms of the mass eigenstates (in which quark masses are made diagonal), by unitary transformations

$$u_{Li}=\sum_j V^{\text{up}}_{ij}\tilde{u}_{Lj}, \qquad d_{Li}=\sum_j V^{\text{down}}_{ij}\tilde{d}_{Lj}$$

then the interaction terms with $W^\pm$ bosons [6] can be cast in the form (Kobayashi and Maskawa 1972)

$$\begin{aligned}\mathcal{L}^{W\text{-exc}} &= \bar{u}^i_L\gamma^\mu W^+_\mu U^{(\text{CKM})}_{ij} d^j_L \\ &\quad + \bar{d}^k_L\gamma^\mu W^-_\mu U^{(\text{CKM})\dagger}_{k\ell} u^\ell_L \end{aligned} \qquad [12]$$

where $U^{\text{CKM}}_{ij}\equiv(V^{\text{up}\dagger}\cdot V^{\text{down}})_{ij}$ is called Cabibbo–Kobayashi–Maskawa (CKM) matrix. It can be parametrized in terms of three Euler angles and one phase

$$U=\begin{pmatrix} U_{ud} & U_{us} & U_{ub} \\ U_{cd} & U_{cs} & U_{cb} \\ U_{td} & U_{ts} & U_{tb}\end{pmatrix}$$
$$=\begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta_{13}} \\ -s_{12}c_{23}-c_{12}s_{23}s_{13}e^{i\delta_{13}} & c_{12}c_{23}-s_{12}s_{23}s_{13}e^{i\delta_{13}} & s_{23}c_{13} \\ s_{12}s_{23}-c_{12}c_{23}s_{13}e^{i\delta_{13}} & c_{12}s_{23}-s_{12}c_{23}s_{13}e^{i\delta_{13}} & c_{23}c_{13}\end{pmatrix} \qquad [13]$$

where $c_{12}=\cos\theta_{12}, s_{23}=\sin\theta_{23}$, etc. The requirement that charge–current weak processes are all described by these matrix elements, satisfying the unitarity relation,

$$\sum_\ell U^{\text{CKM}}_{i\ell}U^{\text{CKM}\dagger}_{\ell k}=\delta_{ik} \qquad [14]$$

gives a very stringent test for the validity of the model.

### *CP* Violation

*CP* (product of charge conjugation and parity transformation) invariance is an approximate symmetry of Nature. Although it is known to be broken by very tiny amounts only, the exact extent and the nature of *CP* violation can have far-reaching consequences.

*CP* violation has first been discovered by Cronin and Fitch (BNL, 1964) in the *K*-meson system; more precise information on the nature of *CP* violation from the neutral kaon decays has been obtained more recently (2000) in NA48 (CERN) and KTeV (Fermilab) experiments. *CP* violation has been established in the *B*-meson systems as well, very recently (2002), by Babar experiments at SLAC and Belle experiments at KEK.

Through the so-called *CPT* theorem, *CP* invariance (or violation) is closely related to the *T* (time-reversal invariance) symmetry. Also, *CP* noninvariance is one of the conditions needed in the cosmological baryon number generation (baryogenesis).

In the GWS theory, with three families of quark flavors (six quarks), there is just one source of *CP* violation: the phase $\delta_{13}$ appearing in the CKM matrix (eqn [13]). For $\delta \neq 0, \pi$, *W*-exchange interactions [12] induce *CP* violation. The earlier and more recent experimental data on $K^0 - \bar{K}^0$ mixing and $K_{L,S}$ decay data appear to be compatible with the CKM mechanism for *CP* violation, but a quantitative comparison with the SM remains somewhat hindered by the difficulty of estimating certain strong interaction effects. The recent confirmation of *CP* violation in *B* systems is made in the context of a global fit with the SM predictions such as the "unitarity triangle" relations, for example,

$$1 + \frac{U_{ud}\,U^*_{ub}}{U_{cd}\,U^*_{cb}} + \frac{U_{td}\,U^*_{tb}}{U_{cd}\,U^*_{cb}} = 0 \qquad [15]$$

(eqn [14]), and by combining data from kaon deays, charmed meson decays, *B* meson decay and mixings, etc., and is a part of direct tests of the GWS model, with nonvanishing *CP* violation CKM

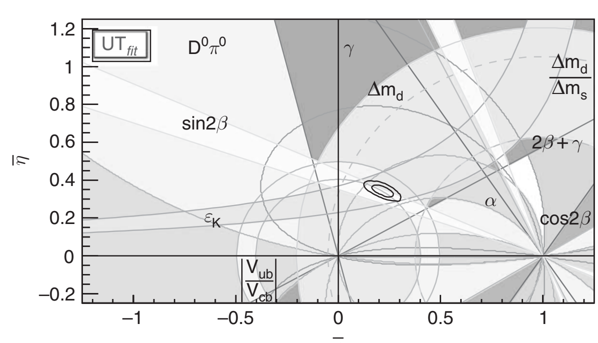

**Figure 1** Unitarity triangle test (Eq. (15)). The small ellipses represent 68% and 95% probability zones for the apex corresponding to $U_{ud}U^*_{ub}/U_{cd}U^*_{cb}$. Reproduced from M. Bona *et al.* (2005) The 2004 UTfit collaboration report on the status of the unitarity triangle in the standard model. Journal of High Energy Physics. 0507: 028–059 (hep-ph/0501199), with permission from IoP Publishing Ltd and the UTfit collaboration.

phase (eqn [16] and **Figure 1**). Recent evidence for nonzero neutrino masses and mixings opens the way to possible *CP* violation in the leptonic processes as well.

Finally, within the SM including strong interactions, there is one more source of *CP* violation: the so-called $\theta$ (vacuum) parameter of QCD.

### *B* and *L* Nonconservation

Another set of approximate symmetries in Nature are the baryon and lepton number conservations. In the electroweak theory, these global symmetries are exact to all orders of perturbation theory. Nonperturbative effects (a sort of barrier penetration in gauge field space) however violate both *B* and *L*; the combination *B–L* is conserved even nonperturbatively though. The nonperturbative electroweak baryon number violation is an extremely tiny effect, the amplitude being proportional to the typical tunneling factor $e^{-2\pi/\alpha}$, but the process is unsuppressed at finite temperatures as might have been experienced by the universe at some early stage after big bang.

*B* or *L* nonconservation can also arise naturally at high energy scales, if the electroweak theory is embedded as the low-energy approximation in a grand unified model. The experimental lower limit of proton lifetime, $\tau_P \geq 10^{32}$ years, from Kamiokande experiments, however severely restricts acceptable models of this type (the simplest SU(5) model is already ruled out).

On the other hand, cosmological baryogenesis requires sufficient amount of baryon number violation, at least in some stage of cosmological expansion. Detailed analyses suggest that the standard electroweak transition might not in itself explain the baryon number $n_P/n_\gamma \sim 10^{-10}$ observed in the present universe. Recent observations of neutrino oscillations suggest the right-handed Majorana-type neutrino masses to be present, which violate the lepton number *L*. In such a case it might be possible that the correct amount of baryon number excess would be generated, through the leptogenesis.

### Global Fit

Various relations exist at the tree level among the masses, scattering cross sections, decay rates, various asymmetries, etc., which can be read off or calculated from the formulas given earlier. These quantities receive corrections at higher orders, and the experimental checks of these modified relations provide precision tests of the model on the one hand, and possibly a hint for new physics, if there is any discrepancy with the prediction. Very often the amplitudes of interest

receive important contributions due to strong interactions, which are difficult to estimate.

The basic parameters of the model, apart from the Higgs mass, and fermion masses and mixing parameters, can be taken to be (1) the fine structure constant, $\alpha = 1/137.035\,999\,11(46)$; (2) the Fermi constant $G_F = 1.166\,37 \times 10^{-5}\,\text{GeV}^{-2}$ (which can be determined from the muon lifetime), and the Z-boson mass, $M_Z = 91.1876 \pm 0.0021$ GeV (observed directly at LEP). $M_W$ and $\sin^2\theta_W$ are then calculable numbers, in terms of these quantities, and depending on $m_t$ (measured independently by CDF and DØ experiments at Fermilab) and on the unknown $M_H$.

Such precision tests of the GWS model are being made, combining the analyses of various decay rates and asymmetries in $B$-meson systems at $B$ factories and in colliders, production and decays of $Z$ and $W$ bosons, elastic $\nu e$ or $\bar{\nu} e$ scatterings, elastic $\nu p$ or $\bar{\nu} p$ scatterings, deep inelastic lepton nucleon (or deuteron) scatterings, the muon anomalous magnetic moment, atomic parity violation experiments, etc.

An overall fit to the data gives an excellent agreement, with the input parameters

$$M_H = 113^{+56}_{-40}\,\text{GeV}, \quad m_t = 176.9 \pm 4.0\,\text{GeV}, \quad \alpha_s(M_Z) = 0.1213 \pm 0.0018$$

For instance (in GeV),

$$M_W = 80.390 \pm 0.018 \quad \text{vs.} \quad 80.412 \pm 0.042 \; \text{(exp. value (LEP))}$$
$$\Gamma_Z = 2.4972 \pm \pm 0.0012 \quad \text{vs.} \quad 2.4952 \pm 0.0023 \; \text{(exp. value)}$$

For $\sin^2\theta_W$ (defined in the so-called $\overline{MS}$ scheme) all data give consistently the value

$$\sin^2\theta_W = 0.231\,20 \pm 0.000\,15$$

(a slightly larger value is reported by an $\nu N$ experiment at Fermilab).

The unitarity-triangle tests of the SM and determination of CKM matrix have already been mentioned. The results of global fit can be summarized in Figure 1, and by the angles

$$\begin{aligned} s_{12} &= 0.2243 \pm 0.0016 \\ s_{23} &= 0.0413 \pm 0.0015 \\ s_{13} &= 0.037 \pm 0.0005 \\ \delta_{13} &= 60^\circ \pm 14^\circ \end{aligned} \qquad [16]$$

For the muon anomalous gyromagnetic ratio $(g-2)$, the experimental data

$$a_\mu^{\text{exp}} = \frac{g_\mu - 2}{2} = (1.116\,5920(37) \pm 0.78) \times 10^{-9}$$

is to be compared with the theoretical prediction

$$a_\mu^{\text{th}} = (1.1165918(83) \pm 0.49) \times 10^{-9}$$

which is slightly smaller $(1.9\sigma)$, where the largest theoretical uncertainty comes from the two-loop hadronic contribution $a_\mu^{\text{had}} \simeq (69.63 \pm 0.72) \times 10^{-9}$ (the QED corrections to $O(\alpha^5)$ are included).

For further details of the analyses and the present status of experimental tests of the electroweak theory, see the reviews by J Erler and P Langacker, and by F J Gilman *et al.*, cited in "Further reading" (most of numbers cited here come from these two reviews).

## Need for Extension of the Model

In spite of such an impressive experimental confirmation, there are reasons to believe that the electroweak theory, in its standard minimal form, is not a complete story. As already mentioned, neutrino oscillations, predicted earlier by Pontecorvo, have recently been experimentally confirmed, giving uncontroversial evidence for nonvanishing neutrino masses and their mixing. This is a clear signal that the theory must be extended. If the mass is instead taken in the form of eqn [11] but with three neutrinos families, the diagonalization in general yields a mixing for the light neutrinos, as for the quarks. Some of the experimental data on the neutrinos are summarized in Table 7.

In addition, the Higgs sector of the theory (the part of the interactions responsible for spontaneous breaking $SU_L(2) \times U(1) \to U_{EM}(1)$) is still largely untested. The theory predicts a physical scalar particle, the Higgs particle, of unknown mass. The present-day expectation for its mass, which combines the experimental lower limit and an indirect upper limit following from the analysis of various radiative corrections, is

$$114\,(\text{GeV}) < m_H < 250\,(\text{GeV})$$

This particle should be observable either in the Tevatron at Fermilab or in the coming LHC

**Table 7** Neutrino mass square differences and mixing

| $\nu_e$ | | $\nu_\mu$ | | $\nu_\tau$ |
|---|---|---|---|---|
| $\Delta_{12} m^2$ | = | (6 – 9) | $\times$ | $10^{-5}\,\text{eV}^2$ |
| $\Delta_{23} m^2$ | = | (1 – 3) | $\times$ | $10^{-3}\,\text{eV}^2$ |

Solar neutrinos and reactor (SNO, SuperKamiokande, KamLAND) experiments give the first results. Atmospheric neutrino data and the long baseline experiment (SuperKamiokande, K2K) provide the second. The mixing angle relevant to the solar and reactor neutrino oscillation is large, $\tan^2\theta_{12} \sim 0.40^{+0.10}_{-0.07}$, while the one related to the atmospheric neutrino data is maximal, $\sin^2 2\theta_{23} \sim 1$. Cosmological considerations give $\sum m_{\nu_i} < O(1\,\text{eV})$.

experiments at CERN; negative results would force upon us a substantial modification of the electroweak theory.

Last, but not least, there are a few theoretical motivations for an extension of the model to be considered necessary. First, the structure of the GWS theory is not entirely determined by the gauge principle. The form of the Higgs self-interactions, as well as their number and the Yukawa couplings of the Higgs scalar to the fermions, are unconstrained by any principle, and the particular, minimal form assumed by Weinberg and Salam is yet to be confirmed experimentally.

In addition, the theory is not really a unified gauge theory: $SU_L(2)$ and U(1) gauge couplings are distinct. One possibility is that the $SU(3)_{QCD} \times SU_L(2) \times U(1)$ theory of the SM is actually a low-energy manifestation of a truly unified gauge theory – grand unified theory (GUT) – defined at some higher mass scale. The simplest version of GUT models based on SU(5) or SO(10) gauge groups has however a difficulty with the proton decay rates, and with the coupling-constant unification itself. Supersymmetric GUTs appear to be more acceptable both from the coupling-constant unification and from the proton lifetime constraints.

A more subtle, but perhaps more severe theoretical problem, is the so-called naturalness problem. At the quantum level, due to the quadratic divergences in the scalar mass, the structure of the theory turns out to be quite peculiar. If the ultraviolet cutoff of the theory is taken to be the Planck mass scale, $\Lambda_{UV} \sim m_{Pl} \sim 10^{19}$ GeV, at which gravity becomes strongly coupled, the theory at $\Lambda_{UV}$ would have to possess parameters which are fine-tuned with an excessive precision. The problem is known also as a "hierarchy" problem.

A way to avoid having such a difficulty is to introduce supersymmetry. In a supersymmetric version of the standard theory – in fact, there are phenomenologically well-acceptable models such as the minimal supersymmetric standard model (MSSM) – this problems is absent due to the cancellation of bosonic and fermionic loop contributions typical of supersymmetric theories. As a result, the properties of the theory at low energies are much less sensitive to those of the theory at the Planck mass scale. Experiments at LHC (expected to be performed after 2008, CERN) should be able to produce a whole set of new particles associated with supersymmetry, if this is a part of the physical law beyond TeV energies.

At a deeper level, however, the hierarchy problem in a more general sense persists, even in supersymmetric models: why the masses of the order of $O(100\ \text{GeV})$ should appear at all in a theory with a natural cutoff of the order of the Planck mass? Furthermore, if the masses of the neutrinos turn out to be of the order of $O(10^{-3}\text{–}10^{0})$ eV, we are left with the problem of understanding the large disparities among the quark and lepton masses, spanning the range of more than 13 orders of magnitudes: another "hierarchy" problem.

It is also possible that the spacetime the physical world lives in is actually higher dimensional: the usual four-dimensional Minkowski spacetime times either compactified or uncompactified "extra dimensions." In theories of this type, some of the difficulties mentioned above might find a natural solution. It is yet to be seen whether a consistent theory of this type can be constructed that correctly account for the properties of the universe we inhabit.

## Bibliographic Notes

A short but comprehensive introduction to the Weinberg–Salam theory is found in Taylor (1976); see also Abers and Lee (1973) and 't Hooft and Veltman (1973).

The reprint collection edited by Taylor (2001) contains many of fundamental papers, e.g., on Yang–Mills theories (by C N Yang, R L Mills, R Shaw), on spontaneous symmetry breaking and its application to gauge theories (by Y Nambu, J Schwinger, P W Anderson, P W Higgs, F Englert, R Brout, T W B Kibble) and on renormalization of Yang–Mills theories and application to the electroweak theory (L D Faddeev, V N Popov, G 't Hooft).

For up-to-date review on precision tests of the GWS theory, and details of the analyses, see Erler and Langacker (2004), and references cited therein.

For a recent review on neutrino experiments, see Shirai (2005). For theory on neutrinos, see Fukugita and Yanagida (2003).

For the unitarity triangle test of the GWS model and determination of CKM matrix elements, see results from the CKM fitter Group (Bret *et al.* 2005), the UTfit Collaboration (Bona *et al.* 2005), and a review by Gilman *et al.* (2005), and references cited therein.

## Introduction

### Motivation: A Model Problem

Many physical problems can be modeled by partial differential equations. Let us consider, for example, the case of an elastic membrane $\Omega$, with fixed boundary $\Gamma$, subject to pressure forces $f$. The vertical membrane displacement is represented by a real-valued function $u$, which solves the equation

$$-\Delta u(x) = f(x), \quad x = (x_1, x_2) \in \Omega \qquad [1]$$

where the Laplace operator $\Delta$ is defined, in two dimensions, by

$$\Delta u = \frac{\partial^2 u}{\partial x_1^2} + \frac{\partial^2 u}{\partial x_2^2}$$

As the membrane is glued to the curve $\Gamma$, $u$ satisfies the condition

$$u(x) = 0, \quad x \in \Gamma \qquad [2]$$

The system [1]–[2] is the homogeneous Dirichlet problem for the Laplace operator. It enters the more general framework of (linear) elliptic boundary value problems, which consist of a (linear) partial differential equation (in the example above, of order two: the highest order in the derivatives) inside an open set $\Omega$ of the whole space $\mathbb{R}^N$, satisfying some "elliptic" property, completed by (linear) conditions on the boundary $\Gamma$ of $\Omega$, called "boundary conditions." In the sequel, we only consider the linear case.

Our aim is to answer the following questions: does this problem admit a solution? in which space? is this solution unique? does it depend continuously on the given data $f$? In case of positive answers, we say that the problem is "well posed" in the Hadamard sense. But other questions can also be raised, such as the sign of the solution, for example, or its regularity. We give a full survey of linear elliptic problems in a bounded or in an exterior domain with a sufficiently smooth boundary and in the whole space. In the general theory of the elliptic problem, we consider only smooth coefficients. We survey the standard theory, which can be found in the several well-known monographs of the 1960s. The new trends in the investigation of the elliptic problems is to consider more general domains with nonsmooth boundaries and nonsmooth coefficients. On the other hand, the regularity results for elliptic systems have not been improved during last 30 years. New trends also require employment of more general function spaces and more general functional background.

The number of references (see "Further reading" section) is strictly limited here; we list only some of the most important publications. The basic facts can usually be found in more places and sometimes we do not mention the particular reference. Among the

very basic references are Friedman (1969), Gilbarg and Trudinger (1977), Dautray and Lions (1988), Hörmander (1964), Ladyzhenskaya and Uraltseva (1968), Lions and Magenes (1968), Renardy and Rogers (1992), and Weinberger (1965); of course, there are many others.

### The Method

To answer the above questions, we generally use, for such elliptic problems, an approach based on what is called a "variational formulation" (see the section "Variational approach"): the boundary-value problem is first transformed into a variational problem of lower order, which is solved in a Hilbertian frame with help of the Lax–Milgram theorem (based on the representation theorem). All questions are then solved (e.g., existence, uniqueness, continuity in terms of the data, regularity). But this variational formalism does not necessary allow to treat all the situations and it is limited to the Hilbertian case. Other strategies can then be developed, based on *a priori* estimates and duality arguments for the existence problem, or maximum principle for the question of unicity. Without forgetting the particular cases where an explicit Green kernel is computable (e.g., the Laplacian operator in the whole space case).

Moreover, the study of linear elliptic equations is directly linked to the background of function spaces. It is the reason why we first deal with Sobolev spaces – both of the integer and fractional order and we survey their basic properties, imbedding and trace theorems. We pay attention to the Riesz and Bessel potentials and we define weighted Sobolev spaces important in the context of unbounded opens. Second, we present the variational approach and the Lax–Milgram theorem as a key point to solve a large class of boundary-value problems. We give examples: the Dirichlet and Neumann problems for the Poisson equation, the Newton problem for more general second-order operators; we also investigate mixed boundary conditions and present an example of a problem of fourth order. Then, we briefly present the arguments for studying general elliptic problems and concentrate on second-order elliptic problems; we recall the weak and strong maximum principle, formulate the Fredholm alternative and tackle the regularity questions. Moreover, we are interested in the existence and uniqueness of solution of the Laplace equation in the whole space and in exterior opens. Finally, we present some particular examples arising from physical problems, either in fluid mechanics (the Stokes system) or in elasticity.

## Sobolev and Other Types of Spaces

Throughout, $\Omega \subset \mathbb{R}^N$ will generally be an open subset of the $N$-dimensional Euclidean space $\mathbb{R}^N$. A domain will be an open and connected subset of $\mathbb{R}^N$. We shall use standard notations for the spaces $L^p(\Omega)$, $C^\infty(\Omega)$, etc., and their norms. Let us agree that $C^{k,r}(\Omega)$, $k \in \mathbb{N}$, $r \in (0,1)$, denote the space of functions $f$ in $C^k(\Omega)$, whose derivatives $D^\alpha f$, $\alpha = (\alpha_1, \ldots, \alpha_N) \in \mathbb{N}^N$, of order $|\alpha| = \sum_{i=1}^N \alpha_i = k$ are all $r$-Hölder continuous. In the notations for some of these spaces, by $\bar{\Omega}$ we mean that the functions have the corresponding property on $\Omega$ and that they can be continuously extended to $\bar{\Omega}$.

Let us recall several fundamental concepts. The space $\mathcal{D}(\Omega)$ of the test functions in $\Omega$ consists of all infinitely differentiable $\varphi$ with a compact support in $\Omega$. A locally convex topology can be introduced here. The elements of the dual space $\mathcal{D}'(\Omega)$ are called the distributions. If $f \in L^1_{\text{loc}}(\Omega)$ (i.e., $f \in L^1(K)$ for all compact subsets $K$ of $\Omega$), then $f$ is a regular distribution; the duality is represented by $\int_\Omega f(x)\varphi(x)\,dx$. If $f \in \mathcal{D}'(\Omega)$, we define the distributional or the weak derivative $D^\alpha$ of $f$ as the distribution $\varphi \mapsto (-1)^{|\alpha|}\langle f, D^\alpha \varphi\rangle$. Plainly, if $f \in L^1_{\text{loc}}$ has "classical" partial derivatives in $L^1_{\text{loc}}$, then it coincides with the corresponding weak derivative.

If $\Omega = \mathbb{R}^N$, it is sometimes more suitable to work with the tempered distributions. The role of $\mathcal{D}(\Omega)$ is played by the space $\mathcal{S}(\mathbb{R}^N)$ of $C^\infty$-functions with finite pseudonorms $\sup |D^\alpha f(x)|(1+|x|)^k, |\alpha|, k = 0, 1, 2, \ldots$. Recall that the Fourier transform $\mathcal{F}$ maps $\mathcal{S}(\mathbb{R}^N)$ into itself and the same is true for the space of the tempered distributions $\mathcal{S}'(\mathbb{R}^N)$.

### Sobolev Spaces of Positive Order

The Sobolev space $W^{k,p}(\Omega)$, $1 \le p \le \infty$, $k \in \mathbb{N}$, is the space of all $f \in L^p(\Omega)$ whose weak derivatives up to order $k$ are regular distributions belonging to $L^p(\Omega)$; in $W^{k,p}(\Omega)$ we introduce the norm

$$\|f\|_{W^{k,p}(\Omega)} = \left( \sum_{|\alpha| \le k} \int_\Omega |D^\alpha f(x)|^p \,dx \right)^{1/p} \qquad [3]$$

when $p < \infty$ and $\max_{|\alpha| \le k} \sup \operatorname{ess}_{x \in \Omega} |D^\alpha f(x)|$ if $p = \infty$. The space $W^{k,p}(\Omega)$ is a Banach space, separable for $p < \infty$ and reflexive for $1 < p < \infty$; it is a Hilbert space for $p = 2$, more simply denoted $H^m(\Omega)$. In the following, we shall consider only the range $p \in (1, \infty)$.

The link with the classical derivatives is given by this well-known fact: a function $f$ belongs to $W^{1,p}(\Omega)$ if and only if it is a.e. equal to a function $\tilde{u}$, absolutely continuous on almost all line segments in $\Omega$ parallel to the coordinate axes, whose (classical) derivatives belong to $L^p(\Omega)$ (the Beppo–Levi theorem).

For $1 < p < \infty$ and noninteger $s > 0$ the Sobolev space $W^{s,p}(\Omega)$ of order $s$ is defined as the space of all $f$ with the finite norm

$$\|f\|_{W^{s,p}(\Omega)} = \left( \|f\|^p_{W_p^{[s]}(\Omega)} + \sum_{|\alpha|=[s]} \int_\Omega \int_\Omega \frac{|D^\alpha f(x) - D^\alpha f(y)|^p}{|x-y|^{N+p(s-[s])}} \right)^{1/p}$$

where $[s]$ is the integer part of $s$ (for details, see, e.g., Adams and Fournier (2003) and Ziemer (1989)).

### Imbedding Theorems

One of the most useful and important features of the functions in Sobolev spaces is an improvement of their integrability properties and the compactness of various imbeddings. Theorems of this type were first proved by Sobolev and Kondrashev. Let us agree that the symbols $\hookrightarrow$ and $\hookrightarrow\hookrightarrow$ stand for an imbedding and for a compact imbedding, respectively.

**Theorem 1** *Let $\Omega$ be a Lipschitz open. Then*

(i) *If $sp < N$, then $W^{s,p}(\Omega) \hookrightarrow L^{p^*}(\Omega)$ with $p^* = Np/(N - ps)$ (the Sobolev exponent). If $|\Omega| < \infty$, then the target space is any $L^r(\Omega)$ with $0 < r \le p^*$.*
*If $\Omega$ is bounded, then $W^{s,p}(\Omega) \hookrightarrow\hookrightarrow L^q(\Omega)$ for all $1 \le q < p^*$.*

(ii) *If $sp > N$, then $W^{j+s,p}(\Omega) \hookrightarrow C^j(\Omega)$ for $j = 0,1,\ldots$. If $\Omega$ has the Lipschitz boundary, then $W^{j+s,p}(\Omega) \hookrightarrow C^{j,\mu}(\bar\Omega)$ for $j = 0,1,\ldots$ and $\mu = s - N/p$.*
*If $sp > N$, then $W^{j+s,p}(\Omega) \hookrightarrow\hookrightarrow C^j(\Omega)$, $j = 0,1,\ldots$ and $W^{j+s,p}(\Omega) \hookrightarrow\hookrightarrow W^j_q(\Omega)$ for all $1 \le q \le \infty$. If, moreover, $\Omega$ has the Lipschitz boundary, then the target space can be replaced by $C^{j,\mu}(\bar\Omega)$ provided $sp > N > (s-1)p$ and $0 < \mu < s - N/p$.*

Note that if the imbedding $W^{s,p}(\Omega) \hookrightarrow L^q(\Omega)$ is compact for some $q \ge p$, then $|\Omega| < \infty$. Moreover, if $\limsup_{r\to\infty} |\{x \in \Omega; r \le |x| < r+1\}| > 0$, then $W^{s,p}(\Omega) \hookrightarrow L^q(\Omega)$ cannot be compact.

### Traces and Sobolev Spaces of Negative Order

Let $s > 0$ and let $\Omega$ be, for simplicity, a bounded open subset of $\mathbb{R}^N$ with boundary $\Gamma$ of class $C^{[s],1}$. Then with the help of local coordinates, we can define Sobolev spaces $W^{s,p}(\Gamma)$ (also denoted $H^s(\Gamma)$ for $p = 2$) on $\Gamma = \partial\Omega$ (see, e.g., Nečas (1967) and Adams and Fournier (2003) for details). If $f \in C(\bar\Omega)$, then $f_{|\Gamma}$ has sense. Introducing the space $\mathcal{D}(\bar\Omega)$ of restrictions in $\Omega$ of functions in $\mathcal{D}(\mathbb{R}^N)$, one can show that if $f \in \mathcal{D}(\bar\Omega)$, we have $\|f_{|\Gamma}\|_{W^{1-1/p,p}(\Gamma)} \le C\|f\|_{W^{1,p}(\Omega)}$ so that, in view of the density of $\mathcal{D}(\bar\Omega)$ in $W^{1,p}(\Omega)$, the restriction of $f$ to $\Gamma$ can be uniquely extended to the whole $W^{1,p}(\Omega)$. The result is the bounded trace operator $\gamma_0 : W^{1,p}(\Omega) \to W^{1-1/p,p}(\Gamma)$. Moreover, every $g \in W^{1-1/p,p}(\Gamma)$ can be extended to a (nonunique) function $f \in W^{1,p}(\Omega)$ and this extension operator is bounded with respect to the corresponding norms.

More generally, let us suppose $\Gamma$ is of class $C^{k-1,1}$ and define the operator $\mathrm{Tr}_n$ for any $f \in \mathcal{D}(\bar\Omega)$ by $\mathrm{Tr}_n f = (\gamma_0 f, \gamma_1 f, \ldots, \gamma_{k-1} f)$, where

$$\gamma_j f(x) = \frac{\partial^j f}{\partial n^j}(x) = \sum_{|\alpha|=j} \frac{j!}{\alpha!}(\partial^\alpha f(x)/\partial x^\alpha) n^\alpha, \quad x \in \Gamma$$

is the $j$th-order derivative of $f$ with respect to the outer normal $n$ at $x \in \Gamma$; by density, this operator can be uniquely extended to a continuous linear mapping defined on the space $W^{k,p}(\Omega)$; moreover, $\gamma_0(W^{k,p}(\Omega)) = W^{k-1/p,p}(\Gamma)$.

The kernel of this mapping is the space $\mathring{W}^{k,p}(\Omega)$ (denoted by $H_0^k(\Omega)$ for $p = 2$), where $\mathring{W}^{s,p}(\Omega)$ is defined as the closure of $\mathcal{D}(\Omega)$ in $W^{s,p}(\Omega)$ ($s > 0$). For $1 < p < \infty$, the following holds: $\mathring{W}^{s,p}(\mathbb{R}^N) = W^{s,p}(\mathbb{R}^N)$, $\mathring{W}^{s,p}(\Omega) = W^{s,p}(\Omega)$ provided $0 < s \le 1$ $p$. If $s < 0$, then the space $W^{s,p}(\Omega)$ is defined as the dual to $\mathring{W}^{-s,p'}(\Omega)$, where $p' = p/(p-1)$ (see, e.g., Triebel (1978, 2001)). Observe that, for an arbitrary $\Omega$, a function $f \in W^{1,p}(\Omega)$ has the zero trace if and only if $f(x)/\mathrm{dist}(x,\Gamma)$ belongs to $L^p(\Omega)$.

For $p = 2$, we simply denote by $H^{-k}(\Omega)$ the dual space of $H_0^k(\Omega)$. In the case of bounded opens, we recall the following useful Poincaré–Friedrichs inequality (for simplicity, we state it here in the Hilbert frame):

**Theorem 2** *Let $\Omega$ be bounded (at least in one direction of the space). Then there exists a positive constant $C_P(\Omega)$ such that*

$$\|v\|_{L_2(\Omega)} \le C_P(\Omega)\|\nabla v\|_{[L_2(\Omega)]^N} \quad \text{for all } v \in H_0^1(\Omega) \qquad [4]$$

### The Whole-Space Case: Riesz and Bessel Potentials

The Riesz potentials $\mathcal{I}_\alpha$ naturally occur when one defines the formal powers of the Laplace operator $\Delta$. Namely, if $f \in \mathcal{S}(\mathbb{R}^N)$ and $\alpha > 0$, then

$$\mathcal{F}\left[(-\Delta)^{\alpha/2} f\right](\xi) = |\xi|^\alpha \mathcal{F}f(\xi).$$

This can be taken formally as a definition of the Riesz potential $\mathcal{I}_\alpha$ on $\mathcal{S}'(\mathbb{R}^N)$,

$$\mathcal{I}_\alpha f(.) = \mathcal{F}^{-1}[|\xi|^{-\alpha}\mathcal{F}f(\xi)](.)$$

for any $\alpha \in \mathbb{R}$. If $0 < \alpha < N$, then $I_\alpha f(x) = (I_\alpha * f)(x)$, where $I_\alpha$ is the inverse Fourier transform of $|\xi|^{-\alpha}$,

$$I_\alpha(x) = C_\alpha |x|^{\alpha-N}$$
$$C_\alpha = \Gamma((N-\alpha)/2)\left(\pi^{N/2}2^\alpha\Gamma(\alpha/2)\right)^{-1}$$

where $\Gamma$ is the Gamma function and $I_\alpha$ is the Riesz kernel. The following formula is also true:

$$I_\alpha(x) = C_\alpha \int_0^\infty t^{(\alpha-N)/2} e^{-\pi|x|^2/t} \frac{dt}{t}$$

Recall that every $f \in \mathcal{S}(\mathbb{R}^N)$ can be represented as the Riesz potential $\mathcal{I}_\alpha g$ of a suitable function $g \in \mathcal{S}(\mathbb{R}^N)$, namely $g = (-\Delta)^{\alpha/2} f$; we get the representation formula

$$f(x) = \mathcal{I}_\alpha g(x) = C_\alpha \int_{\mathbb{R}^N} \frac{g(y)}{|x-y|^{N-\alpha}} dy$$

The standard density argument implies then an appropriate statement for functions in $W^{k,p}(\mathbb{R}^N)$ with an integer $k$ and for the Bessel potential spaces $\mathcal{H}^{\alpha,p}(\mathbb{R}^N)$ – see below for their definition. The original Sobolev imbedding theorem comes from the combination of this representation and the basic continuity property of $I_\alpha, \alpha p < N$,

$$I_\alpha: L^p(\mathbb{R}^N) \to L^q(\mathbb{R}^N), \quad \frac{1}{q} = \frac{1}{p} - \frac{\alpha}{N}$$

To get an isomorphic representation of a Bessel potential space (of a Sobolev space with positive integer smoothness in particular) it is more convenient to consider the Bessel potentials (of order $\alpha \in \mathbb{R}$),

$$\mathcal{G}_\alpha f(x) = (G_\alpha * f)(x) = \mathcal{F}^{-1}\left([1+|\xi|^2]^{-\alpha/2}\mathcal{F}f(\xi)\right)(x)$$

(with a slight abuse of the notations); the following formula for the Bessel kernel $G_\alpha$ is well known:

$$G_\alpha(x) = c_\alpha^{-1} \int_0^\infty t^{(\alpha-N)/2} e^{-(\pi|x|^2/t)-(t/4\pi)} \frac{dt}{t}$$

(cf. the analogous formula for $I_\alpha$), where $c_\alpha = (4\pi)^{\alpha/2}\Gamma(\alpha/2)$. The kernels $G_\alpha$ can alternatively be expressed with help of Bessel or Macdonald functions.

Now we can define the Bessel potential spaces. For $s \in \mathbb{R}$ and $1 < p < \infty$, let $\mathcal{H}^{s,p}(\mathbb{R}^N)$ be the space of all $f \in \mathcal{S}'(\mathbb{R}^N)$ with the finite norm

$$\|f\|_{\mathcal{H}^{s,p}(\mathbb{R}^N)} = \left(\int_{\mathbb{R}^N} \mathcal{F}^{-1}\left((1+|\xi|^2)^{s/2}\mathcal{F}f(\xi)\right)^p d\xi\right)^{1/p}$$

In other words, the spaces $\mathcal{H}^{s,p}(\mathbb{R}^N)$ are isomorphic copies of $L^p(\mathbb{R}^N)$.

For $k = 0, 1, 2, \ldots$, plainly $\mathcal{H}^{k,2}(\mathbb{R}^N) = W^{k,2}(\mathbb{R}^N)$ by virtue of the Plancherel theorem. But it is true also for integer $s$ and general $1 < p < \infty$ (see, e.g., Triebel (1978)).

**Remark 3** Much more comprehensive theory of general Besov and Lizorkin–Triebel spaces in $\mathbb{R}^N$ has been established in the last decades, relying on the the Littlewood–Paley theory. Spaces on opens can be defined as restrictions of functions in the corresponding space on the whole $\mathbb{R}^N$, allowing to derive their properties from those valid for functions on $\mathbb{R}^N$. The justification for that are extension theorems. In particular, there exists a universal extension operator for the Lipschitz open, working for all the spaces mentioned up to now. We refer to Triebel (1978, 2001).

### Unbounded Opens and Weighted Spaces

The study of the elliptic problems in unbounded opens is usually carried out with use of suitable Sobolev weighted space. The Poisson equation

$$-\Delta u = f \quad \text{in } \mathbb{R}^N, \ N \geq 2 \qquad [5]$$

is the typical example; the Poincaré inequality [4] is not true here and it is suitable to introduce Sobolev spaces with weights.

Let $m \in \mathbb{N}$, $1 < p < \infty$, $\alpha \in \mathbb{R}$, $k = m - N/p - \alpha$ if $N/p + \alpha \in \{1, \ldots, m\}$ and $k = -1$ elsewhere. For an open $\Omega \subset \mathbb{R}^N$, we define

$$W_\alpha^{m,p}(\Omega) = \Big\{v \in \mathcal{D}'(\Omega), 0 \leq |\lambda| \leq k, \ \rho^{\alpha-m-|\lambda|}(\log\rho)^{-1}D^\lambda u \in L^p(\Omega), \ k+1 \leq |\lambda| \leq m, \ \rho^{\alpha-m+|\lambda|}D^\lambda u \in L^p(\Omega)\Big\}$$

where $\rho(x) = (1+|x|^2)^{1/2}$. Note that $W_\alpha^{m,p}$ is a reflexive Banach space for the norm $\|.\|_{W_\alpha^{m,p}}$ defined by

$$\|u\|^p_{W_\alpha^{m,p}} = \sum_{0\leq|\lambda|\leq k} \|\rho^{\alpha-m+|\alpha|}(\log\rho)^{-1}D^\lambda u\|^p_{L^p(\Omega)} + \sum_{k+1\leq|\lambda|\leq m} \|\rho^{\alpha-m+|\alpha|}D^\lambda u\|^p_{L^p(\Omega)}$$

We also introduce the following seminorm:

$$|u|_{W_\alpha^{m,p}} = \left(\sum_{|\lambda|=m} \|\rho^\alpha D^\lambda u\|^p_{L^p(\Omega)}\right)^{1/p}$$

Let

$$\mathring{W}_\alpha^{m,p}(\Omega) = \{v \in W_\alpha^{m,p}; \gamma_0(v) = \cdots \gamma_{m-1}(v) = 0\}$$

If $\Omega$ is a Lipschitz domain, then $\overset{\circ}{W}{}^{m,p}_{\alpha}(\Omega)$ is the closure of $\mathcal{D}(\Omega)$ in $W^{m,p}_{\alpha}(\Omega)$, while $\mathcal{D}(\bar{\Omega})$ is dense in $W^{m,p}_{\alpha}(\Omega)$. We denote by $W^{-m,p'}_{-\alpha}(\Omega)$ the dual of $\overset{\circ}{W}{}^{m,p}_{\alpha}(\Omega)$ $(p' = p/(p-1))$. We note that these spaces also contain polynomials,

$$P_j \subset W^{m,p}_{\alpha}(\Omega)$$
$$\Leftrightarrow \begin{cases} j = \left[m - \dfrac{N}{p} - \alpha\right] & \text{if } \dfrac{N}{p} + \alpha \notin Z \\ j = m - \dfrac{N}{p} - \alpha & \text{elsewhere} \end{cases}$$

where $[s]$ is the integer part of $s$ and $P_{[s]} = \{0\}$ if $[s] < 0$. The fundamental property of functions belonging to these spaces is that they satisfy the Poincaré weighted inequality. An open $\Omega$ is an exterior domain if it is the complement of a closure of a bounded domain in $R^N$.

**Theorem 4** *Suppose that $\Omega$ is an exterior domain or $\Omega = \mathbb{R}^N_+$ or $\Omega = \mathbb{R}^N$. Then*

(i) *the seminorm $|\cdot|_{W^{m,p}_{\alpha}(\Omega)}$ is a norm on $W^{m,p}_{\alpha}(\Omega)/P_j$, equivalent to the quotient norm with $j' = \min(m-1, j)$;*
(ii) *the seminorm $|\cdot|_{W^{m,p}_{\alpha}(\Omega)}$ is equivalent to the full norm on $\overset{\circ}{W}{}^{m,p}_{\alpha}(\Omega)$.*

## Variational Approach

Let us first describe the method on the model problem [1]–[2], supposing $f \in L^2(\Omega)$ and $\Omega$ bounded. We first suppose that this problem admits a sufficiently smooth function $u$. Let $v$ be any arbitrary (smooth) function; we multiply eqn [1] by $v(x)$ and integrate with respect to $x$ over $\Omega$; this gives

$$\int_{\Omega} -(\Delta u v)(x)\mathrm{d}x = \int_{\Omega} (f v)(x)\mathrm{d}x$$

Using the following Green's formula ($\mathrm{d}\sigma(x)$ denotes the measure on $\Gamma = \partial\Omega$ and $\partial u(x)/\partial n = \nabla u(x) \cdot n(x)$, where $n(x)$ is the unit normal at point $x$ of $\Gamma$ oriented towards the exterior of $\Omega$):

$$\int_{\Omega} (\Delta u v)(x)\mathrm{d}x = -\int_{\Omega} (\nabla u \cdot \nabla v)(x)\mathrm{d}x + \int_{\Gamma} \left(\frac{\partial u}{\partial n} v\right)(\sigma)\mathrm{d}\sigma \qquad [6]$$

we get, since $v|_{\Gamma} = 0$: $\mathcal{A}(u,v) = L(v)$, where we have set

$$\mathcal{A}(u,v) = \int_{\Omega} \nabla u(x) \cdot \nabla v(x)\mathrm{d}x$$
$$L(v) = \int_{\Omega} f(x) v(x)\mathrm{d}x \qquad [7]$$

The idea is to study in fact this new problem (showing first its equivalence with the boundary-value problem), noting that it makes sense for far less regular functions $u$, $v$ (and also $f$), in fact $u, v \in H^1_0(\Omega)$ (and $f \in H^{-1}(\Omega)$).

### The Lax–Milgram Theorem

The general form of a variational problem is

$$\text{to find } u \in V \text{ such that } \mathcal{A}(u,v) = L(v) \text{ for all } v \in V \qquad [8]$$

where $V$ is a Hilbert space, $\mathcal{A}$ a bilinear continuous form defined on $V \times V$ and $L$ a linear continuous form defined on $V$. We say, moreover, that $\mathcal{A}$ is V-elliptic if there exists a positive constant $\alpha$ such that

$$\mathcal{A}(u,u) \geq \alpha \|u\|^2_V \quad \text{for all } u \in V \qquad [9]$$

The following theorem is due to Lax and Milgram.

**Theorem 5** *Let V be a Hilbert space. We suppose that $\mathcal{A}$ is a bilinear continuous form on $V \times V$ which is V-elliptic and that L is a linear continuous form on V. Then the variational problem [8] has a unique solution u on V. Moreover, if $\mathcal{A}$ is symmetric, u is characterized as the minimum value on V of the quadratic functional E defined by*

$$\text{for all } v \in V, \; E(v) = \tfrac{1}{2}\mathcal{A}(v,v) - L(v) \qquad [10]$$

**Remark 6**

(i) We have the following "energy estimate": $\|u\|_V \leq \frac{1}{\alpha}\|L\|_{V'}$ where $V'$ is the dual space to $V$. In the particular case of our model problem, this inequality shows the continuity of the solution $u \in H^1_0(\Omega)$ with respect to the data $f \in L^2(\Omega)$ (that can be weakened by choosing $f \in H^{-1}(\Omega)$).

(ii) Theorem 5 can be extended to sesquilinear continuous forms $\mathcal{A}$ defined on $V \times V$; such a form is called $V$-elliptic if there exists a positive constant $\alpha$ such that

$$\operatorname{Re}\mathcal{A}(u,u) \geq \alpha\|u\|^2_V \quad \text{for all } u \in V \qquad [11]$$

(iii) Denoting by $A$ the linear operator defined on the space $V$ by $\mathcal{A}(u,v) = \langle Au, v\rangle_{V',V}$, for all $v \in V$, the Lax–Milgram theorem shows that $A$ is an isomorphism from $V$ onto its dual space $V'$, and the problem [8] is equivalent to solving the equation $Au = L$.

(iv) Let us make some remarks concerning the numerical aspects. First, this variational formulation is the starting point of the well-known finite element method: the idea is to compute a solution of an approximate variational problem stated on a finite subspace of $V$ (leading to the resolution of a linear

system), with a precise control of the error with the exact solution $u$. Second, the equivalence with a minimization problem allows the use of other numerical algorithms.

Let us now present some classical examples of second-order elliptic problems than can be solved with help of the variational theory.

### The Dirichlet Problem for the Poisson Equation

We consider the problem on a bounded Lipschitz open $\Omega \subset \mathbb{R}^N$,

$$\begin{aligned} -\Delta u &= f \\ u &= u_0 \quad \text{on } \Gamma = \partial\Omega \end{aligned} \qquad [12]$$

with $u_0 \in H^{1/2}(\Gamma)$, so that there exists $U_0 \in H^1(\Omega)$ satisfying $\gamma_0(U_0) = u_0$. The variational formulation of problem [12] is

$$\begin{aligned} &\text{to find } u \in U_0 + H_0^1(\Omega) \text{ such that} \\ &\text{for all } v \in H_0^1(\Omega),\ \mathcal{A}(u,v) = L(v) \end{aligned} \qquad [13]$$

with $\mathcal{A}$ given by [7] and a more general $L$ with $f \in H^{-1}(\Omega)$, defined by

$$L(v) = \langle f, v\rangle_{H^{-1}(\Omega),H_0^1(\Omega)} \qquad [14]$$

The existence and uniqueness of a solution of [13] follows from Theorem 5 (and Poincaré inequality [4]). Conversely, thanks to the density of $\mathcal{D}(\Omega)$ in $H_0^1(\Omega)$, we can show that $u$ satisfies [12]. More precisely, we get:

**Theorem 7** *Let us suppose $f \in H^{-1}(\Omega)$ and $u_0 \in H^{1/2}(\Gamma)$; let $U_0 \in H^1(\Omega)$ satisfy $\gamma_0(U_0) = u_0$. Then the boundary-value problem [12] has a unique solution $u$ such that $u - U_0 \in H_0^1(\Omega)$. This is also the unique solution of the variational problem [13]. Moreover, there exists a positive constant $C = C(\Omega)$ such that*

$$\|u\|_{H^1(\Omega)} \le C\Big(\|f\|_{H^{-1}(\Omega)} + \|u_0\|_{H^{1/2}(\Gamma)}\Big) \qquad [15]$$

*which shows that $u$ depends continuously on the data $f$ and $u_0$.*

Moreover, using techniques of Nirenberg's differential quotients, we have the following regularity result (see, e.g., Grisvard (1980)):

**Theorem 8** *Let us suppose that $\Omega$ is a bounded open subset of $\mathbb{R}^N$ with a boundary of class $\mathcal{C}^{1,1}$ and let $f \in L^2(\Omega), u_0 \in H^{3/2}(\Gamma)$. Then $u \in H^2(\Omega)$ and each equation in [12] is satisfied almost everywhere (on $\Omega$ for the first one and on $\Gamma$ for the boundary condition). Moreover, there exists a positive constant $C = C(\Omega)$ such that*

$$\|u\|_{H^2(\Omega)} \le C[\|f\|_{L^2(\Omega)} + \|g\|_{H^{3/2}(\Gamma)}] \qquad [16]$$

By induction, if the data are more regular, that is, $f \in H^k(\Omega)$ and $u_0 \in H^{k+3/2}(\Gamma)$ (with $k \in \mathbb{N}$), and if $\Gamma$ is of class $\mathcal{C}^{k+1,1}$, we get $u \in H^{k+2}(\Omega)$.

**Remark 9** Let us point out the importance of the open geometry. For example, if $\Omega$ is a bounded plane polygon, one can find $u \in H_0^1(\Omega)$ with $\Delta u \in \mathcal{C}^\infty(\bar{\Omega})$, such that $u \notin H^{1+\pi/w}(\Omega)$, where $w$ is the biggest value of the interior angles of the polygon. In particular, if the polygon is not convex, the solution of the Dirichlet problem [12] cannot be in $H^2(\Omega)$.

### The Neumann Problem for the Poisson Equation

We consider the problem ($n$ is the unit outer normal on $\Gamma$)

$$\begin{aligned} -\Delta u &= f \quad \text{in } \Omega \\ \frac{\partial u}{\partial n} &= h \quad \text{on } \Gamma \end{aligned} \qquad [17]$$

Setting $E(\Delta) = \{v \in H^1(\Omega);\ \Delta v \in L^2(\Omega)\}$, the space $\mathcal{D}(\bar{\Omega})$ is a dense subspace, and we have the following Green formula for all $u \in E(\Delta)$ and $v \in H^1(\Omega)$:

$$\begin{aligned} &\int_\Omega \Delta u(x)v(x)\mathrm{d}x \\ &= -\int_\Omega \nabla u(x)\cdot\nabla v(x)\mathrm{d}x + \left\langle \frac{\partial u}{\partial n}, \gamma_0 v\right\rangle_{H^{-1/2}(\Gamma),H^{1/2}(\Gamma)} \end{aligned}$$

If $u \in H^1(\Omega)$ satisfies [17] with $f \in L^2(\Omega)$ and $h \in H^{-1/2}(\Gamma)$, then for any function $v \in H^1(\Omega)$, we have, by virtue of the above Green formula,

$$\begin{aligned} \mathcal{A}(u,v) &= \tilde{L}(v) \\ \tilde{L}v &= \int_\Omega (fv)(x)\mathrm{d}x + \langle h, \gamma_0 v\rangle_{H^{-1/2}(\Gamma),H^{1/2}(\Gamma)} \end{aligned}$$

But, here the form $\mathcal{A}$ is not $H^1(\Omega)$-elliptic; in fact, one can check that, if problem [17] has a solution, then we have necessarily (take $v = 1$ above)

$$\int_\Omega f(x)\,\mathrm{d}x + \langle h, 1\rangle_{H^{-1/2}(\Gamma),H^{1/2}(\Gamma)} = 0 \qquad [18]$$

Moreover, we note that if $u$ is a solution, then $u + C$, where $C$ is an arbitrary constant, is also a solution. So the variational problem is not well posed on $H^1(\Omega)$. It can, however, be solved in the quotient space $H^1(\Omega)/\mathbb{R}$, which is a Hilbert space for the quotient norm

$$\|\dot{v}\|_{H^1(\Omega)/\mathbb{R}} = \inf_{k\in\mathbb{R}} \|v + k\|_{H^1(\Omega)} \qquad [19]$$

but also for the seminorm $v \mapsto |v|_{H^1(\Omega)} = \sqrt{\mathcal{A}(v,v)}$, which is an equivalent norm on this quotient space (see Nečas (1967)).

Then, supposing that the data $f$ and $h$ satisfy the "compatibility condition" [18], we can apply the Lax–Milgram theorem to the variational problem

$$\begin{aligned}&\text{to find } \dot{u} \in V \text{ such that}\\ &\mathcal{A}(\dot{u}, \dot{v}) = \tilde{L}(\dot{v}) \text{ for all } \dot{v} \in V\end{aligned} \qquad [20]$$

with $V = H^1(\Omega)/\mathbb{R}$. We get the following result (see, e.g., Nečas (1967):

**Theorem 10** *Let us suppose that $\Omega$ is connected and that the data $f \in L^2(\Omega)$ and $h \in H^{-1/2}(\Gamma)$ satisfy* [18]. *Then the variational problem* [20] *has a unique solution $\dot{u}$ in the space $H^1(\Omega)/\mathbb{R}$ and this solution is continuous with respect to the data, that is, there exists a positive constant $C = C(\Omega)$ such that*

$$|u|_{H^1(\Omega)} \le C\Big(\|f\|_{L^2(\Omega)} + \|h\|_{H^{-1/2}(\Gamma)}\Big)$$
*for all* $u \in \dot{u}$

Moreover, if $\Gamma$ is of class $\mathcal{C}^{1,1}$ and if the data satisfy $f \in L^2(\Omega), g \in H^{1/2}(\Gamma)$, then every $u \in \dot{u}$ is such that $u \in H^2(\Omega)$ and it satisfies each equation in [17] almost everywhere.

### Problem with Mixed Boundary Conditions

Here we consider more general boundary conditions: the Dirichlet conditions on a closed subset $\Gamma_1$ of $\Gamma = \partial\Omega$, and the Neumann, or more generally the "Robin", conditions on the other part $\Gamma_2 = \Gamma - \Gamma_1$. We seek $u$ such that ($f \in L^2(\Omega)$, $h \in L^2(\Gamma_2)$, $a \in L^\infty(\Gamma_2)$)

$$\begin{aligned}-\Delta u &= f \quad \text{in } \Omega\\ u &= 0 \quad \text{on } \Gamma_1\\ au + \frac{\partial u}{\partial n} &= h \quad \text{on } \Gamma_2\end{aligned} \qquad [21]$$

Let $V = \{v \in H^1(\Omega); \gamma_0 v = 0 \text{ on } \Gamma_1\}$. Then [8] is the variational formulation of this problem with

1. $\mathcal{A}(u,v) = \int_\Omega \nabla u(x) \cdot \nabla v(x)\,dx + \int_{\Gamma_2} (a\gamma_0 u \gamma_0 v)(\sigma)d\sigma$;
2. $L(v) = \int_\Omega f(x)v(x)dx + \int_{\Gamma_2} (h\gamma_0 v)(\sigma)d\sigma$.

Supposing, for example, $a \ge 0$, we get a unique solution $u \in V$ for this variational problem by virtue of the Lax–Milgram theorem. Moreover, if $u \in H^2(\Omega)$, then $u$ is the unique solution in $H^2(\Omega) \cap V$ of the problem [21].

### The Newton Problem for More General Operators

Let $\Omega$ be a bounded open subset of $\mathbb{R}^n$. We now consider more general second-order operators of the form $v \mapsto -\nabla.(M\nabla v) + b \cdot \nabla v + cv$, where $b \in [W^{1,\infty}(\Omega)]^N$, $c \in L^\infty(\Omega)$, $M$ is an $N \times N$ square matrix with entries $M_{ij}$, and $\nabla \cdot (M\nabla v)$ stands for

$$\sum_{i,j=1}^{N} \frac{\partial}{\partial x_i}\left[M_{ij}\frac{\partial u}{\partial x_j}\right]$$

We also assume that there is a positive constant $\alpha_M$ such that

$$\sum_{i,j=1}^{N} M_{ij}(x)\xi_i\xi_j \ge \alpha_M \sum_{i=1}^{N} \xi_i^2$$
$$\text{for a.e. } x \in \Omega \text{ and } \xi = (\xi_1, \ldots, \xi_N) \in \mathbb{R}^N$$

For given data $f \in L^2(\Omega), h \in L^2(\Gamma)$, we look for a solution $u$ of the problem

$$\begin{aligned}-\nabla \cdot (M\nabla u) + b \cdot \nabla u + cu &= f \quad \text{in } \Omega\\ au + n \cdot (M\nabla u) &= h \quad \text{on } \Gamma\end{aligned} \qquad [22]$$

We assume that $a \in L^\infty(\Gamma)$. The variational formulation of this problem is still [8], with $V = H^1(\Omega)$ and

$$\begin{aligned}\mathcal{A}(u,v) = &\int_\Omega M\nabla u \cdot \nabla v dx\\ &+ \int_\Omega [b \cdot \nabla u + cu]v dx + \int_\Gamma a\gamma_0 u \gamma_0 v d\sigma\end{aligned} \qquad [23]$$

$$L(v) = \int_\Omega f(x)v(x)dx + \int_\Gamma (h\gamma_0 v)(\sigma)\,d\sigma \qquad [24]$$

If the conditions

$$\begin{aligned}&c - \tfrac{1}{2}\nabla \cdot b \ge C_0 \ge 0 \quad \text{a.e. on } \Omega\\ &a + \tfrac{1}{2} b \cdot \nu \ge C_1 \ge 0 \quad \text{a.e. on } \Gamma\end{aligned}$$

are fulfilled, with $(C_0, C_1) \ne (0,0)$, then the bilinear form $\mathcal{A}$ is $V$-elliptic and the Lax–Milgram theorem applies.

### A Biharmonic Problem

We consider the Dirichlet problem for the operator of fourth order: ($c \in L^\infty(\Omega)$):

$$\Delta^2 u + cu = f \quad \text{in } \Omega \qquad [25]$$

$$u = u_0 \text{ on } \Gamma, \ \frac{\partial u}{\partial n} = h \text{ on } \Gamma \qquad [26]$$

**Theorem 11** *Let us suppose that $\Omega$ has a boundary of class $\mathcal{C}^{1,1}$ and that the data satisfy $f \in H^{-2}(\Omega)$, $u_0 \in H^{3/2}(\Gamma)$, $h \in H^{1/2}(\Gamma)$. Let $U_0 \in H^2(\Omega)$ be such that $\gamma_0(U_0) = u_0$, $\gamma_1(U_0) = h$. Then, if $c \ge 0$ a.e. in $\Omega$, the boundary value problem* [25]–[26] *has a unique*

*solution u such that* $u - U_0 \in H_0^2(\Omega)$, *and u is also the unique solution of the variational problem*

$$\text{to find } u \in U_0 + H_0^2(\Omega) \text{ such that } \mathcal{A}(u,v) = l(v) \text{ for all } v \in H_0^2(\Omega) \qquad [27]$$

*where* $l(v) = \langle f, v\rangle_{H^{-2}(\Omega), H_0^2(\Omega)}$ *and*

$$\mathcal{A}(u,v) = \int_\Omega \Delta u(x)\Delta v(x)\mathrm{d}x + \int_\Omega (cuv)(x)\mathrm{d}x \qquad [28]$$

*Moreover, there exists a positive constant* $C = C(\Omega)$ *such that*

$$\|u\|_{H^2(\Omega)} \le C\,[\|f\|_{H^{-2}(\Omega)} + \|u_0\|_{H^{3/2}(\Gamma)} + \|h\|_{H^{1/2}(\Gamma)}] \qquad [29]$$

*which shows that u depends continuously upon the data f*, $u_0$, *and h*.

**Remark 12** The Hilbert space choice $V$ is of crucial importance for the $V$-ellipticity. In fact, let us consider for example the problem [25], with

$$\Delta u = 0 \text{ on } \Gamma, \quad \frac{\partial \Delta u}{\partial n} = 0 \text{ on } \Gamma \qquad [30]$$

In fact, the associated bilinear form is not $V$-elliptic for $V = H^2(\Omega)$ but it is $V$-elliptic for $V = \{v \in L^2\,(\Omega);\ \Delta v \in L^2\Omega)\}$.

## General Elliptic Problems

Here $\Omega$ will be a bounded and sufficiently regular open subset of $\mathbb{R}^N$. Let us consider a general linear differential operator of the form

$$A(x,D)u = \sum_{|\mu| \le l} a_\mu(x) D^\mu u, \quad a_\mu(x) \in \mathbb{C} \qquad [31]$$

Setting $A_0(x,\xi) = \sum_{|\mu|=l} a_\mu(x)\xi^\mu$, we say that the operator $A$ is elliptic at a point $x$ if $A_0(x,\xi) \ne 0$ for all $\xi \in \mathbb{R}^N - \{0\}$. One can show that, if $N \ge 3$, $l$ is even, that is, $l = 2m$; the same result holds for $N = 2$ if the coefficients $a_\mu$ are real. Moreover, for $N \ge 3$, every elliptic operator is properly elliptic, in the following sense: for any independent vectors $\xi$, $\xi'$ in $\mathbb{R}^N$, the polynomial $\tau \mapsto A_0(.,\xi + \tau\xi')$ has $m$ roots with positive imaginary part.

The aim here is to study boundary-value problems of the following type:

$$Au = f \quad \text{in } \Omega \qquad [32]$$

$$B_j u = g_j \quad \text{on } \Gamma, \quad j = 0, \ldots, m-1, \qquad [33]$$

where $A$ is properly elliptic on $\bar{\Omega}$, with sufficiently regular coefficients, and the operators $B_j$ are boundary operators, of order $m_j \le 2m-1$, that must satisfy some compatibility conditions with respect to the operator $A$ (see Renardy and Rogers (1992) for details; these conditions were introduced by Agmon, Douglis, and Nirenberg). For example, $A = (-1)^m\Delta^m$ and $B_j = \partial^j/\partial n^j$ is a convenient choice.

In order to show that problem [32]–[33] has a solution $u \in H^{2m+r}(\Omega)$ ($r \in \mathbb{N}$), the idea is to show that the operator $\mathcal{P}$ defined by $u \mapsto \mathcal{P}(u) = (Au, B_0u, \ldots, B_{m-1}u)$ is an index operator from $H^{2m+r}(\Omega)$ into $G = H^r(\Omega) \times \Pi_{j=0}^{m-1} H^{2m+r-m_j-1/2}(\Gamma)$ and to express the compatibility conditions through the adjoint problem.

We recall that a linear continuous operator $\mathcal{P}$ is an index operator if

(1) $\dim \operatorname{Ker} \mathcal{P} < \infty$, and $\operatorname{Im} \mathcal{P}$ closed;
(2) $\operatorname{codim} \operatorname{Im} \mathcal{P} < \infty$.

Then the index $\chi(\mathcal{P})$ is given by $\chi(\mathcal{P}) = \dim \operatorname{Ker} \mathcal{P} - \operatorname{codim} \operatorname{Im} \mathcal{P}$. We recall the following Peetre's theorem:

**Theorem 13** *Let E, F, and G be three reflexive Banach spaces such that* $E \hookrightarrow\hookrightarrow F$, *and* $\mathcal{P}$ *a linear continuous operator from E to G. Then condition (1) is equivalent to: "there exists* $C \ge 0$, *such that for all* $u \in E$, *we have* $\|u\|_E \le C(\|\mathcal{P}u\|_G + \|u\|_F)$."

Applying this theorem to our problem [32]–[33], condition (1) results from *a priori* estimates of the following type:

$$\|u\|_{H^{2m+r}(\Omega)} \le C\left(\|\mathcal{P}u\|_G + \|u\|_{H^{2m+r-1}(\Omega)}\right)$$

and condition (2) by similar *a priori* estimates for the dual problem.

## Second-Order Elliptic Problems

We consider a second-order differential operator of the "divergence form"

$$Au = -\sum_{i,j=1}^N (a^{ij}(x)u_{x_i})_{x_j} + \sum_{i=1}^N b^i(x)u_{x_i} + c(x)u \qquad [34]$$

with given coefficient functions $a^{ij}, b^i, c\,(i,j = 1, \ldots, N)$, and where we have used the notation $u_{x_i} = \frac{\partial u}{\partial x_i}$. Such operators are said uniformly strongly elliptic in $\Omega$ if there exists $\alpha > 0$ such that

$$\sum_{|i|=|j|=1} a^{ij}(x)\xi^i\xi^j \ge \alpha|\xi|^2 \quad \text{for all } x \in \Omega,\ \xi \in \mathbb{R}^N$$

**Remark 14** There exist elliptic problems for which the associated variational problem does not necessarily satisfy the ellipticity condition. Let us consider

the following example, due to Seeley: let $\Omega = \{(r,\theta) \in (\pi, 2\pi) \times [0, 2\pi]\}$ and

$$A = -\left(e^{i\theta}\frac{\partial}{\partial\theta}\right)^2 - e^{2i\theta}\left(1 + \frac{\partial^2}{\partial r^2}\right)$$

One can check that, for all $\lambda \in \mathbb{C}$, the problem $Au + \lambda u = f$ in $\Omega$ and $u = 0$ on $\Gamma$ admits nonzero solutions $u$ which are given by (with $\mu$ such that $\mu^2 = \lambda$) $u = \sin r \cos(\mu e^{-i\theta})$ and $u = \sin r \sin(\mu e^{-i\theta})$ for $\lambda \neq 0$; $u = \sin r$ and $u = \sin\theta\, e^{-i\theta}$ for $\lambda = 0$.

Most of the results concerning existence, unicity, and regularity for second-order elliptic problems can be established thanks to a maximum principle. There exist different types of maximum principles, which we now present.

### Maximum Principle

**Theorem 15** (Weak maximum principle). *Let $A$ be a uniformly strongly elliptic operator of the form [34] in a bounded open $\Omega \subset \mathbb{R}^N$, with $a^{ij}, b^i, c \in L^\infty(\Omega)$ and $c \geq 0$. Let $u \in C^2(\Omega) \cap C(\bar{\Omega})$ and*

$$Au \geq 0 \ [\textit{resp. } Au \leq 0] \quad \textit{in } \Omega$$

*Then*

$$\inf_{\Omega} u \geq \inf_{\partial\Omega} u^- \ [\textit{resp. } \sup_{\Omega} u \leq \sup_{\partial\Omega} u^+]$$

*where $u^+ = \max(u, 0)$ and $u^- = -\min(u, 0)$. If $c = 0$ in $\Omega$, one can replace $u^-$ [resp. $u^+$] by $u$.*

**Theorem 16** (Strong principle maximum). *Under the assumptions of the above theorem, if $u$ is not a constant function in $C^2(\Omega) \cap C(\bar{\Omega})$ such that $Au \geq 0$ [resp. $Au \leq 0$], then $\inf_\Omega u < u(x)$ [resp. $\sup_\Omega u > u(x)$], for all $x \in \Omega$.*

**Remark 17** These two maximum principles can be adapted to elliptic operators in nondivergence form, that is,

$$Au = -\sum_{i,j=1}^{N} a^{ij}(x) u_{x_i x_j} + \sum_{i=1}^{N} b^i(x) u_{x_i} + c(x) u \qquad [35]$$

### Fredholm Alternative

We now present some existence results which are based on the Fredholm alternative rather than on the variational method.

Let us consider two Hilbert spaces $V$ and $H$, where $V$ is a dense subspace of $H$ and $V \hookrightarrow\hookrightarrow H$. Denoting by $V'$ the dual space of $V$, and identifying $H$ with its dual space, we have the following imbeddings: $V \hookrightarrow H \hookrightarrow V'$. Let $\mathcal{A}$ be a sesquilinear form on $V \times V$, $V$-coercive with respect to $H$, that is, there exist $\lambda_0 \in \mathbb{R}$ and $\alpha > 0$ such that

$$\mathrm{Re}(\mathcal{A}(v,v)) + \lambda_0 \|v\|_H^2 \geq \alpha \|v\|_V^2 \quad \text{for all } v \in V$$

Denoting by $A$ the operator associated with the bilinear form $\mathcal{A}$ (see Remark 6(iii)), the equation $Au = f$ is equivalent to $u - \lambda_0 Tu = g$, with $T = (A + \lambda_0 \mathrm{Id})^{-1}$ and $g = Tf$. Note that $T$ is an isomorphism from $H$ onto $D(A) = \{u \in H; Au \in H\}$).

The operator $T: H \to H$ is compact and, thanks to the Fredholm alternative, there are two situations:

1. either $\mathrm{Ker}\, A = 0$ and $A$ is an isomorphism from $D(A)$ onto $H$;
2. or $\mathrm{Ker}\, A \neq 0$; then $\mathrm{Ker}\, A$ is of finite dimension, and the problem $Au = f$ with $f \in H$ admits a solution if and only if $f \in \mathrm{Im}\, A = [\mathrm{Ker}(A^*)]^\perp$.

We now give another example in a non-Hilbertian frame. Let us consider the problem (Grisvard 1980): $Au = f$ in $\Omega$ and $Bu = g$ on $\Gamma$, where $\Gamma$ is of class $C^{1,1}$, $A$, which is defined by [34], is uniformly strongly elliptic with $a^{ij} = a^{ji} \in C^{0,1}(\bar{\Omega})$, $b^i, c \in L^\infty(\Omega)$, and $Bu = \gamma_0(u)$ or $Bu = \gamma_1(u)$. One can show that the operator $u \mapsto (Au, Bu)$ is a Fredholm operator of index zero from $W^{2,p}(\Omega)$ in $L^p(\Omega) \times W^{2-d-1/p,p}(\Gamma)$ (with $d = 0$ if $Bu = \gamma_0(u)$ and $d = 1$ if $Bu = \gamma_1(u)$).

### Regularity

Assume that $\Omega$ is a bounded open. Suppose that $u \in H_0^1(\Omega)$ is a weak solution of the equation

$$\begin{aligned} Au &= f \quad \text{in } \Omega \\ u &= 0 \quad \text{on } \Gamma \end{aligned} \qquad [36]$$

where $A$ has the divergence form [34]. We now address the question whether $u$ is in fact smooth: this is the regularity problem for weak solutions.

**Theorem 18** ($H^2$-regularity). *Let $\Omega$ be open, of class $C^{1,1}$, $a^{ij} \in C^1(\bar{\Omega})$, $b^i, c \in L^\infty(\Omega)$, $f \in L^2(\Omega)$. Suppose, furthermore, that $u \in H^1(\Omega)$ is a weak solution of [36]. Then $u \in H^2(\Omega)$ and we have the estimate*

$$\|u\|_{H^2(\Omega)} \leq C(\|f\|_{L^2(\Omega)} + \|u\|_{L^2(\Omega)})$$

*where the constant $C$ depends only on $\Omega$ and on the coefficients of $A$.*

**Theorem 19** (Higher regularity). *Let $m$ be a nonnegative integer, $\Omega$ be open, of class $C^{m+1,1}$ and assume that $a^{ij} \in C^{m+1}(\bar{\Omega})$, $b^i$, $c \in C^{m+1}(\bar{\Omega})$, $f \in H^m(\Omega)$. Suppose, furthermore, that $u \in H^1(\Omega)$ is a weak solution of [36]. Then $u \in H^{m+2}(\Omega)$ and*

$$\|u\|_{H^{m+2}(\Omega)} \leq C(\|f\|_{H^m(\Omega)} + \|u\|_{L^2(\Omega)})$$

*where the constant C depends only on $\Omega$ and on the coefficients of A. In particular, if $m > N/2$, then $u \in C^2(\bar{\Omega})$. Moreover, if $\Omega$ is of $C^\infty$ class and $f \in C^\infty(\bar{\Omega})$, $a^{ij} \in C^\infty(\bar{\Omega})$, $b^i, c \in C^\infty(\bar{\Omega})$, then $u \in C^\infty(\bar{\Omega})$.*

**Remark 20**

(i) If $u \in H_0^1(\Omega)$ is the unique solution of [36], one can omit the $L^2$-norm of $u$ in the right-hand side of the above estimate.
(ii) Moreover, let us suppose the coefficients $a^{ij}, b^i$ and $c$ are all $C^\infty$ and $f \in C^\infty(\Omega)$; then, if $u \in H^1(\Omega)$ satisfies $Au = f, u \in C^\infty(\Omega)$; this is due to the "hypoellipticity" property satisfied by the operator $A$.

We have a similar result in the $L^p$ frame (Grisvard 1980):

**Theorem 21** ($W^{2,p}$-regularity). *Let $\Omega$ be open, of class $C^{1,1}$, $a^{ij} \in C^1(\bar{\Omega})$, $b^i$, $c \in L^\infty(\Omega)$. Suppose, furthermore, that $b^i = 0$, $1 \le i \le N$ and $c \ge 0$ a.e. Then for every $f \in L^p(\Omega)$ there exists a unique solution $u \in W^{2,p}(\Omega)$ of [36].*

## Unbounded Open

### The Whole Space

Note in passing that we shall work with the weighted Sobolev spaces $W_\alpha^{m,p}(\Omega)$ defined in the subsection "Unbounded opens and weighted spaces."

**Theorem 22** *The following claims hold true:*

(i) *Let $f \in W_0^{-1,p}(\mathbb{R}^N)$ satisfy the compatibility condition*

$$\langle f, 1\rangle_{W_0^{-1,p}(\mathbb{R}^N)\times W_0^{1,p'}(\mathbb{R}^N)} = 0 \quad \textit{if } p' \ge N$$

*Then the problem [5] has a solution $u \in W_0^{1,p}(\mathbb{R}^N)$, which is unique up to an element in $\mathcal{P}_{[1-N/p]}$ and satisfies the estimate*

$$\|u\|_{W_0^{1,p}(\mathbb{R}^N)/\mathcal{P}_{[1-N/p]}} \le C\|f\|_{W_0^{-1,p}(\mathbb{R}^N)}$$

*Moreover, if $1 < p < N$, then $u = E * f$.*

(ii) *If $f \in L^p(\mathbb{R}^N)$, then the problem [5] has a solution $u \in W_0^{2,p}(\mathbb{R}^N)$, which is unique up to an element in $\mathcal{P}_{[2-N/p]}$ and if $1 < p < N/2$, then $u = E * f$.*

The Calderón–Zygmund inequality

$$\left\|\frac{\partial^2 \varphi}{\partial x_i \partial x_j}\right\|_{L^p(\mathbb{R}^N)} \le C(N,p)\|\Delta\varphi\|_{L^p(\mathbb{R}^N)}$$
$$\varphi \in \mathcal{D}(\mathbb{R}^N)$$

and Theorem 4 are crucial for establishing Theorem 22.

Further, point (i) means that the Riesz potential of second order satisfies

$$I_2\colon W_0^{-1,p}(\mathbb{R}^N) \perp \mathcal{P}_{[1-N/p']} \to W_0^{1,p}(\mathbb{R}^N)/\mathcal{P}_{[1-\frac{N}{p'}]}$$

(where the initial space is the orthogonal complement of $\mathcal{P}_{[1-N/p']}$ in $W_0^{-1,p}(\mathbb{R}^N)$) and it is an isomorphism.

Note that here

$$W_0^{1,p}(\mathbb{R}^N) = \{v \in L^{p^*}(\mathbb{R}^N); \nabla v \in L^p(\mathbb{R}^N)\}$$

for $1 < p < N$ and $1/p^* = 1/p - 1/N$. And for $1 < r < N/2$, we also have the continuity property

$$I_2\colon L^r(\mathbb{R}^N) \to L^q(\mathbb{R}^N), \text{ for } \frac{1}{q} = \frac{1}{r} - \frac{2}{N}$$

**Remark 23** The problem

$$u - \Delta u = f \quad \text{in } \mathbb{R}^N \qquad [37]$$

is of a completely different nature than the problem [5]. The class of function spaces appropriate for the problem [37] are the classical Sobolev spaces. With the help of the Calderón–Zygmund theory, one can prove that if $f \in L^p(\mathbb{R}^N)$, then the unique solution of [37] belongs to $W^{2,p}(\mathbb{R}^N)$ and can be represented as the Bessel potential of second order (see Stein (1970)): $u = G * f$, where $G$ is the appropriate Bessel kernel, that is, $G$, for which $\widehat{G}(\xi) \sim (1 + |\xi|^2)^{-1/2}$. Recall that in particular $G(x) \sim |x|^{-1}e^{-|x|}$ for $N = 3$. In the Hilbert case, $f \in L^2(\mathbb{R}^N)$, we get

$$(1 + |\xi|^2)\widehat{u} \in L^2(\mathbb{R}^N)$$

which, by Plancherel's theorem, implies that $u \in H^2(\mathbb{R}^N)$. For $f \in W^{-1,p}(\mathbb{R}^N)$, the problem [37] has a unique solution $u \in W^{1,p}(\mathbb{R}^N)$ satisfying the estimate

$$\|u\|_{W^{1,p}(\mathbb{R}^N)} \le C(p,n)\|f\|_{W^{-1,p}(\mathbb{R}^N)}$$

### Exterior Domain

We consider the problem in an exterior domain with the Dirichlet boundary condition

$$\begin{aligned} -\Delta u &= f \quad \text{in } \Omega \\ u &= g \quad \text{on } \Gamma = \partial\Omega \end{aligned} \qquad [38]$$

where $f \in W_0^{-1,p}(\Omega)$ and $g \in W^{1-1/p,p}(\partial\Omega)$. Invoking the results for $\mathbb{R}^N$ and bounded domains, one can prove the existence of a solution $u \in W_0^{1,p}(\Omega)$ which is unique up to an element of the kernel $A_0^p(\Omega) = \{z \in$

$W_0^{1,p}(\Omega); \Delta z = 0\}$ provided that $f$ satisfies the compatibility condition

$$\langle f, \varphi \rangle = \left\langle g, \frac{\partial \varphi}{\partial n} \right\rangle \quad \text{for all } \varphi \in A_0^{p'}(\Omega)$$

The kernel can be characterized in the following way: it is reduced to $\{0\}$ if $p=2$ or $p<N$ and if not, then

$$A_0^p(\Omega) = \{C(\lambda - 1); C \in \mathbb{R}\} \quad \text{if } p \geq N \geq 3$$

where $\lambda$ is (unique) solution in $W_0^{1,2}(\Omega) \cap W_0^{1,p}(\Omega)$ of the problem $\Delta\lambda = 0$ in $\Omega$ and $\lambda = 1$ on $\partial\Omega$, and

$$A_0^p(\Omega) = \{C(\mu - u_0);\ C \in \mathbb{R}\} \quad \text{if } p > N = 2$$

where $u_0(x) = (2\pi|\Gamma|)^{-1} \int_\Gamma \log|y - x|\, \mathrm{d}\sigma_y$ and $\mu$ is the only solution in $W_0^{1,2}(\Omega) \cap W_0^{1,p}(\Omega)$ of the problem $\Delta\mu = 0$ in $\Omega$ and $\mu = u_0$ on $\Gamma$.

**Remark 24** Similar results exist for the Neumann problem in an exterior domain (see Amrouche *et al.* (1997)). The framework of the spaces $W_\alpha^{m,p}(\mathbb{R}_+^N)$ for the Dirichlet problem in $\mathbb{R}_+^N$ was also considered in the literature. For a more general theory see Kozlov and Maz'ya (1999).

## Elliptic Systems

### The Stokes System

The Stokes problem is a classical example in the fluid mechanics. This system models the slow motion with the field of the velocity $\boldsymbol{u}$ and the pressure $\pi$, satisfying

$$(\mathrm{S}) \qquad \begin{aligned} -\nu\Delta\boldsymbol{u} + \nabla\pi &= \boldsymbol{f} \quad \text{in} \quad \Omega \\ \operatorname{div}\boldsymbol{u} &= h \quad \text{in} \quad \Omega \\ \boldsymbol{u} &= \boldsymbol{g} \quad \text{on} \quad \Gamma = \partial\Omega \end{aligned}$$

where $\nu > 0$ denotes the viscosity, $\boldsymbol{f}$ is an exterior force, $\boldsymbol{g}$ is the velocity of the fluid on the domain boundary, and $h$ measures the compressibility of the fluids (if $h=0$, it is an incompressible fluid). The functions $h$ and $\boldsymbol{g}$ must satisfy the compatibility condition

$$\int_\Omega h(x)\,\mathrm{d}x = \int_\Gamma \boldsymbol{g} \cdot \boldsymbol{n}\,\mathrm{d}\sigma \qquad [39]$$

**Theorem 25** *Let $\Omega$ be a Lipschitz bounded domain in $\mathbb{R}^N$, $N \geq 2$. Let $\boldsymbol{f} \in H^{-1}(\Omega)^N$, $h \in L^2(\Omega)$, and $g \in H^{1/2}(\Gamma)^N$ satisfy [39]. Then the problem* (S) *has a unique solution $(\boldsymbol{u}, \pi) \in H^1(\Omega)^N \times L^2(\Omega)/\mathbb{R}$ satisfying the* a priori *estimate*

$$\begin{aligned} &\|\boldsymbol{u}\|_{H^1(\Omega)} + \|\pi\|_{L^2(\Omega)/\mathbb{R}} \\ &\quad \leq C\left(\|\boldsymbol{f}\|_{H^{-1}(\Omega)} + \|h\|_{L^2(\Omega)} + \|g\|_{H^{1/2}(\Gamma)}\right) \end{aligned}$$

In order to prove Theorem 25, one can start with a homogeneous problem. The procedure of finding $\boldsymbol{u}$ is a simple application of the Lax–Milgram theorem. Application of de Rham's theorem gives the pressure $\pi$. We introduce the space

$$\mathcal{V} = \{\boldsymbol{v} \in \mathcal{D}(\Omega)^N;\ \operatorname{div}\boldsymbol{v} = 0\}$$

and define $\boldsymbol{F} \in H^{-1}(\Omega)^N$ by

$$\langle \boldsymbol{F}, \boldsymbol{v} \rangle_{H^{-1} \times \overset{\circ}{H}{}^1} = 0 \quad \text{for all } \boldsymbol{v} \in \mathcal{V}$$

Moreover, there exists $\pi \in L^2(\Omega)$, unique up to an additive constant, and such that $\boldsymbol{F} = \nabla\pi$. The problem (S), which we transform to the homogeneous case ($h=0, g=0$), can be formulated on an abstract level. Let $X$ and $M$ be two real Hilbert spaces and consider the following variational problem: Given $\boldsymbol{L} \in \boldsymbol{X}'$ and $X \in M'$, find $(\boldsymbol{u}, \pi) \in X \times M$ such that

$$\begin{aligned} \mathcal{A}(\boldsymbol{u}, \boldsymbol{v}) + B[\boldsymbol{v}, \pi] &= \boldsymbol{L}(\boldsymbol{v}), \quad \boldsymbol{v} \in \boldsymbol{X} \\ B[\boldsymbol{u}, q] &= X(q), \quad q \in M \end{aligned} \qquad [40]$$

where the bilinear forms $\mathcal{A}$, $B$ and the linear form $\boldsymbol{L}$ are defined by

$$\mathcal{A}(\boldsymbol{u}, \boldsymbol{v}) = \int_\Omega \nabla\boldsymbol{u} \cdot \nabla\boldsymbol{v}$$

$$B[\boldsymbol{v}, q] = -\int_\Omega [q\nabla \cdot \boldsymbol{v}]$$

$$L(\boldsymbol{v}) = \int_\Omega \boldsymbol{f} \cdot \boldsymbol{v}$$

**Theorem 26** *If the bilinear form $\mathcal{A}$ is coercive in the space*

$$V = \{\boldsymbol{v} \in X;\ B[\boldsymbol{v}, q] = 0\} \quad \text{for all } q \in M$$

*that is, if there exists $\alpha > 0$ such that*

$$\mathcal{A}(\boldsymbol{v}, \boldsymbol{v}) \geq \alpha\|\boldsymbol{v}\|_X^2, \quad \boldsymbol{v} \in V$$

*then the problem [40] has a unique solution $(\boldsymbol{u}, \pi)$ if and only if the bilinear form $\mathcal{B}$ satisfies the* "inf–sup" *condition*:

*there exists $\beta > 0$ such that*

$$\inf_{q \in M} \sup_{v \in X} \frac{\mathcal{B}(\boldsymbol{v}, q)}{\|\boldsymbol{v}\|_X \|q\|_M} \geq \beta$$

As for the Dirichlet problem, the regularity result is the following:

**Theorem 27** *Let $\Omega$ be a bounded domain in $\mathbb{R}^N$, of the class $C^{m+1,1}$ if $m \in \mathbb{N}$ and $C^{1,1}$ if $m = -1$. Let $f \in W^{m,p}(\Omega)^N, h \in W^{m+1,p}(\Omega)$ and $\boldsymbol{g} \in W^{m+2-1/p,p}(\Gamma)^N$ satisfy condition [39]. Then the problem* (S) *has a unique solution $(\boldsymbol{u}, \pi) \in W^{m+2,p}(\Omega)^N \times W^{m+1,p}(\Omega)/\mathbb{R}$.*

**Remark 28** It is possible to solve (S) under weaker assumption, for instance, if $f \in W^{-1/p}(\Omega')$, $h=0$ and $g \in W^{-1/p,p}(\Gamma)^N$. We can prove that then $(u,\pi) \in L^p(\Omega)^N \times W^{-1,p}(\Omega)$.

### The Linearized Elasticity

The equations governing the displacement $u=(u_1,u_2,u_3)$ of a three-dimensional structure subjected to an external force field $f$ are written as ($\Omega$ is a bounded open subset of $\mathbb{R}^3$ and $\Gamma=\partial\Omega$)

$$-\mu\Delta u - (\lambda+\mu)\nabla(\nabla\cdot u) = f \quad \text{in } \Omega$$
$$u = 0 \quad \text{on } \Gamma_0$$
$$\sum_{j=1}^{3} \sigma_{ij}(u)\nu_j = g_i \quad \text{on } \Gamma_1 = \Gamma - \Gamma_0$$

where $\lambda > 0$ and $\mu > 0$ are two material characteristic constants, called the Lamé coefficients, and ($v=(v_1,v_2,v_3)$)

$$\sigma_{ij}(v) = \sigma_{ji}(v) = \lambda\delta_{ij}\sum_{k=1}^{3}\varepsilon_{kk}(v) + 2\mu\varepsilon_{ij}(v) \qquad [41]$$
$$\text{with } \varepsilon_{ij}(v) = \varepsilon_{ji}(v) = \tfrac{1}{2}(\partial_j v_i + \partial_i v_j)$$

where $\delta_{ij}$ denotes the Kronecker symbol, that is, $\delta_{ij}=1$, for $i=j$ and $\delta_{ij}=0$, for $i\neq j$. These equations describe the equilibrium of an elastic homogeneous isotropic body that cannot move along $\Gamma_0$; along $\Gamma_1$, surface forces of density $g=(g_1,g_2,g_3)$ are given. The case $\Gamma_1=\emptyset$ physically corresponds to clamped structures. The matrix with entries $\varepsilon_{ij}(u)$ is the linearized strain tensor while $\sigma_{ij}(u)$ represents the linearized stress tensor; the relationship [41] between these tensors is known as Hooke's law. We refer for example to Ciarlet and Lions (1991) and Nečas and Hlaváček (1981) (and references therein) for most of the results stated in this paragraph. The variational formulation of this problem is

$$\text{to find } u \in V \text{ such that}$$
$$\mathcal{A}(u,v) = L(v) \text{ for all } v \in V \qquad [42]$$

where the bilinear form $\mathcal{A}$ and the linear form $L$ are given by

$$\mathcal{A}(u,v) = \int_\Omega [\lambda(\nabla\cdot u)(\nabla\cdot v) + 2\mu\sum_{i,j=1}^{3}\varepsilon_{ij}(u)\varepsilon_{ij}(v)](x)dx, \qquad [43a]$$

$$L(v) = \int_\Omega f(x)\cdot v(x)dx + \int_{\Gamma_1} g(\sigma)\cdot v(\sigma)d\sigma \qquad [43b]$$

The functional space $V$ is defined as

$$V = \{v=(v_1,v_2,v_3) \in [H^1(\Omega)]^3; \ \gamma_0 v_i = 0 \text{ on } \Gamma_0,\ 1\le i\le 3\}$$

To prove the ellipticity of $\mathcal{A}$, one needs the following Korn inequality: There exists a positive constant $C(\Omega)$ such that, for all $v=(v_1,v_2,v_3) \in [H^1(\Omega)]^3$, we have

$$\|v\|_{1,\Omega} \le C(\Omega)\left[\sum_{i,j=1}^{3}\|\varepsilon_{ij}(v)\|^2_{L^2(\Omega)} + \sum_{i=1}^{3}\|v_i\|^2_{L^2(\Omega)}\right]^{1/2} \qquad [44]$$

The following result holds true:

**Theorem 29** *Let $\Omega$ be a bounded open in $\mathbb{R}^3$ with a Lipschitz boundary, and let $\Gamma_0$ be a measurable subset of $\Gamma$, whose measure (with respect to the surface measure $d\Gamma(x)$) is positive. Then the mapping*

$$v \mapsto \left[\sum_{i,j=1}^{3}\|\varepsilon_{ij}(v)\|^2_{L^2(\Omega)}\right]^{1/2}$$

*is a norm on $V$, equivalent to the usual norm $\|.\|_{1,\Omega}$.*

As a consequence, we get:

**Theorem 30** *Under the above assumptions, there exists a unique $u \in V$ solving the variational problem [42]–[43]. This solution is also the unique one which minimizes the energy functional*

$$E(v) = \frac{1}{2}\int_\Omega\left[\lambda(\nabla\cdot v)^2 + 2\mu\sum_{i,j=1}^{3}[\varepsilon_{ij}(v)]^2\right](x)\,dx - \left[\int_\Omega f(x)\cdot v(x)\,dx + \int_{\Gamma_1} g(\sigma)\cdot v(\sigma)\,d\sigma\right]$$

*over the space $V$.*

# Entanglement

**R F Werner**, Technische Universität Braunschweig, Braunschweig, Germany

## Introduction

Entanglement is a type of correlation between subsystems, which cannot be explained by the action of a classical random generator. It is a key notion of quantum information theory and corresponds closely to the possibility of channels which transmit quantum information, and cannot be simulated by classical channels. In this article, we consider the development of the concept, and its qualitative aspects. The quantitative aspects are treated in a separate article (*see* Entanglement Measures).

## Historical Development

The first realization that quantum mechanics comes with new, and perhaps rather strange, correlations came in the famous 1935 paper by Einstein, Podolsky, and Rosen (EPR) (Einstein *et al.* 1935), in which they set up a paradox showing that the statistics of certain quantum states could not be realized by assigning wave functions to subsystems. It was in response to this paper that Schrödinger (1935), in the same year, coined the term "entanglement," as well as its German equivalent "*Verschränkung*." The subject lay dormant for a long time, since Bohr, in his reply, completely ignored the entanglement theme, and there was a widespread reluctance in the physics community to consider problems of interpretation. The leaf turned slowly with Bohm's reduced model of the EPR paradox using spins rather than continuous variables, and decisively with Bell's 1964 strengthening of the paradox (Bell 1964). He showed that not only wave functions assigned to individual systems failed to describe the correlations predicted by quantum mechanics, but any set of classical parameters assigned to the subsystems. This eliminated all reference to a possibly dubious quantum ontology and all reference to the quantum formalism from the argument. Bell derived a set of inequalities from the assumption that each subsystem could be described in terms of classical variables, and that these (possibly hidden) variables would not be changed by the mere choice of a measurement for the distant correlated system. The only relation to quantum mechanics was then the simple quantum calculation showing, in certain situations, such as the state described by EPR, quantum mechanics predicted a violation of Bell's inequalities. This immediately suggested an experiment, and although it was difficult at first to find an efficient source of suitably quantum-correlated pairs of particles, the experiments that have been made since then have supported the quantum-mechanical result beyond reasonable doubt. This came too late for Einstein, whose research program in quantum mechanics had been precisely to build a "local hidden-variable theory" of the type seen in contradiction with Bell's inequality. But at least the EPR paper had finally received the response it deserved.

In Schrödinger's work, entanglement was a purely qualitative term for the strange way the subsystems

seemed to be intertwined as soon as one insisted on discussing their individual properties. After Bell's work, the favored mathematical definition of entanglement would probably have been the existence of measurements on the subsystems, such that Bell's inequality (or some generalization derived on the same assumptions) is violated. However, around 1983 another notion of (the lack of) entanglement was independently proposed by Primas (1983) and Werner (1983). According to this definition, a quantum state $\rho$ is called unentangled if it can be written as

$$\rho = \sum_{\alpha} p_\alpha \rho_\alpha^1 \otimes \rho_\alpha^2 \qquad [1]$$

where the $\rho_\alpha^i$ are arbitrary states of the subsystems ($i = 1, 2$), which depend on a "hidden variable" $\alpha$, drawn by a classical random generator with probabilities $p_\alpha$. Such states are now called separable, which is a bit awkward, since the notion is typically applied to systems which are widely separated. However, the term is so firmly established that it is hopeless to try to improve on it.

In any case, it was shown by Werner (1989) that there are nonseparable states, which nevertheless satisfy Bell's inequalities and all its generalizations. The next step was the observation by Popescu (1994) that entanglement could be distilled: this is a process by which some number of moderately entangled pair states is converted to a smaller number of highly entangled states, using only local quantum operations, and classical communication between the parties. For some time it seemed that this might close the gap, that is, that the failure of separability might be equivalent to "distillability" (i.e., the existence of a distillation procedure producing arbitrarily highly entangled states from many copies of the given one). However, this turned out to be false, as shown by the Horodecki family in 1998 (Horodecki *et al.* 1998), by explicitly exhibiting bound entangled, that is, nonseparable, but also not distillable states. In 2003 Oppenheim and the Horodeckis introduced a further distinction, namely whether it is possible to extract a secret key from copies of a given quantum state by local quantum operations and public classical communication (Horodecki *et al.* 2005). This task had hitherto been viewed as an application of entanglement distillation, but it turned out that secret key can be distilled from some bound entangled (but never from separable) states.

For the entanglement theory of multipartite states, that is, states on systems composed of three or more parts, between which no quantum interaction takes place, one key observation is that new entanglement properties must be expected with any increase of the number of parties. As shown by Bennett *et al.* (1999), there are states of three parties which cannot be written in the three-party analog of [1], but are nevertheless separable for all three splits of the system into one vs. two subsystems.

The crucial advance of entanglement theory, however, lies not so much in the distinctions outlined above, but in the quantitative turn of the theory. With the discovery of the teleportation and dense coding processes (Bennett and Wiesner 1992, Bennett *et al.* 1993), entanglement changed its role from a property of counterintuitive contortedness to a resource, which is used up in teleportation and similar processes. Distillation is then seen as a method to upgrade a given source to a new source of highly entangled states suitable for this purpose, and it is not just the possibility of doing this, but the rate of this conversion, which becomes the focus of the investigation. All the tasks in which entanglement appears suggest quantitative measures of entanglement. In addition, there are many entanglement measures, which appear natural from a mathematical point of view, or are introduced simply because they can be estimated relatively easily and in turn give bounds on other entanglement measures of interest. The current situation is that there is no shortage of entanglement measures in the literature, but it is not yet clear which ones will be of interest in the long run. Some of these measures are described in Entanglement Measures.

The current state of entanglement theory is marked firstly by some long-standing open problems in the basic bipartite theory on the one hand (additivity of the entanglement of formation, the existence of NPT bound entangled states, and more recently the existence of entangled states with vanishing key rate). Secondly, there is significant effort to try to compute some of the entanglement measures, at least for simple subclasses of states. This is so difficult, because many definitions involve an optimization over operations on an asymptotically large system. Thirdly, there is a new trend in multipartite entanglement theory, namely looking specifically at entanglement in lattice structures such as spin systems of harmonic-oscillator lattices. Here one can expect very fruitful interaction with the statistical mechanics and solid-state physics in the near future.

## Qualitative Entanglement Theory

### Setup

Throughout this section, we will consider density operators on a Hilbert space split in some fixed way into a tensor product of a Hilbert space $\mathcal{H}_A$ for

Alice's system and a Hilbert space $\mathcal{H}_B$ for Bob's system, that is, $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B$. For simplicity, we will mostly consider finite-dimensional spaces, and if a dimension parameter $d < \infty$ appears, it is understood that $d = \dim \mathcal{H}_A = \dim \mathcal{H}_B$. By $\mathcal{B}(\mathcal{H})$ we will denote the set of bounded operators on a Hilbert space, and by $\mathcal{B}_*(\mathcal{H})$ the set of trace-class operators. We distinguish these even in the finite-dimensional case, because of their different norms. By $\mathfrak{S}$ we will denote the state space of the combined system, that is, the set of positive elements of $\mathcal{B}_*(\mathcal{H})$ with trace 1.

For such a density operator $\rho = \rho^{AB}$ we denote by $\rho^A$ and $\rho^B$ the restrictions to the subsystems, defined by the partial trace over the other system, or by $\mathrm{tr}(\rho^A F) = \mathrm{tr}(\rho^{AB}(F \otimes \mathbb{1}))$. We denote by $\Theta$ the operation of matrix transposition, and by $\mathrm{id} \otimes \Theta$ the partial transposition, applied only to the second tensor factor. Since transposition is not completely positive (*see* Channels in Quantum Information Theory) partial transposition may take positive operators to non-positive operators. The relative entropy (*see* Entropy and Quantitative Transversality) of two density operators $\rho, \sigma$ will be used with the convention $S(\rho||\sigma) = \mathrm{tr}\,\rho(\log \rho - \log \sigma)$.

### Witnesses and the Criterion of Positivity of Partial Transpose

A state $\rho$ is called separable iff it is of the form [1], and entangled otherwise. The set of separable states $\mathfrak{C}$ is a convex subset of the set $\mathfrak{S}$ of all states. Its extreme points are obvious from the representation [1], namely the pure product states $\rho = |\phi_A \otimes \phi_B\rangle\langle\phi_A \otimes \phi_B|$. Since $\mathfrak{C}$, like $\mathfrak{S}$, is a convex set in $(d^4 - 1)$ dimensions, Caratheodory's theorem asserts that the sum can be taken to be a decomposition into $d^4$ such terms. For a given $\rho$, deciding whether it is separable or entangled, hence, involves a nonlinear search problem in roughly $4d^5$ real parameters, namely the vector components of the $\phi_A, \phi_B$ appearing in the sum.

Dually, the convex set $\mathfrak{C}$ can be described by a set of linear inequalities. Here is a simple way of generating such inequalities: let $T : \mathcal{B}_*(\mathcal{H}_B) \to \mathcal{B}(\mathcal{H}_A)$ be a positive linear map, that is, a map taking positive matrices to positive matrices. Then for $\rho_A, \rho_B \geq 0$ the expression $\mathrm{tr}(\rho_A T(\rho_B))$ is positive. It is also bilinear, so we can find a Hermitian operator $T^\natural \in \mathcal{B}(\mathcal{H}_A \otimes \mathcal{H}_B)$ such that

$$\mathrm{tr}(\rho_A T(\rho_B)) = \mathrm{tr}((\rho_A \otimes \rho_B) T^\natural)$$

Since the left-hand side is positive, we see by taking convex combinations that $\mathrm{tr}(\rho T^\natural) \geq 0$ for all separable states $\rho$. Hence, if we find a state with a negative expectation of $T^\natural$, we can be sure it is entangled. Therefore, such operators $T^\natural$ are called entanglement witnesses. This is often a useful criterion, especially when one has some additional information about the state, allowing for an intelligent choice of witness. It is known from the theory of ordered vector spaces and their tensor products that the set of witnesses constructed above is complete. Hence, in principle, checking all such witnesses provides a necessary and sufficient criterion for entanglement. However, in practice this remains a difficult task, because the extreme points of the set of positive maps are only known for some low dimensions.

By restricting $T$ to completely positive maps, we get a useful necessary criterion. It can be seen that it is equivalent to

$$(\mathrm{id} \otimes \Theta)(\rho) \geq 0$$

that is, to the positivity of the partial transpose (PPT). States with this property are called "PPT states" in current jargon.

### Pure States, Purification

For pure states, that is, for the extreme points of $\mathfrak{S}$, separability is trivial to decide: since for pure states the sum [1] can only be a single term, a pure state is separable iff it factorizes.

A useful observation is that, for pure states $\rho = |\Phi\rangle\langle\Phi|$, all information about entanglement is contained in the spectrum of the reduced states. Consider a vector $\Phi \in \mathcal{H}_A \otimes \mathcal{H}_B$ of the form

$$\Phi = \sum_\alpha \sqrt{r_\alpha}\, \phi_\alpha^A \otimes \phi_\alpha^B \qquad [2]$$

where $\phi_\alpha^A \in \mathcal{H}_A$ and $\phi_\alpha^B \in \mathcal{H}_B$ are orthonormal systems, $r_\alpha > 0$, and $\sum_\alpha r_\alpha = 1$. Then it is easy to check that $\rho^A = \sum_\alpha r_\alpha |\phi_\alpha^A\rangle\langle\phi_\alpha^A|$ is the spectral resolution of the restriction. Conversely, by diagonalizing the restriction of a general unit vector $\Phi$, we find a biorthogonal decomposition of the from [2], also known as the Schmidt decomposition. The Schmidt spectrum $\{r_1, \ldots, r_d\}$ hence classifies vectors up to local basis changes in $\mathcal{H}_A$ and $\mathcal{H}_B$.

Since any $\rho^A$ can appear in this construction, we see that any mixed state can be considered as the restriction of a pure state, which is essentially unique, namely up to the choice of basis in the purifying system B, and up to perhaps adding or deleting some irrelevant dimensions in $\mathcal{H}_B$. The resulting vector $\Phi$ is known as the purification of $\rho_A$.

The extreme cases of [2] are pure product states on the one hand, and vectors, for which $\rho^A = \mathbb{1}/d$ is the totally chaotic state. These are known as maximally entangled and embody, in the most extreme way, the observation that in quantum

mechanics, as opposed to classical probability, the restriction of a pure state may be mixed.

Let us fix a maximally entangled vector $\Omega$, and the matching Schmidt bases, so that

$$\Omega = \frac{1}{\sqrt{d}} \sum_k |kk\rangle \qquad [3]$$

where we have used the simplified ket notation, in which only the basis label is written. Then, an arbitrary vector can be written as $\Phi = (X \otimes \mathbb{1})\Omega = (\mathbb{1} \otimes X^{\mathrm{T}})\Omega$, where $X^{\mathrm{T}}$ denotes the matrix transpose of $X$. Clearly, this vector is again maximally entangled iff $X$ is unitary. Hence, the set of maximally entangled vectors is a single orbit under unilateral unitary transformations, and we even have the choice to which side we apply the unitaries.

### Teleportation

Suppose we have an orthonormal basis of maximally entangled vectors $\Phi_\alpha \in \mathcal{H}_{\mathrm{A}} \otimes \mathcal{H}_{\mathrm{B}}$. By the remarks above, this is equivalent to choosing unitaries $U_\alpha, \alpha = 1, \ldots, d^2$ such that $\Phi_\alpha = (U_\alpha \otimes \mathbb{1})\,\Omega$, and $\mathrm{tr}(U_\alpha^* U_\beta) = d\delta_{\alpha\beta}$. For example, a finite Weyl system constitutes such a system of unitaries, which shows that we can find realizations in any dimension $d$.

Suppose that Alice and Bob each own part of a system prepared in the state $\Omega$ then they can transmit perfectly the state of a $d$-dimensional system, using only classical communication. Classical communication by itself would never suffice to transmit quantum information, and the entangled resource $\Omega$ by itself does not allow the transmission of any signal. But the combination of these resources does the trick: Alice measures the observable associated with the basis $\Phi_\alpha$ on the combined system formed by the unknown input and her part of the entangled pair. The result $\alpha$ is then transmitted to Bob, who performs a $U_\alpha$-rotation on his part of the entangled pair, producing the output state of the teleportation. One can show by direct calculation that this is exactly equal to the input state.

Note that the resource $\Omega$ is destroyed in this process, so that for every transmission we need a fresh entangled pair. Less than maximally entangled states instead of $\Omega$ lead to less-than-perfect transmission, which can be extended to quantitative relations between entanglement and channel capacity.

## Special Systems

### Qubits

For qubit pairs, there is a special basis of maximally entangled vectors, which has some amazing properties. It consists of the vectors $\Phi_0 = \Omega$, and $\Phi_k = \mathrm{i}(\sigma_k \otimes \mathbb{1})\Omega$, where $\sigma_k, k = 1, 2, 3$, denotes the Pauli matrices. Then a vector is maximally entangled iff its components are real in this basis, up to a common phase. A unitary matrix of determinant 1 factorizes into $U_1 \otimes U_2$ iff its matrix elements are real, up to a common phase.

For qubit pairs, and also for dimensions $2 \otimes 3$, the partial transposition criterion for entanglement is necessary and sufficient, as shown by Woronowicz and the Horodecki family.

### Orthogonally Invariant States

A state $\rho$ on $\mathbb{C}^d \otimes \mathbb{C}^d$ is called orthogonally invariant if, for any orthogonal matrix $U$ (with respect to some fixed product basis) $[\rho, U \otimes U] = 0$. This leaves a three-dimensional space of operators, spanned by the identity, the permutation $F = \sum_{i,j} |ij\rangle\langle ji|$, and its partial transpose $\widehat{F} = \sum_{i,j} |ii\rangle\langle jj|$, which is $d$ times the projection onto the maximally entangled vector $\Omega$. Figure 1 shows the plane of Hermitian operators $\rho$ with the described symmetry and $\mathrm{tr}\,\rho = 1$. Convenient coordinates are $\mathrm{tr}\,\rho F$ and $\mathrm{tr}\,\rho \widehat{F}$. Note that these are defined for any density operator, and are also invariant under the "twirl" operation $\rho \mapsto \int \mathrm{d}U (U \otimes U)\rho(U \otimes U)^*$, using the Haar measure $\mathrm{d}U$, which projects onto the orthogonally invariant states. Hence, the diagram provides a section as well as a projection of the state space. The intersection of the positive operators with those having positive partial transpose is the set of PPT states, which in this case coincides with the separable states. The thin lines correspond to states of higher symmetry, namely on the one hand the "isotropic states" commuting with $U \otimes \bar{U}$, with $\bar{U}$ the complex conjugate of $U$, and the "Werner states" commuting with all unitaries $U \otimes U$. Their intersection point is the normalized trace.

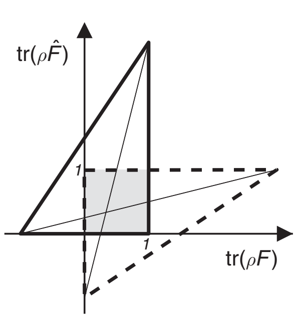

**Figure 1** The plane of orthogonally invariant unit trace Hermitian operators of a $3 \otimes 3$-system. The upright triangle gives the positive operators, and the dashed one those with positive partial transpose. The shaded area gives the PPT states.

### Gaussians

In general, the entanglement in systems with infinite-dimensional Hilbert spaces is more difficult to analyze. However, if the system is characterized by variables satisfying canonical commutation relations, like positions and momenta, or the components of the free quantum electromagnetic field, there is a special class of states, which is again characterized by low-dimensional matrices. This allows the discussion of entanglement questions, in a way largely parallel to the finite-dimensional theory.

Let $R_1, \ldots, R_{2f}$ denote the canonical operators, where $f$ is the number of degrees of freedom. The commutation relations can be summarized as $\mathrm{i}[R_\mu, R_\nu] = \sigma_{\mu\nu}\mathbb{1}$, where $\sigma$ is the symplectic matrix. Operators $R_\mu$ have a common set of analytic vectors, and generate the unitary Weyl operators $W(a) = \exp(\mathrm{i}a^\mu R_\mu)$, which describe the phase space displacements. Gaussian states are those making $a \mapsto \mathrm{tr}\,\rho W(\rho)$ a Gaussian function or, equivalently, those with Gaussian Wigner function. Up to a gloal displacement, they are completely characterized by the covariance matrix

$$\gamma_{\mu\nu} = \mathrm{tr}\,\rho(R_\mu R_\nu + R_\nu R_\mu) \qquad [4]$$

The only constraint for a real symmetric matrix to be a covariance matrix of a quantum state is that $\gamma + \mathrm{i}\sigma$ is a positive semidefinite matrix, which is a version of the uncertainty relations.

Now for entanglement theory, we take some of the degrees of freedom as Alice's and some as Bob's. Separability can be characterized in terms of $\gamma$, namely by the condition that $\gamma \geq \gamma'$, where $\gamma'$ is the covariance matrix of a Gaussian product state. Similarly, partial transposition can be implemented as an operation on covariance matrices, which allows a simple verification of the PPT condition. It turns out that as long as one partner has only a single degree of freedom, the PPT condition is necessary and sufficient for separability, but this fails for larger systems.

The pure Gaussian states allow a normal form with respect to local symplectic transformations analogous to the Schmidt decomposition. For the minimal case of one degree of freedom on either side, one obtains a one-parameter family of "two mode squeezed states." Its limit for infinite squeezing parameter is the state used by EPR (Einstein *et al.* 1935), which, however, makes rigorous mathematical sense only as a singular state, that is, a linear functional on $\mathcal{B}(\mathcal{H})$, which can no longer be represented as the trace with a density operator.

### Multipartite Stars

A key feature of entanglement in a multipartite system is usually referred to as "monogamy": when Alice shares a highly entangled state with Bob, her system cannot also be highly entangled with Bill. More formally, suppose that a multipartite state for systems $\mathrm{A}, \mathrm{B}_1, \ldots, \mathrm{B}_n$ is given, such that the restriction to each pair $\mathrm{AB}_k$ is the same bipartite state $\rho$. Then as $n$ becomes larger, the existence of such a star-shaped extension constrains $\rho$ to become less and less entangled. In fact, as $n \to \infty$, this condition is equivalent to the separability of $\rho$.

## Open Problems

Recall from the introduction the following chain of inclusions:

$$\begin{aligned} \text{separable states} &\subset \text{states with vanishing key rate} \\ &\subset \text{PPT state} \\ &\subset \text{undistillable states} \\ &\subset \text{all states} \end{aligned}$$

The second and fourth inclusions are strict, but for the first and third one might have equality, for all we know. Especially for the third inclusion, this is a long-standing problem.

Finally, we would like to point out that qualitative and conceptual aspects of entanglement are surveyed by Bub (2001), Popescu and Rohrlich (1998), and Horodecki *et al.* (2001). For quantitative aspects *see* Entanglement Measures.

# Entanglement Measures

**R F Werner**, Institut für Mathematische Physik, Braunschweig, Germany

## Introduction

Entanglement, or quantum correlation, is one of the central concepts in quantum information theory. Its theory can be roughly separated into three parts. The first is *qualitative*, that is, it addresses the question "Is this state entangled or not?" The second, *comparative* part asks "Is this state more entangled than that state?," and finally the *quantitative* theory asks "How entangled is this state?," and gives its answers in the form of entanglement measures assigning a number to every state. Quantitative questions come up naturally whenever entanglement is used as a resource for tasks of quantum information processing. For example, entangled states are in a way the fuel for the processes of teleportation and dense coding: in each transmission step a maximally entangled pair system is required, and cannot be used for a further transmission. The process also works with less than maximally entangled states, but then it also becomes less efficient. Since entangled states created in the laboratory typically have imperfections, it becomes important to understand the rates at which imperfectly entangled states may be distilled to maximally entangled ones, and this rate is a direct measure of the usefulness of the given state for many purposes. The quantitative, task related turn is a new development in the study of the foundations of quantum mechanics. It has been imported from classical information theory, where this way of thinking has been standard for a long time. The combination makes the particular flavor of quantum information theory.

In this article we consider the comparative and quantitative aspects of entanglement. The historical aspects and qualitative theory are treated in a separate article (*see* Entanglement), to which we refer for basic notions and notations. The example of teleportation suggests close links between quantitative entanglement theory and the theory of capacity Bennett *et al.* (1996), which is the transfer rate of quantum information through a given channel. These connections are described in Quantum Channels: Classical Capacity.

We follow the notations of the basic article on entanglement (*see* Entanglement). In particular, $\Theta$ denotes the transpose operation, and $(\mathrm{id}\otimes\Theta)$ the partial transpose. A state is called "PPT" if its partial transpose is positive. The two physicists operating the laboratories in which the two parts of a bipartite system are kept are called Alice and Bob, as usual. The restriction of a state $\rho$ to Alice's subsystem is denoted by $\rho^{\mathrm{A}}$.

## Comparative Entanglement and Protocols

### Protocols

In this section we introduce relations of the kind "state $\rho_1$ is more entangled than $\rho_2$." We take this to mean that $\rho_2$ can be obtained by applying to $\rho_1$ some operations which "cannot create entanglement." The definition of a class of operations of which this can be claimed then defines the comparison. It turns out that there are different choices for the class of such operations, depending on the resources available for the transformation steps. The class of operations is usually referred to as a *protocol*.

Certainly local operations performed separately by Alice and Bob cannot increase entanglement. Alice and Bob might have to make some choices, and even if they make these according to a

prearranged scheme, by using a shared table of random numbers, entanglement will not be generated. In this restrictive protocol, which we abbreviate by LO, for "local operations," no communication is allowed. It is clear that by just discarding the initial state, and preparing a new one, based on the random instruction allows Alice and Bob to make any separable state, so these states come out as the "least entangled" ones for this and any richer protocol.

Next we might allow classical communication from Alice to Bob. That is, Bob's decision to perform some operation in his laboratory is allowed to depend on measuring results obtained by Alice in an earlier stage. Of course, Alice is not allowed to send quantum systems, since in this case she might just send a particle entangled to one of her own, and *any* state could be generated. This protocol is referred to as "local operations and one-way classical communication" (LOWC). Obviously, we might also allow Bob to talk back, arriving at "local operations and classical communication" (LOCC). This is the protocol underlying most of the work in entanglement theory.

The drawback of the LOCC protocol is that its operations are extremely difficult to characterize: an LOCC operation can take many rounds, and there is no way to simplify a general operation to some kind of standard form. This is the main reason why other protocols have been considered. For example, it is obvious that an LOCC operation can be written as a sum of tensor products of local operations, in a form reminiscent of the definition of separability. However, such "separable superoperators" may fall outside LOCC. Another property easily checked for all LOCC operations is that PPT states go into PPT states. The protocol "PPT-preserving operations" (PPTP) can also be characterized as the set of channels $T$ for which $(\mathrm{id}\otimes\Theta)T(\mathrm{id}\otimes\Theta)$ is positive (although not necessarily completely positive). This condition is relatively easy to handle mathematically, so that the best way to show that some $\rho_1$ cannot be converted to $\rho_2$ by LOCC is often to show that this transition is impossible under PPTP. The drawback of the PPTP protocol is that it may create some entanglement after all, namely arbitrary PPT states. So it properly belongs to a modified entanglement theory in which separability is replaced by the PPT condition.

### Converting Pure States and Majorization

The entanglement ordering is exactly known for pure states due to a famous theorem by Nielsen (1999): a pure state $\rho_1$ is *more entangled* than a pure state $\rho_2$ under the LOCC protocol iff the restriction $\rho_1^{\mathrm{A}}$ is *more mixed* than the restriction $\rho_2^{\mathrm{A}}$ in the sense of majorization of spectra (i.e., for every $k$ the sum of the $k$ largest eigenvalues of $\rho_1^{\mathrm{A}}$ is less than the corresponding sum for $\rho_2^{\mathrm{A}}$). Equivalently, there is a doubly stochastic channel (completely positive linear map preserving both the identity and the trace functional) taking $\rho_2^{\mathrm{A}}$ to $\rho_1^{\mathrm{A}}$.

An interesting aspect of this theory is the phenomenon of *catalysis*: It may happen that although $\rho_1$ cannot be converted by LOCC to $\rho_2, \rho_1\otimes\sigma$ can be converted to $\rho_2\otimes\sigma$. The "catalyst" $\sigma$ is a resource borrowed at the beginning of the transformation, and is returned unchanged afterwards. The order relation allowing such catalysts is yet to be fully characterized.

### Asymptotic Conversion

In many applications we are not interested in exact conversion of one state to another, but are quite satisfied if the transformation can be done with a small controlled error. In particular, when we ask for the *achievable conversion rate* between many copies of the states involved, we allow small errors, but require the errors to go to zero. Given any protocol, and states $\rho_1, \rho_2$, we say that $\rho_1$ can be converted to $\rho_2$ with rate $r$ if, for all sufficiently large $n$, there is a channel of the protocol, which takes $n$ copies of $\rho_1$, that is, the state $\rho_1^{\otimes n}$, to a state $\rho'$ which approximates roughly $m\approx rn$ copies of $\rho_2$, in the sense that $m\geq rn$, and the trace norm $\|\rho'-\rho_2^{\otimes m}\|$ goes to zero.

Of course, one is usually interested in the supremum of the achievable conversion rates, which we call simply the maximal conversion rate. In particular, when $\rho_2$ is the maximally entangled pure state of a qubit pair (usually called the "singlet"), the maximal rate is called the *distillable entanglement* $E_{\mathrm{D}}(\rho_1)$. In the other direction, when $\rho_1$ is the singlet, we call the inverse of the maximal conversion rate the *entanglement cost* $E_{\mathrm{C}}(\rho_2)$. These are two of the key entanglement measures to be discussed below.

In general, $E_{\mathrm{D}}(\rho)<E_{\mathrm{C}}(\rho)$, so the asymptotic conversion between different states is usually not reversible. However, this is the case for pure states, and one finds

$$E_{\mathrm{D}}(\rho)=E_{\mathrm{C}}(\rho)=S(\rho^{\mathrm{A}}) \qquad [1]$$

where $S(\rho)=-\mathrm{tr}\,\rho\log_2(\rho)$ denotes the von Neumann entropy (*see* Entropy and Quantitative Transversality) based on the binary logarithm.

Since one can do the conversion between different pure states via singlets, it is clear that the maximal conversion rate from a pure state $\rho_1$ to a pure state $\rho_2$

equals $S(\rho_1^A)/S(\rho_2^A)$. Hence, in contrast to the ordering given by Nielsen's theorem, all pure states are interconvertible, and the ordering is described by a single number. For this simplification, the allowance of small errors is crucial. Without asymptotically small but nonzero errors, it would also be impossible to obtain singlets from any generic mixed state.

## Entanglement Measures

### Properties of Interest

We now consider more systematically functions $E: \mathfrak{S} \to \mathbb{R}$ defined on the states spaces of arbitrary bipartite quantum systems. When can we regard this as a measure of entanglement? The minimal requirements are that $E(\rho) \geq 0$ for all $\rho$, and $E(\rho) = 0$ for separable states. Since the choice of local bases should be irrelevant, we will require $E((U_A \otimes U_B)\rho(U_A \otimes U_B)^*) = E(\rho)$ for unitaries $U_A, U_B$. We also *normalize* all entanglement measures so that $E(\sigma) = 1$, when $\sigma$ is the maximally entangled state of a pair of qubits. Beyond that, consider the following:

1. $\boldsymbol{V}$ (*Convexity* $E(\sum_\alpha p_\alpha \rho_\alpha) \leq \sum_\alpha p_\alpha E(\rho_\alpha)$) Starting from any $E$, possibly defined only on a subset containing the pure states, we can enforce this property by taking the *convex hull* (or "roof") co$E$, defined as the largest convex function, which is $\leq E$ wherever it is defined.
2. $\boldsymbol{M}$ (*Monotonicity*) Suppose that some LOCC protocol applied to $\rho$ returns some classical parameter $\alpha$ with probability $p_\alpha$, and in that case a bipartite state $\rho_\alpha$. Then $\sum_\alpha p_\alpha E(\rho_\alpha) \leq E(\rho)$.
3. $\boldsymbol{A}^-$ (*Subadditivity* $E(\rho_1 \otimes \rho_2) \leq E(\rho_1) + E(\rho_2)$) In this and the following, the tensor products of bipartite states are to be reordered from $A_1B_1A_2B_2$ to $(A_1A_2)(B_1B_2)$, so the separation into Alice's and Bob's subsystems is respected.
4. $\boldsymbol{A}^+$ (*Superadditivity* $E(\rho_1 \otimes \rho_2) \geq E(\rho_1) + E(\rho_2)$)
5. $\boldsymbol{A}^{++}$ (*Strong superadditivity* $E(\rho_{12}) \geq E(\rho_1) + E(\rho_2)$) Here $\rho_i$ denotes the restriction of a general state $\rho_{12}$ to the $i$th subsystem.
6. $\boldsymbol{A}^\infty$ (*Weak additivity* $E(\rho^{\otimes n}) = nE(\rho)$) This can be enforced by *regularization*, going from $E$ to

$$E^\infty(\rho) = \lim_n \frac{1}{n} E(\rho^{\otimes n})$$

   Note that this is implied by *additivity*, which is the conjunction of $\boldsymbol{A}^+$ and $\boldsymbol{A}^-$.
7. $\boldsymbol{C}$ (*Continuity*) Here it is crucial to postulate the right kind of dimensional dependence. A good choice is to demand that $|E(\rho_1) - E(\rho_2)| \leq \log d f(\|\rho_1 - \rho_2\|)$, where $f$ is some function with $\lim_{t\to 0} f(t) = 0$.
8. $\boldsymbol{L}$ (*Lockability*) A property related to, but not equal to, discontinuity: a measure is called lockable, if the loss (i.e., the tracing out) of a single qubit by Alice or Bob can make $E(\rho)$ drop by an arbitrarily large amount.

### The Collection of Entanglement Measures

The following are the main entanglement measures discussed in the literature. Note that all measures defined by conversion rates in principle depend on the protocol used. Unless otherwise stated, we will only consider LOCC. For every function we list in brackets the properties which are known.

1. $E_F$ (*Entanglement of formation* $[\boldsymbol{V}, \boldsymbol{M}, \boldsymbol{A}^-, \boldsymbol{C}, \boldsymbol{L}]$) This is defined as the convex hull of the entanglement of pure states given by eqn [1]. For qubit pairs, there is a closed formula due to Wootters (1998), orthogonally invariant states (Vollbrecht and Werner 2001) (see 00510), and permutation symmetric 2-mode Gaussians. One of the big open questions is whether $E_F$ is additive. This is equivalent to $E_F$ satisfying $\boldsymbol{A}^{++}$, and also to the additivity of Holevo's $\chi$-capacity of quantum channels (see Quantum Channels: Classical Capacity).
2. $E_C$ (*Entanglement cost* $[\boldsymbol{V}, \boldsymbol{M}, \boldsymbol{A}^-, \boldsymbol{A}^\infty, \boldsymbol{C}, \boldsymbol{L}]$) This was already defined in the section "Asymptotic conversion." It has been shown to be equal to the regularization of $E_F$, that is, $E_C = E_F^\infty$. If $E_F$ would turn out to be additive, we would thus have $E_C = E_F$.
3. $E_D$ (*Distillable entanglement* $[\boldsymbol{M}, \boldsymbol{A}^{++}, \boldsymbol{A}^\infty]$) Again, see the section "Asymptotic conversion." This is one of the important measures from the practical point of view, but notoriously difficult to compute explicitly. Convexity of $E_D$ is an open problem related to the existence of bound entangled, but not PPT states.
4. $E_\rightarrow$ (*One-way distillable entanglement* $[\boldsymbol{M}, \boldsymbol{A}^{++}, \boldsymbol{A}^\infty]$) Same as $E_D$, but restricting to the LOWC protocol. Obviously, $E_\rightarrow(\rho) \leq E_D(\rho)$. There are examples of proper inequality "$<$" (Bennett *et al.* 1996). $E_\rightarrow$ is more directly linked to quantum capacity than $E_D$, which in turn corresponds to the quantum capacity, allowing classical backwards communication as a resource.
5. $E_N$ (*Logarithmic negativity* $[\boldsymbol{M}, \boldsymbol{A}^-, \boldsymbol{A}^+, \boldsymbol{L}]$) This is a quantitative companion of the PPT criterion: one sets $E_N(\rho) = \log_2 \|(\mathrm{id} \otimes \Theta)(\rho)\|$, where the norm is the trace norm. For PPT states, $\rho$ this is equal to the trace, and $E_N(\rho) = 0$. If the partial transpose has negative eigenvalues, the sum of their absolute values is $>1$, and $E_N(\rho) > 0$. $E_N$ is an easily computed upper bound to $E_D$, but gives the wrong value for nonmaximally entangled pure states.

6. $E_R$ (*Relative entropy of entanglement* [$V, M, A^-$]) This measure (Vedral *et al.* 1997) is motivated geometrically: it is simply the relative entropy distance of $\rho$ to the separable subset: $E_R(\rho) = \inf_\sigma S(\rho\|\sigma)$, where $\sigma$ ranges over all separable states. $E_R$ is an upper bound to $E_D$. However, it can be improved by taking the distance to the PPT states rather than the separable states, and by combining with $E_N$, in the following way:
7. $E_B$ (*The Rains bound* [$V, M, A^-, C$]) Following Rains (2001), we set

$$E_B(\rho) = \inf_\sigma (S(\rho\|\sigma) + E_N(\sigma))$$

   where the infimum is over all states $\sigma$. This is still an upper bound to $E_D$, although clearly smaller than both $E_R$ (take only separable $\sigma$) and $E_N$ (take $\sigma = \rho$). No example of $E_D(\rho) < E_R(\rho)$ is known, but any bound entangled non-PPT state would be such an example.
8. $E_S$ (*Squashed entanglement* [$V, M, A^-, A^{++}, C, L$]) This measure, introduced by Christandl and Winter (2004), amazingly has all the good properties, but is as difficult to compute as any of the other measures. $E_S(\rho^{AB})$ is the infimum over the entropy combination

$$S(\rho^{AC}) + S(\rho^{BC}) - S(\rho^{ABC}) - S(\rho^{C})$$

   over all extensions $\rho^{ABC}$ of the given state $\rho^{AB}$ to a system enlarged by a part C, where the density operators in the above expression are the restrictions of $\rho^{ABC}$ to the subsystems indicated.
9. $E_K$ (*Key rate* [$V, M, A^-$]) The bit rate at which secret key can be generated is certainly larger than $E_D$, since distillation is one way to do it. It is, in general, strictly larger, since there are undistillable states with positive key rate.
10. $E_C$ (*Concurrence* [$V$]) This measure was originally only defined for qubit pairs, as a step in Wootter's (1998) formula for $E_F$ in this case. It has an extension to arbitrary dimensions (Rungta *et al.* 2001), namely the convex hull of the function $c(|\psi\rangle\langle\psi|) = \sqrt{2(1 - \mathrm{tr}(\rho^2))}$, where $\rho = |\psi\rangle\langle\psi|^A$ is the reduced density operator. Both upper and lower bounds exist in the literature. The main interest in this measure stems from the fact that it has interesting extensions to the multipartite case.

To conclude, we would like to point out that many of the themes discussed in this article were set by Bennett *et al.* (1996); their article is worth reading even today. Good review articles covering entanglement measures, with more complete references, are Plenio and Virmani (2005), Bruß (2002), and Donald *et al.* (2002).

# Entropy and Quantitative Transversality

**G Comte**, Université de Nice Sophia Antipolis, Nice, France

## Introduction

A mathematical law for a physical phenomenon, describing the variation of a value $y(\in \mathbb{R})$ in terms of parameters $x_i \in \mathbb{R}$, $i \in \{1, \ldots, n\}$, is usually given:

1. in the simplest cases (and hence in exceptional cases), by an explicit functional equation $y = F(x_1, \ldots, x_n)$, or
2. by an implicit equation $G(y, x_1, \ldots, x_n) = 0$, or
3. more generally, by a partial differentiable equation,

$$H\left(y, \frac{\partial^{|\alpha_1|}y}{\partial x_{i_1} \cdots \partial x_{i_{\alpha_1}}}, \ldots, \frac{\partial^{|\alpha_k|}y}{\partial x_{j_1} \cdots \partial x_{j_{\alpha_k}}}, x_1, \ldots, x_n\right) = 0 + \text{initial values}$$

In the first case, the exact equation $y = F(x_1, \ldots, x_n)$ fully describes the behavior of $y$ as $(x_1, \ldots, x_n)$ vary, but in practice this information is too substantive: using the Taylor formula, knowledge of the value $y^0$ at some point $(x_1^0, \ldots, x_n^0)$ and of the value of

$$\nabla F_{(x_1^0,\ldots,x_n^0)} = \left(\frac{\partial F}{\partial x_1}, \ldots, \frac{\partial F}{\partial x_n}\right)(x_1^0, \ldots, x_n^0)$$

is enough to predict, with controlled accuracy, by linear approximation, the behavior of $y$ for parameters $(x_1, \ldots, x_n)$ close to $(x_1^0, \ldots, x_n^0)$.

In the case (2), both the parameters $(x_1, \ldots, x_n)$ and the value $y$ belong to the set $M = \{(y, x_1, \ldots, x_n) \in \mathbb{R}^{n+1}; G(y, x_1, \ldots, x_n) = 0\}$, and we would like to know whether or not this set may be (at least locally around one of its point $(y^0, x_1^0, \ldots, x_n^0)$) a graph of some function $(x_1, \ldots, x_n) \mapsto y = F(x_1, \ldots, x_n)$, as in the case (1). Using the implicit function theorem, we may try to reduce our equation to the explicit equation of (1), and then perform a linear approximation involving $\nabla F_{(x_1^0,\ldots,x_n^0)}$. Assuming that *a priori* we know a value $y^0$ such that for $(x_1^0, \ldots, x_n^0)$, $(y^0, x_1^0, \ldots, x_n^0) \in M$, this reduction is possible, locally around $(y^0, x_1^0, \ldots, x_n^0)$, under the condition that

$$\frac{\partial G}{\partial y}(y^0, x_1^0, \ldots, x_n^0) \neq 0$$

In this situation

$$\nabla F_{(x_1^0,\ldots,x_n^0)} = -\left(\frac{\partial G}{\partial x_1}, \ldots, \frac{\partial G}{\partial x_n}\right) \times (y^0, x_1^0, \ldots, x_n^0) \Big/ \frac{\partial G}{\partial y}(y^0, x_1^0, \ldots, x_n^0)$$

Now, as it is normally the case, when they come from observation, the variables $x_1, \ldots, x_n$ are known with an estimate and one sees that the larger

$$\left|\left(\frac{\partial G}{\partial x_1}, \ldots, \frac{\partial G}{\partial x_n}\right)(y^0, x_1^0, \ldots, x_n^0) \Big/ \frac{\partial G}{\partial y}(y^0, x_1^0, \ldots, x_n^0)\right|$$

is, the worse the estimate on $y$ near $y^0$.

Furthermore, assuming that $M$ is locally a graph of a function $(x_1, \ldots, x_n) \mapsto y = F(x_1, \ldots, x_n)$, for a given $(x_1, \ldots, x_n)$, the exact expression of $y = F(x_1, \ldots, x_n)$ and consequently the exact value of $\nabla F_{(x_1,\ldots,x_n)}$ is not possible to obtain; we have to approach it using an algorithm (classically the Newton algorithm), and closer

$$\frac{\partial G}{\partial y}(y^0, x_1^0, \ldots, x_n^0)$$

is to 0, the more such an algorithm is unstable.

Finally, in the case (3), skipping technical details, we encounter the same type of difficulties: we have to avoid small values for some gradient functions at a given point, in order to obtain, locally at some point $(x_1^0, \ldots, x_n^0)$, in a stable way, reliable information on $y$ in terms of $(x_1, \ldots, x_n)$.

To sum up, the prediction of a physical phenomenon by a mathematical law greatly depends not only on the noncancellation of some gradient functions, but, as we deal with approximations and algorithms, on how different those gradient functions are from zero.

This principle, of course, extends directly to applied problems (see the last of our examples in the final section): being close to singular values essentially means that the control (e.g., of the positions of some device by a manipulator) is poor.

The geometric counterpart of this analytic phenomenmon is called "transversality," the condition for some function $G$ to have a nonzero partial derivative

$$\frac{\partial G}{\partial y}(y^0, x_1^0, \ldots, x_n^0)$$

is equivalent to the condition

$$\nabla G_{(y^0, x_1^0,\ldots,x_n^0)} \oplus Ox_1 \cdots x_n = \mathbb{R}^{n+1}$$

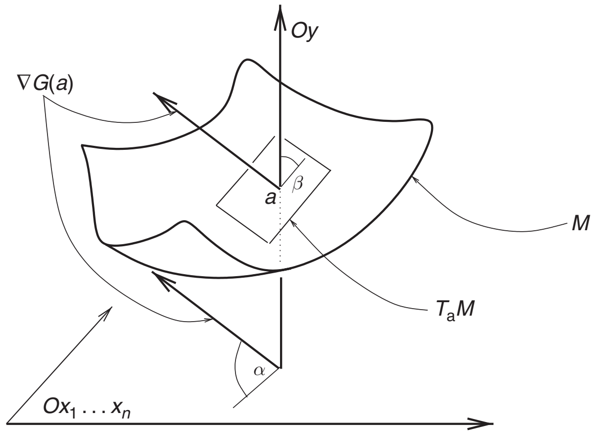

**Figure 1** Transversality of the manifold *M* and *Oy*.

or to the condition

$$T_{(y^0, x_1^0, \ldots, x_n^0)} M \oplus Oy = \mathbb{R}^{n+1}$$

where $T_a M$ is the tangent space of $M$ at $a \in M$.

We say that $\nabla G_{(y^0, x_1^0, \ldots, x_n^0)}$ is transverse to the space of parameters $Ox_1 \cdots x_n$ at $(y^0, x_1^0, \ldots, x_n^0)$, or that $M$ is transverse to $Oy$ at $(y^0, x_1^0, \ldots, x_n^0)$.

For some quantity $\epsilon > 0$, the condition that

$$\left| \left( \frac{\partial G}{\partial x_1}, \ldots, \frac{\partial G}{\partial x_n} \right) (y^0, x_1^0, \ldots, x_n^0) \Big/ \frac{\partial G}{\partial y} (y^0, x_1^0, \ldots, x_n^0) \right| \geq \frac{1}{\epsilon}$$

means that the angle $\alpha = (\widehat{\nabla G_{(y^0, x_1^0, \ldots, x_n^0)}, Ox_1 \cdots x_n})$ or the angle $\beta = (\widehat{T_{(y^0, x_1^0, \ldots, x_n^0)} M, Oy})$ is smaller than $\epsilon$ (see Figure 1).

Our purpose in the sequel is to indicate how we can quantify the situations described above (the defect of transversality), in order to generically or almost generically avoid them with quantified accuracy.

## Quantifying Transversality

Given two submanifolds $M$ and $N$ of the Euclidean space $\mathbb{R}^n$, we can measure the transversality defect of $(M, N)$ at $x \in \mathbb{R}^n$ with a differential criterion, both analytical and geometric.

Let us first introduce some notations. For a given linear map $L : \mathbb{R}^n \to \mathbb{R}^p$, the image by $L$ of the unit ball of $\mathbb{R}^n$ is an $r$-dimensional ellipsoid in $\mathbb{R}^p$ with semi-axes denoted as $l_1(L) \geq \cdots \geq l_r(L)$, where $r$ is the rank of $L$. For $r < p$, we denote $l_{r+1}(L) = 0, \ldots, l_p(L) = 0$.

Now, let $x \in M \cap N$; let $\pi : \mathbb{R}^n \to T_x N^\perp$ be the projection onto the orthogonal space of $T_x N$, $p = n - \dim(N)$ and $\pi_{|M}$ the restriction of $\pi$ to $M$.

### Definitions

We say that $(M, N)$ is transverse at $x$, and we denote it by $M \pitchfork_x N$, if and only if $\pi_{|M}$ is a submersion at $x$, that is, $D\pi_{|M(x)} : T_x M \to T_x N^\perp$ is onto.

For a given $\Lambda = (\epsilon_1, \ldots, \epsilon_p)$, $\epsilon_1 \geq \cdots \geq \epsilon_p$, we say that $(M, N)$ is $\Lambda$-nontransverse at $x$, and we denote it by $M \not\pitchfork_x^\Lambda N$, if and only if $l_i(D\pi_{|M(x)}) \leq \epsilon_i, \forall\, i \in \{1, \ldots, p\}$.

With these notations, we have: $M \not\pitchfork_x N$ (*i.e.*, $(M, N)$ nontransverse at $x$) if and only if $x \notin M \cap N$ or $M \not\pitchfork_x^\Lambda N$, for some $\Lambda$ with $\epsilon_p = 0$, and the more $(M, N)$ is $\Lambda$-nontransverse, with $\Lambda$ close to $(\epsilon_1, \ldots, \epsilon_{p-1}, 0)$, the less the manifolds $M$ and $N$ seem transverse at $x \in M \cap N$ (see Figure 2).

The final step in our formalism to give a convenient quantitative approach of transversality is the following: let $X$, $Y$ be two (real) Riemannian manifolds, $f : X \to Y$ a (smooth) mapping, $N \subset Y$ a submanifold of $Y$ with codimension $p$ in $N$, $y \in N$, and $\Phi : \mathcal{O} \to \mathbb{R}^p$ a submersion, where $\mathcal{O}$ is an open neighborhood of $x$ in $Y$, such that $\Phi^{-1}(\{0\}) = N \cap \mathcal{O}$. Then we say that $(f, N)$ is transverse at $x$, and we denote it by $f \pitchfork_x N$, if and only if $f \circ \Phi$ is submersive in $x$.

For a given $\Lambda = (\epsilon_1, \ldots, \epsilon_p)$, $\epsilon_1 \geq \cdots \geq \epsilon_p$, we say that $(f, N)$ is $(\Phi, \Lambda)$-nontransverse at $x$, and we denote it by $f \not\pitchfork_x^{(\Phi,\Lambda)} N$, if and only if $l_i(D[f \circ \Phi]_{(x)}) \leq \epsilon_i, \forall\, i \in \{1, \ldots, p\}$.

Clearly, we recognize the definition of transversality and of $\Lambda$-nontransversality of two submanifolds $M, N$ of $\mathbb{R}^n$ by letting $f : M \to \mathbb{R}^n$ be the inclusion and $\Phi = \pi_{|M}$ (for more details on transversality and stability, see, e.g., Golubitski and Guillemin (1973)).

With the definitions and notations above, our general problem may be posed as follows:

> For a $C^k$-regular $(k \in \mathbb{N} \cup \{\infty\})$ mapping $f : \mathbb{R}^n \to \mathbb{R}^p$ and a given $\Lambda = (\epsilon_1, \ldots, \epsilon_p)$, how large is the set $\Delta(f, B_r, \Lambda) = f(\Sigma(f, B_r, \Lambda))$, where $\Sigma(f, B_r, \Lambda) = \{x \in B_r \subset \mathbb{R}^n;\ l_i(Df_{(x)}) \leq \epsilon_i,\ \forall i \in \{1, \ldots, p\}\}$ and $B_r$ is a ball of radius $r$ in $\mathbb{R}^n$?

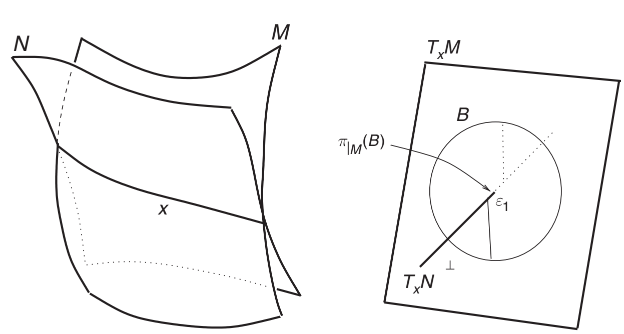

**Figure 2** Almost-nontransversality of *M* and *N*.

The "bad" set $\Delta(f, B_r, \Lambda)$ is called the set of $\Lambda$-almost critical values of $f$ (restricted to $B_r$). Our purpose is to show that one can control its size in terms of $k$ and $\Lambda$. However, before explicitly stating quantitative results, let us precise what we understand by "big set" or by "size of a set."

## Measure and Dimensions

We have a very natural way to measure a subset $A$ of a metric space. To do this, we consider $\alpha \geq 0$ a real number and we denote

$$\mathcal{A}_\nu = \left\{ (D_i)_{i \in \mathbb{N}}; A \subset \bigcup_{i \in \mathbb{N}} D_i \text{ and } |D_i| \leq \nu \right\}$$

where $|D_i|$ is the diameter of $D_i$,

$$\mathcal{H}^\alpha_\nu(A) = \inf \left\{ \sum_{i \in \mathbb{N}} |D_i|^\alpha; (D_i)_{i \in \mathbb{N}} \in \mathcal{A}_\nu \right\}$$

and

$$\mathcal{H}^\alpha(A) = \lim_{\nu \to 0} \mathcal{H}^\alpha_\nu(A) \in \mathbb{R} \cap \{\infty\}$$

$\mathcal{H}^\alpha(A)$ is called the $\alpha$-dimensional Hausdorff measure of $A$. It appears that when $\mathcal{H}^\alpha(A) \neq \infty$, $\mathcal{H}^{\alpha'}(A) = 0$ for $\alpha' > \alpha$, and when $\mathcal{H}^\alpha(A) \neq 0$, $\mathcal{H}^{\alpha'}(A) = \infty$ for $\alpha' < \alpha$. This gives rise to the following definition of the Hausdorff dimension of $A$:

$$\begin{aligned} \dim_{\mathcal{H}}(A) &= \inf\{\alpha; \mathcal{H}^\alpha(A) = 0\} \\ &= \sup\{\alpha; \mathcal{H}^\alpha(A) = \infty\} \end{aligned}$$

The Hausdorff dimension generalizes the classical notions of dimension, for instance, when $A$ is a subset of $\mathbb{R}^n, \dim_{\mathcal{H}}(A) \leq n$, a $d$-dimensional manifold has Hausdorff dimension $d$, and $\mathcal{H}^n(A)$ is the same as the Lebesgue measure $\mathcal{L}_n$ of $A$ (for a very large class of subset $A$, which we do not describe here. For more details on geometric measure theory, see Falconer (1986) and Federer (1969)).

Another convenient notion of dimension is the (metric) entropy dimension. Let us briefly define it. For a bounded subset $A$ in some metric space and a real number $\alpha > 0$, we denote $M(\alpha, A)$ the minimal number of closed balls of radius $\leq \alpha$, covering $A$. $H_\alpha(A) = \log_2(M(\alpha, A))$ is called the $\alpha$-entropy of the set $A$. This terminology was introduced in Kolmogorov and Tihomirov (1961) and reflects the fact that $H_\alpha(A)$ is the amount of information needed to digitally memorize $A$ with accuracy $\alpha$. The entropy dimension of $A$, $\dim_e(A)$, is the order of $M(\alpha, A)$ as $\alpha \to 0$. Precisely,

$$\begin{aligned} \dim_e(A) &= \limsup_{\alpha \to 0} \frac{\log(M(\alpha, A))}{\log(1/\alpha)} \\ &= \inf\{\delta; M(\alpha, A) \leq (1/\alpha)^\delta, \\ &\quad \text{for sufficiently small } \alpha\} \end{aligned}$$

We clearly have

$$\dim_{\mathcal{H}}(A) \leq \dim_e(A)$$

For any bounded set $A$ in $\mathbb{R}^n$, we can bound $M(\alpha, A)$ from above by a polynomial in $1/\alpha$ (see Ivanov (1975) and Yomdin and Comte (2004)):

$$M(\alpha, A) \leq c(n) \sum_{i=0}^{n} V_i(A)(1/\alpha)^i$$

where $c(n)$ only depends on $n$ and $V_i(A)$ (the $i$th variation of the set $A$) is the mean value, with respect to $P$ (for a suitable measure), of the number of connected components of $A \cap P$, with $P$ an affine $(n-i)$-dimensional space of $\mathbb{R}^n$.

Since for $A$ contained in a $d$-dimensional manifold, $V_i(A) = 0$ for $i > d$, we deduce from this inequality that in this case $M(\alpha, A)$ is bounded from above by a polynomial of degree $\leq d$ in $1/\alpha$.

Our goal is to explain that we can be more precise than this general inequality when $A$ is a set of critical or almost-critical values of a $\mathcal{C}^k$ mapping.

## Transversality Is a Generic Situation

The results in this section concern critical values, and not almost-critical values. They show that a "generic" point of the target space is not a critical value, and the more regular, the mapping the smaller the set of critical values. Such theorems relating the regularity of a mapping and the size of its critical values are called Morse–Sard type theorems (see Sard (1942, 1958, 1965)). The simplest theorem in this direction is the following:

**Theorem 1** ($\mathcal{C}^\infty$ Morse–Sard theorem) (Morse 1939, Sard 1942, Holm 1987). *Let $f: \mathbb{R}^n \to \mathbb{R}^p$ be a $\mathcal{C}^\infty$-regular mapping. Then $\mathcal{H}^p(\Delta(f, B_r)) = 0$, where $\Delta(f, B_r) = f(\Sigma(\mathrm{f}, \mathrm{B_r}))$ and $\Sigma(f, B_r)$ is the set of points $x \in B_r$ where* $\mathrm{rank}(Df_{(x)}) < p$.

The set $\Delta(f, B_r)$ is the image, under $f$, of the points of the ball $B_r$ in the source space at which $f$ is not submersive, that is, the set of critical values of $f$. Consequently, the Morse–Sard theorem ensures that for almost all points $y$ in the target space, $f^{-1}(\{y\})$ is either empty or a smooth submanifold of the source space of dimension $n - p$.

Note that $\Delta(f, B_r) = \Delta(f, B_r, \Lambda)$ for some convenient $\Lambda = (\epsilon_1, \ldots, \epsilon_p)$ with $\epsilon_p = 0$, because $x \mapsto l_i(Df_{(x)})$ is bounded on $B_r$, for all $i \in \{1, \ldots, p\}$.

Now, we can concentrate our attention on more singular points than the critical ones, those at which the rank $\rho$ of $f$ is prescribed. Let us denote such points by $\Delta^\rho(f, B_r)$, for $\rho < p$. By definition, $\Delta^\rho(f, B_r) = f(\Sigma^\rho(f, B_r))$, where $\Sigma^\rho(f, B_r) = \{x \in B_r \subset R^n; \mathrm{rank}(Df_{(x)}) \leq \rho\}$. With these notations, the result for rank-$r$ critical values is the following:

**Theorem 2** ($\mathcal{C}^k$ Morse–Sard theorem for rank-$r$ critical values) (Federer 1969). *Let $f: \mathbb{R}^n \to \mathbb{R}^p$ be a $\mathcal{C}^k$-regular mapping. Then $\mathcal{H}^{\rho+(n-\rho)/k}(\Delta^\rho(f, B_r)) = 0$. In particular,*

$$\dim_{\mathcal{H}}(\Delta^\rho(f, B_r)) \leq \rho + \frac{n-\rho}{k}$$

One can produce examples showing that the bound of Theorem 2 is the sharpest one (see Comte (1996), Whitney (1935), Grinberg (1985), and Yomdin and Comte (2004)).

We note that Theorem 1 is a corollary of Theorem 2 (just replace $k$ by $\infty$ and $\rho$ by $p-1$ in Theorem 2). This result tells nothing about the entropy dimension of $\Delta^\rho(f, B_r)$; in the next section, we will bound the growth of entropy of almost-critical values.

## Almost-Transversality Is Almost Generic

In this section, $f: \mathbb{R}^n \to \mathbb{R}^p$ is a $\mathcal{C}^k$ mapping. We denote by $K$ a Lipschitz constant of $D^{k-1}f$ on $B_r$ and by $R_k(f)$ the quantity $(K/(k-1)!) \cdot r^k$. We have:

**Theorem 3** ($\mathcal{C}^k$ quantitative Morse–Sard theorem) (Yomdin 1983 Yomdin and Comte 2004). *Let $f: \mathbb{R}^n \to \mathbb{R}^p$ be a $\mathcal{C}^k$ mapping, $\Lambda = (\epsilon_1, \ldots, \epsilon_p)$, $\epsilon_1 \geq \cdots \geq \epsilon_p$, and let us denote $\epsilon_0 = 1$. We have (for $\alpha \leq R_k(f)$):*

$$M(\alpha, \Delta(f, B_r, \Lambda)) \leq C \cdot \sum_{i=0}^{p} \epsilon_0 \cdots \epsilon_i \left(\frac{r}{\alpha}\right)^i \left(\frac{R_k(f)}{\alpha}\right)^{(n-i)/k}$$

*where $C$ is a constant depending only on $n$, $p$, and $k$.*

As a corollary, one can bound the entropy dimension of $\Delta^\rho(f, B_r)$ by $\rho + (n-\rho)/k$, and hence its Hausdorff dimension, again finding Theorem 2: we just have to put $\epsilon_{\rho+1} = 0$ and $\epsilon_1, \ldots, \epsilon_\rho$ large enough, that is, $\epsilon_i \geq \lambda_i(Df_{(x)})$, for all $x \in B_r$, in Theorem 3, to obtain:

**Theorem 4** ($\mathcal{C}^k$ entropy Morse–Sard theorem) (Yomdin 1983 Yomdin and Comte 2004). *Let $f: \mathbb{R}^n \to \mathbb{R}^p$ be a $\mathcal{C}^k$ mapping, let us denote $\epsilon_0 = 1$ and $\epsilon_i = \sup\{\lambda_i(Df_{(x)}); x \in B_r\}$, for $i \in \{1, \ldots, \rho\}$. We have (for $\alpha \leq R_k(f)$):*

$$M(\alpha, \Delta^\rho(f, B_r)) \leq C \cdot \sum_{i=0}^{\rho} \epsilon_0 \cdots \epsilon_i \left(\frac{r}{\alpha}\right)^i \left(\frac{R_k(f)}{\alpha}\right)^{(n-i)/k}$$

*where $C$ is a constant depending only on $n$, $p$, and $k$. In particular,*

$$\dim_{\mathcal{H}}(\Delta^\rho(f, B_r)) \leq \dim_e(\Delta^\rho(f, B_r)) \leq \rho + \frac{n-\rho}{k}$$

Again we have examples showing that this bound is sharp (see Yomdin and Comte 2004).

Furthermore, the mapping $f$ in Theorems 2–4 may be of real differentiability class (Hölder smoothness class $\mathcal{C}^k$), with the same conclusions in these theorems. That is, $k$ may be a real number written as $k = p + \beta$ with $\beta \in [0, 1]$, $p \in \mathbb{N}\backslash\{0\}$, and $f$ is $\mathcal{C}^k$ means that $f$ is $p$ times differentiable and there exists a constant $C > 0$ such that for all $x, y \in B_r, \|D^p f_{(x)} - D^p f_{(y)}\| \leq C \cdot \|x - y\|^\beta$ (see Yomdin and Comte (2004)).

## Examples

Let us denote by $A$ the set of real polynomial mappings of degree $d$ and of the following type:

$$x \mapsto Q(a, x) = 1 + \sum_{j=1}^{d} a_j x^j$$

with $a = (a_1, \ldots, a_d)$ and $\|a\| \leq 1$ (where $\|\|$ is the Euclidean norm of $\mathbb{R}^d$). We identify the set $A$ with $B^d(0,1) = \{a \in \mathbb{R}^d; \|a\| \leq 1\}$.

We want to bound the $\alpha$-entropy of the set of such polynomials for which the real roots are multiple or almost multiple.

We denote by $V$ the set $V = \{(a, x) \in \mathbb{R}^{d+1}; Q(a, x) = 0\}$. At points $(a, x)$ of $V$ with $\nabla Q_{(a,x)} \neq 0$, $V$ is a $\mathcal{C}^\infty$ manifold of codimension 1 of $\mathbb{R}^{d+1}$. We denote by $V^{\mathrm{reg}} = \{(a, x) \in V; \nabla Q_{(a,x)} \neq 0\}$ and by $V^{\mathrm{sing}} = \{(a, x) \in V; \nabla Q_{(a,x)} = 0\} = V \setminus V^{\mathrm{reg}}$. By Whitney (1957), $V^{\mathrm{sing}}$ is a union of smooth manifolds of dimension $\leq d-1$.

A root $x$ of a polynomial $Q(a, \cdot)$ is multiple if and only if

$$Q(a, x) = \frac{\partial Q}{\partial x}(a, x) = 0$$

Consequently, the set $A^\Sigma$ of polynomials of $A$ with multiple roots is $\pi(V^{\mathrm{sing}}) \cup \Delta(\pi_{|V^{\mathrm{reg}}})$, where $\pi: \mathbb{R}^{d+1} \to \mathbb{R}^d$ is the standard projection $\pi(a, x) = a$, and $\Delta(\pi_{|V^{\mathrm{reg}}})$ is the set $\{(a, x) \in V^{\mathrm{reg}}; Ox \subset T_{(a,x)} V^{\mathrm{reg}}\}$ of critical values of $\pi_{|V^{\mathrm{reg}}}$. By Sard's theorem

(Theorem 2), $\dim_{\mathcal{H}}(\Delta(\pi_{|V^{\mathrm{reg}}})) \leq d-1$. Since $\dim_{\mathcal{H}}(\pi(V^{\mathrm{sing}})) \leq d-1$, we obtain: $\dim_{\mathcal{H}}(A^{\Sigma}) \leq d-1$: thus, having distinct roots is a generic property.

Let, as above, $\Lambda = (\epsilon_1, \ldots, \epsilon_d)$ with $\epsilon_1 \geq \cdots \geq \epsilon_d$ and $\epsilon_0 = 1$. A root $x$ of a polynomial $Q(a,\cdot) \in A$ is said to be $\Lambda$-almost multiple if and only if $Q(a,x) = 0$ and $V \not\pitchfork_x^{\Lambda} Ox$, that is, $(a,x) \in V^{\mathrm{sing}}$ or $\sin(T_{(a,x)}V^{\mathrm{reg}}, Ox) \leq \epsilon_d$. This condition only concerns $\epsilon_d$ and we can take $\epsilon_1 = \cdots = \epsilon_{d-1} = 1$. We denote $A^{\Sigma,\Lambda}$ to be the set of polynomials of $A$ with (at least) a $\Lambda$-almost multiple root. By Theorem 3,

$$M(\alpha, A^{\Sigma,\Lambda} \backslash \pi(V^{\mathrm{sing}})) \leq C \cdot \left[\sum_{i=0}^{d-1}\left(\frac{1}{\alpha}\right)^i + \epsilon_d \cdot \left(\frac{1}{\alpha}\right)^d\right]$$

But $\pi(V^{\mathrm{sing}})$ being a finite union of manifolds of dimension at most $d-1$, we finally obtain

$$M(\alpha, A^{\Sigma,\Lambda}) \leq C' \cdot \left[\sum_{i=0}^{d-1}\left(\frac{1}{\alpha}\right)^i + \epsilon_d \cdot \left(\frac{1}{\alpha}\right)^d\right]$$

Thus, having no $\Lambda$-almost multiple root is $\Lambda$-almost a generic property. In Figure 3, we represent $V$ for $d = 3$ and $a_3 = 1$,

$$W = \left\{(a,x) \in \mathbb{R}^{d+1};\ \frac{\partial Q}{\partial x}(a,x) = 0\right\}$$

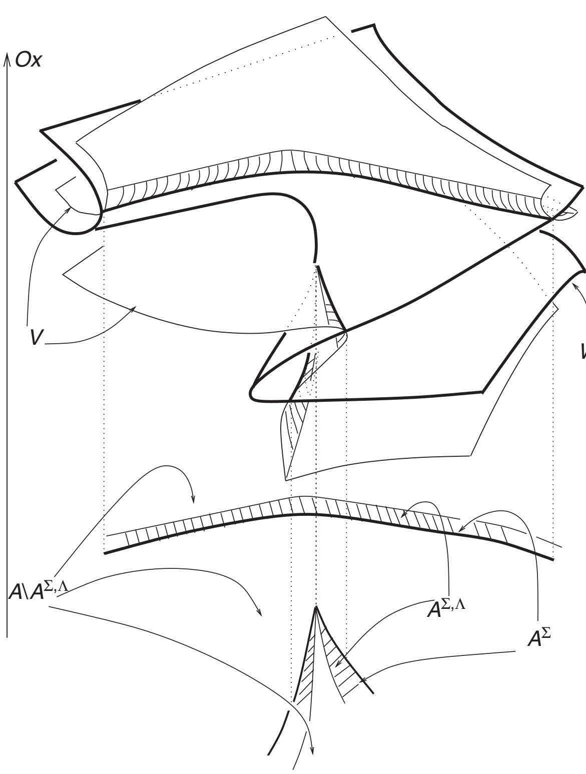

**Figure 3** The space of polynomials of type $1 + a_1x + a_2x + x^3$ with almost-multiple roots.

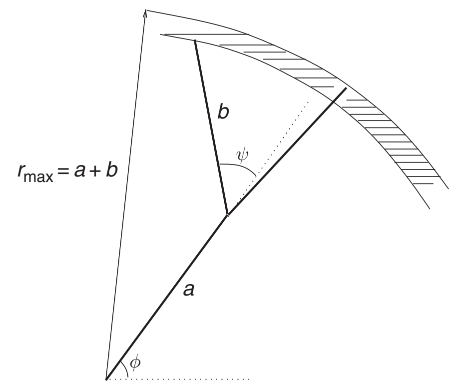

**Figure 4** Almost-critical points of the distance function of $P$ to the origin.

The next example comes from robotics: let us consider a planar robotic manipulator consisting of two jointed bars of length $a$ and $b$, as presented in Figure 4. We may parametrize the positions of the endpoint $P$ of this device by the angles $\phi$ and $\psi$ (see Figure 4). Now the distance $r$ from the origin to $P$ is $r^2 = \|P\|^2 = a^2 + b^2 + 2ab\cos(\psi)$. The critical points of $r$ are given by

$$\frac{\mathrm{d}r}{\mathrm{d}\psi}(\psi) = -2ab\sin(\psi) = 0$$

and correspond to the circle $\psi = 0$. The critical value of $r$ is $a+b$. Near these critical positions, the control of $r$ with respect to $\psi$ is poor; we would like to avoid those near-critical values. Given $\epsilon > 0$, the condition

$$\left|\frac{\mathrm{d}r}{\mathrm{d}\psi}(\psi)\right| \leq \epsilon$$

implies $|\psi| \leq \arcsin(\epsilon/2ab)$, and the $\epsilon$-near-critical values of $r$ are

$$r_{\max}^2 - r^2 \leq 2ab[1 - \cos(\arcsin(\epsilon/2ab))]$$

where $r_{\max}$ is $a+b$; thus, they are contained in an interval of length $\leq c \cdot \epsilon^2/(4ab \cdot r_{\max})$, and $M(\alpha, \Delta(r,\epsilon)) \leq c \cdot \epsilon^2/(4ab \cdot r_{\max} \cdot \alpha)$ (Theorem 3 gives $M(\alpha, \Delta(r,\epsilon)) \leq C(1 + \epsilon/\alpha)$.

# Equivariant Cohomology and the Cartan Model

**E Meinrenken**, University of Toronto, Toronto, ON, Canada

## Introduction

If a compact Lie group $G$ acts on a manifold $M$, the space $M/G$ of orbits of the action is usually a singular space. Nonetheless, it is often possible to develop a "differential geometry" of the orbit space in terms of appropriately defined equivariant objects on $M$. This article is mostly concerned with "differential forms on $M/G$." A first idea would be to work with the complex of "basic" forms on $M$, but for many purposes this complex turns out to be too small. A much more useful complex of equivariant differential forms on $M$ was introduced by Cartan (1950). In retrospect, Cartan's approach presented a differential form model for the equivariant cohomology of $M$, as defined by A Borel (1960). Borel's construction replaces the quotient $M/G$ by a better-behaved (but usually infinite-dimensional) homotopy quotient $M_G$, and Cartan's complex should be viewed as a model for forms on $M_G$.

One of the features of equivariant cohomology are the localization formulas for the integrals of equivariant cocycles. The first instance of such an integration formula was the "exact stationary phase formula," discovered by Duistermaat and Heckman. This formula was quickly recognized by Berline and Vergne (1983) and Atiyah and Bott (1984), as a localization principle in equivariant cohomology. Today, equivariant localization is a basic tool in mathematical physics, with numerous applications.

This article begins with Borel's topological definition of equivariant cohomology, then proceeds to describe H Cartan's more algebraic approach, and concludes with a discussion of localization principles.

As additional references for the material covered here, we particularly recommend books by Berline, Getzler, and Vergne (1992) and Guillemin and Sternberg (1999).

## Borel's Model of $H_G(M)$

Let $G$ be a topological group. A $G$-space is a topological space $M$ on which $G$ acts by transformations $g \mapsto a_g$, in such a way that the action map

$$a : G \times M \to M \qquad [1]$$

is continuous. An important special case of $G$-spaces are principal $G$-bundles $E \to B$, that is, $G$-spaces locally isomorphic to products $U \times G$.

**Definition 1** A classifying bundle for $G$ is a principal $G$-bundle $EG \to BG$, with the following universal property: for any principal $G$-bundle $E \to B$, there is a map $f : B \to BG$, unique up to homotopy, such that $E$ is isomorphic to the pullback bundle $f^*EG$. The map $f$ is known as a "classifying map" of the principal bundle.

To be precise, the base spaces of the principal bundles considered here must satisfy some technical condition. For a careful discussion, see Husemoller (1994). Classifying bundles exist for all $G$ (by a construction due to Milnor (1956)), and are unique up to $G$-homotopy equivalence.

It is a basic fact that principal $G$-bundles with contractible total space are classifying bundles.

**Examples 2**

(i) The bundle $\mathbb{R} \to \mathbb{R}/\mathbb{Z} = S^1$ is a classifying bundle for $G = \mathbb{Z}$.

(ii) Let $\mathcal{H}$ be a separable complex Hilbert space, $\dim \mathcal{H} = \infty$. It is known that unit sphere $S(\mathcal{H})$ is contractible. It is thus a classifying U(1)-bundle, with the projective space $P(\mathcal{H})$ as base. More generally, the Stiefel manifold $\mathrm{St}(k, \mathcal{H})$ of unitary $k$-frames is a classifying U($k$)-bundle, with base the Grassmann manifold $\mathrm{Gr}(k, \mathcal{H})$ of $k$-planes.

(iii) Any compact Lie group $G$ arises as a closed subgroup of U($k$), for $k$ sufficiently large. Hence, the Stiefel manifold $\mathrm{St}(k, \mathcal{H})$ also serves as a model for $EG$.

(iv) The based loop group $G = L_0K$ of a connected Lie group $K$ acts by gauge transformations on the space of connections $\mathcal{A}(S^1) = \Omega^1(S^1, \mathfrak{k})$. This is a classifying bundle for $L_0K$, with base $K$. The quotient map takes a connection to its holonomy.

For any commutative ring $R$ (e.g., $\mathbb{Z}, \mathbb{R}, \mathbb{Z}_2$), let $H(\cdot\,; R)$ denote the (singular) cohomology with coefficients in $R$. Recall that $H(\cdot\,; R)$ is a graded commutative ring under cup product.

**Definition 3** The equivariant cohomology $H_G(M) = H_G(M; R)$ of a $G$-space $M$ is the cohomology ring of its homotopy quotient $M_G = EG \times_G M$:

$$H_G(M; R) = H(M_G; R) \qquad [2]$$

Equivariant cohomology is a contravariant functor from the category of $G$-spaces to the category of $R$-modules. The $G$-map $M \to \mathrm{pt}$ induces an algebra homomorphism from $H_G(\mathrm{pt}) = H(BG)$ to $H_G(M)$. In this way, $H_G(M)$ is a module over the ring $H(BG)$.

**Example 4** (Principal $G$-bundles). Suppose $E \to B$ is a principal $G$-bundle. The homotopy quotient $E_G$ may be viewed as a bundle $E \times_G EG$ over $B$. Since the fiber is contractible, there is a homotopy equivalence

$$E_G \simeq B \qquad [3]$$

and therefore $H_G(E) = H(B)$.

**Example 5** (Homogeneous spaces). If $K$ is a closed subgroup of a Lie group $G$, the space $EG$ may be viewed as a model for $EK$, with $BK = EG/K = EG \times_K (G/K)$. Hence,

$$H_G(G/K) = H(BK) \qquad [4]$$

Let us briefly describe two of the main techniques for computing $H_G(M)$.

1. *Leray spectral sequences*. If $R$ is a field, the equivariant cohomology may be computed as the $E_\infty$ term of the spectral sequence for the fibration $M_G \to BG$. If $BG$ is simply connected (as is the case for all compact connected Lie groups), the $E_2$-term of the spectral sequence reads

$$E_2^{p,q} = H^p(BG) \otimes H^q(M) \qquad [5]$$

2. *Mayer–Vietoris sequences*. If $M = U_1 \cup U_2$ is a union of two $G$-invariant open subsets, there is a long exact sequence

$$\cdots \to H_G^k(M) \to H_G^k(U_1) \oplus H_G^k(U_2) \to$$
$$\to H_G^k(U_1 \cap U_2) \to H_G^{k+1}(M) \to \cdots$$

More generally, associated to any $G$-invariant open cover, there is a spectral sequence converging to $H_G(M)$.

**Example 6** Consider the standard U(1)-action on $S^2$ by rotations. Cover $S^2$ by two open sets $U_\pm$, given as the complement of the south pole and north pole, respectively. Since $U_+ \cap U_-$ retracts onto the equatorial circle, on which U(1) acts freely, its equivariant cohomology vanishes except in degree 0. On the other hand, $U_\pm$ retract onto the poles $p_\pm$. Hence, by the Mayer–Vietoris sequence the map $H^k_{\mathrm{U}(1)}(S^2) \cong H^k_{\mathrm{U}(1)}(p_+) \oplus H^k_{\mathrm{U}(1)}(p_-)$ given by pullback to the fixed points is an isomorphism for $k > 0$. Since the pullback map is a ring homomorphism, we conclude that $H_{\mathrm{U}(1)}(S^2; R)$ is the commutative ring generated by two elements $x_\pm$ of degree 2, subject to a single relation $x_+x_- = 0$.

## $\mathfrak{g}$-Differential Algebras

Let $G$ be a Lie group, with Lie algebra $\mathfrak{g}$. A $G$-manifold is a manifold $M$ together with a $G$-action such that the action map [1] is smooth. We would like to introduce the concept of equivariant differential forms on $M$. This complex should play the role of differential forms on the infinite-dimensional space $M_G$. In Cartan's approach, the starting point is an algebraic model for the differential forms on the classifying bundle $EG$.

The algebraic machinery will only depend on the infinitesimal action of $G$. It is therefore convenient to introduce the following concept.

**Definition 7** Let $\mathfrak{g}$ be a finite-dimensional Lie algebra. A $\mathfrak{g}$-manifold is a manifold $M$, together with a Lie algebra homomorphism $a: \mathfrak{g} \to \mathfrak{X}(M), \xi \mapsto a_\xi$ into the Lie algebra of vector fields on $M$, such that the map $\mathfrak{g} \times M \to TM, (\xi, m) \mapsto a_\xi(m)$ is smooth.

Any $G$-manifold $M$ becomes a $\mathfrak{g}$-manifold by taking $a_\xi$ to be the generating vector field

$$a_\xi(m) := \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} a_{\exp(-t\xi)}(m) \qquad [6]$$

Conversely, if $G$ is simply connected, and $M$ is a $\mathfrak{g}$-manifold for which all of the vector fields $a_\xi$ are complete, the $\mathfrak{g}$-action integrates uniquely to an action of the group $G$.

The de Rham algebra $(\Omega(M), \mathrm{d})$ of differential forms on a $\mathfrak{g}$-manifold $M$ carries graded derivations $L_\xi = L(a_\xi)$ (Lie derivatives, degree 0) and $\iota_\xi = \iota(a_\xi)$ (contractions, degree –1). One has the following graded commutation relations:

$$[\mathrm{d}, \mathrm{d}] = 0, \qquad [L_\xi, \mathrm{d}] = 0, \qquad [\iota_\xi, \mathrm{d}] = L_\xi \qquad [7]$$

$$[\iota_\xi, \iota_\eta] = 0, \quad [L_\xi, L_\eta] = L_{[\xi,\eta]_\mathfrak{g}}, \quad [L_\xi, \iota_\eta] = \iota_{[\xi,\eta]_\mathfrak{g}} \qquad [8]$$

More generally, the following definitions are introduced.

**Definition 8** A $\mathfrak{g}$-differential algebra ($\mathfrak{g}$-da) is a commutative graded algebra $A = \bigoplus_{n=0}^{\infty} A^n$, equipped with graded derivations $\mathrm{d}, L_\xi, \iota_\xi$ of degrees $1, 0, -1$ (where $L_\xi, \iota_\xi$ depend linearly on $\xi \in \mathfrak{g}$), satisfying the graded commutation relations [7] and [8].

**Definition 9** For any $\mathfrak{g}$-da $A$, one defines the horizontal subalgebra $\mathcal{A}_{\mathrm{hor}} = \bigcap_\xi \ker(\iota_\xi)$, the invariant subalgebra $\mathcal{A}^\mathfrak{g} = \bigcap_\xi \ker(L_\xi)$, and the basic subalgebra $\mathcal{A}_{\mathrm{basic}} = \mathcal{A}_{\mathrm{hor}} \cap \mathcal{A}^\mathfrak{g}$.

Note that the basic subalgebra is a differential subcomplex of $A$.

**Definition 10** A connection on a $\mathfrak{g}$-da is an invariant element $\theta \in A^1 \otimes \mathfrak{g}$, with the property $\iota_\xi \theta = \xi$. The curvature of a connection is the element $F^\theta \in A^2 \otimes \mathfrak{g}$ given as $F^\theta = \mathrm{d}\theta + (1/2)[\theta, \theta]_\mathfrak{g}$.

$\mathfrak{g}$-da's $\mathcal{A}$ admitting connections are the algebraic counterparts of (smooth) principal bundles, with $\mathcal{A}_{\mathrm{basic}}$ playing the role of the base of the principal bundle.

## Weil Algebra

The Weil algebra $W\mathfrak{g}$ is the algebraic analog to the classifying bundle $EG$. Similar to $EG$, it may be characterized by a universal property:

**Theorem 11** *There exists a* $\mathfrak{g}$-da $W\mathfrak{g}$ *with connection* $\theta_W$, *having the following universal property*: *if* $\mathcal{A}$ *is a* $\mathfrak{g}$-da *with connection* $\theta$, *there is a unique algebra homomorphism* $c : W\mathfrak{g} \to \mathcal{A}$ taking $\theta_W$ to $\theta$.

Clearly, the universal property characterizes $W\mathfrak{g}$ up to a unique isomorphism. To get an explicit construction, choose a basis $\{e_a\}$ of $\mathfrak{g}$, with dual basis $\{e^a\}$ of $\mathfrak{g}^*$. Let $y^a \in \wedge^1 \mathfrak{g}^*$ be the corresponding generators of the exterior algebra, and $v^a \in S^1 \mathfrak{g}^*$ the generators of the symmetric algebra. Let

$$W^n \mathfrak{g} = \bigoplus_{2i+j=n} S^i \mathfrak{g}^* \otimes \wedge^j \mathfrak{g}^* \qquad [9]$$

carry the differential

$$\mathrm{d}y^a = v^a + \tfrac{1}{2} f^a_{bc} y^b y^c \qquad [10]$$

$$\mathrm{d}v^a = -f^a_{bc} v^b y^c \qquad [11]$$

where $f^a_{bc} = \langle e^a, [e_b, e_c]_\mathfrak{g} \rangle$ are the structure constants of $\mathfrak{g}$. Define the contractions $\iota_a = \iota_{e_a}$ by

$$\iota_a y^b = \delta^b_a, \qquad \iota_a v^b = 0 \qquad [12]$$

and let $L_a = [\mathrm{d}, \iota_a]$. Then $L_a$ are the generators for the adjoint action on $W\mathfrak{g}$. The element $\theta_W = y^a \otimes e_a \in W^1\mathfrak{g} \otimes \mathfrak{g}$ is a connection on $W\mathfrak{g}$. Notice that we could also use $y^a$ and $\mathrm{d}y^a$ as generators of $W\mathfrak{g}$. This identifies $W\mathfrak{g}$ with the Koszul algebra, and implies:

**Theorem 12** $W\mathfrak{g}$ *is acyclic*, *that is*, *the inclusion* $\mathbb{R} \to W\mathfrak{g}$ *is a homotopy equivalence.*

Acyclicity of $W\mathfrak{g}$ corresponds to the contractibility of the total space of $EG$.

The basic subalgebra of $W\mathfrak{g}$ is equal to $(S\mathfrak{g}^*)^\mathfrak{g}$, and the differential restricts to zero on this subalgebra, since d changes parity. Hence, if $\mathcal{A}$ is a $\mathfrak{g}$-da with connection, the characteristic homomorphism $c : W\mathfrak{g} \to \mathcal{A}$ induces an algebra homomorphism, $(S\mathfrak{g}^*)^\mathfrak{g} \to H(\mathcal{A}_{\mathrm{basic}})$. This homomorphism is independent of $\theta$:

**Theorem 13** *Suppose* $\theta_0, \theta_1$ *are two connections on a* $\mathfrak{g}$-da $\mathcal{A}$. *Then their characteristic homomorphisms* $c_0, c_1 : W\mathfrak{g} \to \mathcal{A}$ are $\mathfrak{g}$-*homotopic. That is*, *there is a chain homotopy intertwining contractions and Lie derivatives*.

**Remark 14** One obtains other interesting examples of $\mathfrak{g}$-da's if one drops the commutativity assumption from the definition. For instance, suppose $\mathfrak{g}$ carries an invariant scalar product. Let $\mathrm{Cl}(\mathfrak{g})$ be the corresponding Clifford algebra, and $\mathrm{U}(\mathfrak{g})$ the enveloping algebra. The noncommutative Weil algebra (introduced by Alekseev and Meinrenken 2002)

$$\mathcal{W}\mathfrak{g} = U\mathfrak{g} \otimes \mathrm{Cl}(\mathfrak{g}) \qquad [13]$$

is a (noncommutative) $\mathfrak{g}$-da, with the derivations d, $L_a, \iota_a$ defined on generators by the same formulas as for $W\mathfrak{g}$.

## Equivariant Cohomology of $\mathfrak{g}$-da's

In analogy to $H_G(M) := H(M_G)$, we now declare:

**Definition 15** The equivariant cohomology algebra of a $\mathfrak{g}$-da $\mathcal{A}$ is the cohomology of the differential algebra $\mathcal{A}_\mathfrak{g} := (W\mathfrak{g} \otimes \mathcal{A})_{\text{basic}}$:

$$H_\mathfrak{g}(\mathcal{A}) := H(\mathcal{A}_\mathfrak{g}) \qquad [14]$$

The equivariant cohomology $H_\mathfrak{g}(\mathcal{A})$ has functorial properties parallel to those of $H_G(M)$. In particular, $H_\mathfrak{g}(A)$ is a module over

$$H_\mathfrak{g}(\{0\}) = H((W\mathfrak{g})_{\text{basic}}) = (S\mathfrak{g}^*)^\mathfrak{g} \qquad [15]$$

**Theorem 16** *Suppose $\mathcal{A}$ is a $\mathfrak{g}$-da with connection $\theta$, and let $c: W\mathfrak{g} \to \mathcal{A}$ be the characteristic homomorphism. Then*

$$W\mathfrak{g} \otimes \mathcal{A} \to \mathcal{A}, \qquad w \otimes x \mapsto c(w)\, x \qquad [16]$$

*is a $\mathfrak{g}$-homotopy equivalence, with $\mathfrak{g}$-homotopy inverse the inclusion*

$$\mathcal{A} \to W\mathfrak{g} \otimes \mathcal{A}, \qquad x \mapsto 1 \otimes x \qquad [17]$$

*In particular, there is a canonical isomorphism*

$$H(\mathcal{A}_{\text{basic}}) \cong H_\mathfrak{g}(\mathcal{A}) \qquad [18]$$

**Proof** By Theorem 13, the automorphism $w \otimes x \mapsto 1 \otimes c(w)\, x$ of $W\mathfrak{g} \otimes \mathcal{A}$ is $\mathfrak{g}$-homotopic to the identity map.

□

The above definition of the complex $\mathcal{A}_\mathfrak{g}$ is often referred to as the Weil model of equivariant cohomology, while the term Cartan model is reserved for a slightly different description of $\mathcal{A}_\mathfrak{g}$. Identify the space $(S\mathfrak{g}^* \otimes \mathcal{A})^\mathfrak{g}$ with the algebra of equivariant $\mathcal{A}$-valued polynomial functions $\alpha: \mathfrak{g} \to \mathcal{A}$. Define a differential $\mathrm{d}_\mathfrak{g}$ on this space by setting

$$(\mathrm{d}_\mathfrak{g}\alpha)(\xi) = \mathrm{d}(\alpha(\xi)) - \iota_\xi \alpha(\xi) \qquad [19]$$

**Theorem 17** (H Cartan). *The natural projection $W\mathfrak{g} \otimes \mathcal{A} \to S\mathfrak{g}^* \otimes \mathcal{A}$ restricts to an isomorphism of differential algebras, $\mathcal{A}_\mathfrak{g} \cong (S\mathfrak{g}^* \otimes \mathcal{A})^\mathfrak{g}$.*

Suppose $\mathcal{A}$ carries a connection $\theta$. The $\mathfrak{g}$-homotopy equivalence [16] induces a homotopy equivalence $\mathcal{A}_\mathfrak{g} \to \mathcal{A}_{\text{basic}}$ of the basic subcomplexes. By explicit calculation, the corresponding map for the Cartan model is given by

$$(S\mathfrak{g}^* \otimes \mathcal{A})^\mathfrak{g} \to \mathcal{A}_{\text{basic}}, \qquad \alpha \mapsto P^\theta_{\text{hor}}(\alpha(F^\theta)) \qquad [20]$$

Here $\alpha(F^\theta) \in \mathcal{A}^\mathfrak{g}$ is the result of substituting the curvature of $\theta$, and $P_{\text{hor}}: \mathcal{A} \to \mathcal{A}_{\text{hor}}$ is horizontal projection. On elements of $(S\mathfrak{g}^*)^\mathfrak{g} \subset (S\mathfrak{g}^* \otimes \mathcal{A})^\mathfrak{g}$, the map [20] specializes to the Chern–Weil homomorphism.

There is an algebraic counterpart of the Leray spectral sequence: introduce a filtration

$$F^p \mathcal{A}_\mathfrak{g}^{p+q} := \bigoplus_{2i \geq p} (S^i \mathfrak{g}^* \otimes \mathcal{A}^q)^\mathfrak{g} \qquad [21]$$

Since second term in the equivariant differential [19] raises the filtration degree by 2, it follows that

$$E_2^{p,q} = (S^{p/2}\mathfrak{g}^*)^\mathfrak{g} \otimes H^q(\mathcal{A}) \qquad [22]$$

for $p$ even, $E_2^{p,q} = 0$ for $p$ odd. In fortunate cases, the spectral sequence collapses at the $E_2$-stage (see below).

## Equivariant de Rham Theory

We will now restrict ourselves to the case that $\mathcal{A} = \Omega(M)$ is the algebra of differential forms on a $G$-manifold, where $G$ is compact and connected.

**Theorem 18** (Equivariant de Rham theorem). *Suppose $G$ is a compact, connected Lie group, and that $M$ is a $G$-manifold. Then there is a canonical isomorphism*

$$H_G(M; \mathbb{R}) \cong H_\mathfrak{g}(\Omega(M)) \qquad [23]$$

*where the left-hand side is the equivariant cohomology as defined by the Borel construction.*

Motivated by this result, the notation can be changed slightly; write

$$\Omega_G(M) = (S\mathfrak{g}^* \otimes \Omega(M))^G \qquad [24]$$

for the Cartan complex of equivariant differential forms, and $\mathrm{d}_G$ for the equivariant differential [19].

**Remark 19** Theorem 18 fails, in general, for noncompact Lie groups $G$. A differential form model for the noncompact case was developed by Getzler (1990).

**Example 20** Let $(M, \omega)$ be a symplectic manifold, and $a: G \to \mathrm{Diff}(M)$ a Hamiltonian group action. That is, $a$ preserves the symplectic form, $a_g^*\omega = \omega$, and there exists an equivariant moment map $\Phi: M \to \mathfrak{g}^*$ such that $\iota_\xi \omega + \mathrm{d}\langle \Phi, \xi \rangle = 0$. Then the equivariant symplectic form $\omega_G(\xi) := \omega + \langle \Phi, \xi \rangle$ is equivariantly closed.

**Example 21** Let $G$ be a Lie group, and denote, respectively, by

$$\theta^{\mathrm{L}} = g^{-1}\mathrm{d}g \text{ and } \theta^{\mathrm{R}} = \mathrm{d}g g^{-1} \qquad [25]$$

the left- and right-invariant Maurer–Cartan forms. Suppose $\mathfrak{g} = \mathrm{Lie}(G)$ carries an invariant scalar product "·", and consider the closed 3-form

$$\phi = \frac{1}{12}\,\theta^L \cdot [\theta^L, \theta^L] \qquad [26]$$

Then

$$\phi_G(\xi) = \phi + \frac{1}{2}(\theta^L + \theta^R) \cdot \xi \qquad [27]$$

is a closed equivariant extension for the conjugation action of $G$. More generally, transgression gives explicit differential forms $\phi_j$ generating the cohomology ring $H(G) = (\wedge\mathfrak{g}^*)^G$. Closed equivariant extensions of these forms were obtained by Jeffrey (1995), using a construction of Bott–Shulman.

A $G$-manifold is called equivariantly formal if

$$H_G(M) = (S\mathfrak{g}^*)^G \otimes H(M) \qquad [28]$$

as an $(S\mathfrak{g}^*)^G$-module. Equivalently, this is the condition that the spectral sequence [22] for $H_G(M)$ collapses at the $E_2$-term. $M$ is equivariantly formal under any of the following conditions: (1) $H^q(M) = 0$ for $q$ odd, (2) the map $H_G(M) \to H(M)$ is onto, (3) M admits a $G$-invariant Morse function with only even indices, and (4) $M$ is a symplectic manifold and the $G$-action is Hamiltonian. (The last fact is a theorem due to Ginzburg and Kirwan.

**Example 22** The conjugation action of a compact Lie group is equivariantly formal, by criterion [2]. In this case, eqn [28] is an isomorphism of algebras.

It is important to note that eqn [28] is not an algebra isomorphism, in general. Already the rotation action of $G = \mathrm{U}(1)$ on $M = S^2$, discussed in Example 6, provides a counter-example.

**Theorem 23** (Injectivity). *Suppose $T$ is a compact torus, and $M$ is $T$-equivariantly formal. Then the pullback map $H_T(M) \to H_T(M^T)$ to the fixed point set is injective.*

Since the pullback map to the fixed point set is an algebra homomorphism, one can sometimes use this result to determine the algebra structure on $H_T(M)$: let $\alpha_r \in H(M)$ be generators of the ordinary cohomology algebra, and let $(\alpha_r)_T$ be equivariant extensions. Denote by $x_r \in H_T(M^T)$ the pullbacks of $(\alpha_r)_T$ to the fixed point set, and let $y_i$ be a basis of $\mathfrak{t}^*$, viewed as elements of $S\mathfrak{t}^* \subset H_T(M^T)$. Then $H_T(M)$ is isomorphic to the subalgebra of $H_T(M^T)$ generated by the $x_r$ and $y_j$.

The case of nonabelian compact groups $G$ may be reduced to maximal torus $T$ using the following result. Observe that for any $G$-manifold $M$, there is a natural action of the Weyl group $W = N(T)/T$ on $H_T(M)$.

**Theorem 24** *The natural restriction map*

$$H_G(M; \mathbb{R}) \to H_T(M; \mathbb{R})^W \qquad [29]$$

*onto the Weyl group invariants is an algebra isomorphism.*

**Remark 25** The Cartan complex [24] may be viewed as a small model for the differential forms on the infinite-dimensional space $M_G$. In the noncommutative case, there exists an even "smaller" Cartan model, with underlying complex $(S\mathfrak{g}^*)^G \otimes \Omega(M)^G$, involving only invariant differential forms on $M$ (see Alekseev and Meinrenken (2005) and Goresky, Kottwitz, and MacPherson (1998)).

## Equivariant Characteristic Forms

Let $G$ be a compact Lie group, and $E \to B$ a principal $G$-bundle with connection $\theta \in \Omega^1(E) \otimes \mathfrak{g}$. Suppose the principal $G$-action commutes with the action of a compact Lie group $K$ on $E$, and that $\theta$ is $K$-invariant. The $K$-equivariant curvature of $\theta$ is defined as follows:

$$F_K^\theta = \mathrm{d}_K\theta + \frac{1}{2}[\theta, \theta] \in \Omega_K^2(E) \otimes \mathfrak{g}$$

By the equivariant version of eqn [20], there is a canonical chain map

$$\Omega_{K\times G}(E) \to \Omega_K(B) \qquad [30]$$

defined by substituting the $K$-equivariant curvature for the $\mathfrak{g}$-variable, followed by horizontal projection with respect to $\theta$. The Cartan map [30] is homotopy inverse to the pullback map from $\Omega_K(B)$ to $\Omega_{K\times G}(B)$.

**Example 26** The complex $\Omega_{K\times G}(E)$ contains a subcomplex $(S\mathfrak{g}^*)^G$. The restriction of eqn [30] is the equivariant Chern–Weil map

$$(S\mathfrak{g}^*)^G \to \Omega_K(B) \qquad [31]$$

Forms in the image of eqn [31] are equivariantly closed; they are called the $K$-equivariant characteristic forms of $E$.

**Example 27** Similarly, if $\mathcal{V} \to B$ is a $K$-equivariant vector bundle with structure group $G \subset \mathrm{GL}(k)$, one defines the $K$-equivariant characteristic forms of $\mathcal{V}$ to be those of the corresponding bundle of $G$-frames in $\mathcal{V}$.

For instance, suppose $\mathcal{V}$ is an oriented $K$-equivariant vector bundle of even rank $k$, with an invariant metric and compatible connection. The Pfaffian defines an invariant polynomial on $\mathfrak{so}(k)$:

$$\zeta \mapsto \det{}^{1/2}(\zeta/2\pi) \qquad [32]$$

(equal to 0 if $k$ is odd). The $K$-equivariant characteristic form of degree $k$ on $B$ determined by eqn [32] is known as the equivariant Euler form

$$\mathrm{Eul}_K(\mathcal{V}) \in \Omega_K^k(B) \qquad [33]$$

Similarly, one defines equivariant Pontrjagin forms of $\mathcal{V}$, and (for Hermitian vector bundles) equivariant Chern forms.

**Example 28** Suppose $G$ is a maximal rank subgroup of the compact Lie group $K$. The bundle $K \to K/G$ admits a unique $K$-invariant connection. Hence, one obtains a canonical chain map $(S\mathfrak{g}^*)^G \to \Omega_K(K/G)$, realizing the isomorphism $H_K(K/G) \cong (S\mathfrak{g}^*)^G$. In particular, any $G$-invariant element of $\mathfrak{g}^*$ defines a closed $K$-equivariant 2-form on $K/G$. For instance, symplectic forms on coadjoint orbits are obtained in this way.

Suppose $M$ is a $G$-manifold, and let $Q = E \times_G M$ be the associated bundle. For any $K$-invariant connection on $E$, one obtains a chain map

$$\Omega_G(M) \to \Omega_{K\times G}(E \times M) \to \Omega_K(Q) \qquad [34]$$

by composing the pullback to $E \times M$ with the Cartan map for the principal bundle $E \times M \to Q$.

**Example 29** Suppose $(M, \omega)$ is a Hamiltonian $G$-manifold, with moment map $\Phi : M \to \mathfrak{g}^*$. The image of $\omega_G = \omega + \Phi$ under the map [34] defines a closed $K$-equivariant 2-form on $Q$. This construction is of importance in symplectic geometry, where it arises in the context of Sternberg's minimal coupling.

## Equivariant Thom Forms

Let $\pi : \mathcal{V} \to B$ be a $G$-equivariant oriented real vector bundle of rank $k$ over a compact base $B$. There is a canonical chain map, called fiber integration

$$\pi_* : \Omega^\bullet(\mathcal{V})_{\mathrm{cp}} \to \Omega^{\bullet-k}(B) \qquad [35]$$

where the subscript indicates "compact support." It is characterized by the following properties:

(1) for a form of degree $k$, the value of its fiber integral at $x \in B$ is equal to the integral over the fiber $\mathcal{V}_x$, and
(2)

$$\pi_*(\alpha \wedge \pi^*\beta) = \pi_*\alpha \wedge \beta \qquad [36]$$

for all $\alpha \in \Omega(\mathcal{V})_{cp}$ and $\beta \in \Omega(B)$. Fiber integration extends to $G$-equivariant differential forms, and commutes with the equivariant differential.

**Theorem 30** (Equivariant Thom isomorphism). *Fiber integration defines an isomorphism,*

$$H_G^{\bullet+k}(\mathcal{V})_{cp} \to H_G^\bullet(B) \qquad [37]$$

An equivariant Thom form for a $G$-vector bundle is a cocycle $\mathrm{Th}_G(\mathcal{V}) \in \Omega_G^k(\mathcal{V})_{cp}$, with the property,

$$\pi_*\mathrm{Th}_G(\mathcal{V}) = 1 \qquad [38]$$

Given $\mathrm{Th}_G(\mathcal{V})$, the inverse to eqn [37] is realized on the level of differential forms as

$$\Omega_G^\bullet(B) \to \Omega_G^{\bullet+k}(E), \qquad \alpha \mapsto \mathrm{Th}_G(\mathcal{V}) \wedge \pi^*\alpha \qquad [39]$$

A beautiful "universal" construction of Thom forms was obtained by Mathai and Quillen (1986). Using eqn [34], it suffices to describe an $\mathrm{SO}(k)$-equivariant Thom form for the trivial bundle $\mathbb{R}^k \to \{0\}$. Using multi-index notation for ordered subsets $I \subset \{1, \ldots, k\}$,

$$\mathrm{Th}_{\mathrm{SO}(k)}(\mathbb{R}^k)(\zeta) = \frac{\mathrm{e}^{-\|x\|^2}}{\pi^{k/2}} \sum_I \epsilon_I \det{}^{1/2}\left(\frac{\zeta_I}{2}\right)(\mathrm{d}x)^{I^c} \qquad [40]$$

Here the sum is over all subsets $I$ with $|I|$ even, and $I^c$ is the complement of $I$. The matrix $\zeta_I$ is obtained from $\zeta$ by deleting all rows and columns that are not in $I$, and $\det^{1/2}$ is defined as a Pfaffian. Finally, $\epsilon_I$ is the sign of the shuffle permutation defined by $I$, that is, $(\mathrm{d}x)^I(\mathrm{d}x)^{I^c} = \epsilon_I\,\mathrm{d}x_1 \cdots \mathrm{d}x_k$. As shown by Mathai and Quillen, the form [40] is equivariantly closed, and clearly eqn [38] holds since the top degree part is just a Gaussian. If $k$ is even, the Mathai–Quillen formula can also be written, on the open dense where $\zeta \in \mathfrak{so}(k)$ is invertible, as

$$\mathrm{Th}_{\mathrm{SO}(k)}(\mathbb{R}^k)(\zeta) = \det{}^{1/2}\left(\frac{\zeta}{2\pi}\right)\mathrm{e}^{-\|x\|^2 - \langle \mathrm{d}x, \zeta^{-1}(\mathrm{d}x)\rangle} \qquad [41]$$

The form $\mathrm{Th}_{\mathrm{SO}(k)}(\mathbb{R}^k)$ given by these formulas does not have compact support, but is rapidly decreasing at infinity. One obtains a compactly supported Thom form, by applying an $SO(k)$-equivariant diffeomorphism from $\mathbb{R}^k$ onto some open ball of finite radius.

Note that the pullback of eqn [40] to the origin is equal to $\det^{1/2}(\zeta/2\pi)$ (equal to 0 if $k$ is odd). This implies:

**Theorem 31** *Let $\iota : B \to \mathcal{V}$ denote the inclusion of the zero section. Then*

$$\iota^*\mathrm{Th}_G(\mathcal{V}) = \mathrm{Eul}_G(\mathcal{V}) \qquad [42]$$

*where $\mathrm{Eul}_G(\mathcal{V}) \in \Omega_G^k(B)$ is the equivariant Euler form.*

Suppose, $M$ is a $G$-manifold, and $S$ a closed $G$-invariant submanifold with oriented normal

bundle $\nu_S$. Choose a $G$-equivariant tubular neighborhood embedding

$$\nu_S \to U \subset M \qquad [43]$$

and let $\mathrm{PD}_G(S) \in \Omega_G(M)_{cp}$ be the image of $\mathrm{Th}_G(\mathcal{V})$ under this embedding. The form $\mathrm{PD}_G(S)$ has the property

$$\int_M \mathrm{PD}_G(S) \wedge \alpha = \int_S \iota_S^* \alpha \qquad [44]$$

for all closed equivariant forms $\alpha \in \Omega_G(M)$. It is called an "equivariant Poincaré dual" of $S$. By construction, the pullback to $S$ is the equivariant Euler form:

$$\iota_S^* \mathrm{PD}_G(S) = \mathrm{Eul}_G(\nu_S) \qquad [45]$$

Equivariant Poincaré duality takes transversal intersections of $G$-manifolds to wedge products, similar to the nonequivariant case.

**Remark 32** In general, the $(S\mathfrak{g}^*)^G$-submodule generated by Poincaré duals of $G$-invariant submanifolds is strictly smaller than $H_G(M)$. In this sense, the terminology "duality" is misleading.

## Localization Theorem

In this section, $T$ will denote a torus. Suppose $M$ is a compact oriented $T$-manifold. For any component $F$ of the fixed point set of $T$, the action of $T$ on $\nu_F$ fixes only the zero section $F$. This implies that the normal bundle $\nu_F$ has even rank and is orientable. Fix an orientation, and give $F$ the induced orientation.

Since $T$ is compact, the list of stabilizer groups of points in $M$ is finite. Call $\xi \in \mathfrak{t}$ generic if it is not in the Lie algebra of any of these stabilizers, other than $T$ itself. In this case, value $\mathrm{Eul}_T(\nu_F, \xi)$ of the equivariant Euler form is invertible as an element of $\Omega(F)$.

**Theorem 33** (Integration formula). *Suppose $M$ is a compact oriented $T$-manifold, where $T$ is a torus. Let $\alpha \in \Omega_T(M)$ be a closed equivariant form, and let $\xi \in \mathfrak{t}$ be generic. Then*

$$\int_M \alpha(\xi) = \sum_F \int_F \frac{\iota_F^* \alpha(\xi)}{\mathrm{Eul}_T(\nu_F, \xi)} \qquad [46]$$

*where the sum is over the connected components of the fixed point set.*

Rather than fixing $\xi$, one can also view eqn (46) as an equality of rational functions of $\xi \in \mathfrak{t}$.

**Remark 34** The integration formula was obtained by Berline and Vergne (1983), based on ideas of Bott (1967). The topological counterpart, as a "localization principle," was proved independently by Atiyah and Bott (1984). More abstract versions of the localization theorem in equivariant cohomology had been proved earlier by Borel, Chiang–Skjelbred and others.

**Remark 35** If $\alpha = \mathrm{PD}_T(F) \wedge \beta$, where $\beta$ is equivariantly closed, the integration formula is immediate from the property [44] of Poincaré duals. The essence of the proof is to reduce to this case.

**Remark 36** The localization contributions are particularly nice if $F = \{p\}$ is isolated (which can only happen if $\dim M$ is even). In this case, $\iota_F^* \alpha(\xi)$ is simply the value of the function $\alpha_{[0]}(\xi)$ at $p$. For the Euler form, one has

$$\mathrm{Eul}(\nu_F, \xi) = (-1)^{\dim M/2} \prod \langle \mu_j(p), \xi \rangle \qquad [47]$$

where $\mu_j(p) \in \mathfrak{t}^*$ are the (real) weights of the action on the tangent space $T_p M$. (Here we have chosen an isomorphism $T_p M \cong \mathbb{C}^l$ compatible with the orientation.) Hence, if all fixed points are isolated,

$$\int_M \alpha(\xi) = (-1)^{\dim M/2} \sum_p \frac{\alpha_{[0]}(\xi)(p)}{\prod_j \langle \mu_j(p), \xi \rangle} \qquad [48]$$

**Example 37** Let $M$ be a compact oriented manifold, and $e(M) = \int_M \mathrm{Eul}(TM)$ its Euler characteristic. Suppose a torus $T$ acts on $M$. Then

$$e(M) = \sum_F e(F) \qquad [49]$$

where the sum is over the fixed point set of $T$. This follows from the integral of the equivariant Euler form $\alpha(\xi) = \mathrm{Eul}_T(M, \xi)$, by letting $\xi \to 0$ in the localization formula. In particular, if $M$ admits a circle action with isolated fixed points, the number of fixed points is equal to the Euler characteristic.

In a similar fashion, the localization formula gives interesting expressions for other characteristic numbers of manifolds and vector bundles, in the presence of a circle action. Some of these formulas were discovered prior to the localization formula, see in particular Bott (1967).

**Example 38** In this example, we show that for a simply connected, simple Lie group $G$ the 3-form $\phi \in \Omega^3(G)$ defined in eqn [26] is integral, provided "·" is taken to be the basic inner product (for which the length squared of the short coroots equals 2). Since any such $G$ is known to contain an SU(2) subgroup, it suffices to prove this for $G = \mathrm{SU}(2)$. Consider the conjugation action of the maximal torus $T \cong \mathrm{U}(1)$, consisting of diagonal matrices. The fixed point set for this action is $T$ itself. The normal

bundle $\nu_F$ is trivial, with $T$ acting on the fiber $\mathfrak{g}/\mathfrak{t}$ by the negative root $-\alpha$. Hence, $\mathrm{Eul}(\nu_F, \xi) = \langle \alpha, \xi \rangle$. Let $\breve{\alpha} \in \mathfrak{t}$ be the coroot, defined by $\langle \alpha, \breve{\alpha} \rangle = 2$. By definition, $\langle \alpha, \breve{\alpha} \rangle = 2$. Let us integrate the $T$-equivariant extension $\phi_T(\xi)$ (cf. [27]). Its pullback to $T$ is $\theta^T \cdot \xi$, where $\theta^T \in \Omega(T, \mathfrak{t})$ is the Maurer–Cartan form. The integral of $\theta^T$ is a generator of the integral lattice, that is, it equals $\breve{\alpha}$. Thus,

$$\int_{\mathrm{SU}(2)} \phi_T(\xi) = \frac{\int_T \theta^T \cdot \xi}{\langle \alpha, \xi \rangle} = \frac{\breve{\alpha} \cdot \xi}{\langle \alpha, \xi \rangle} = 1 \qquad [50]$$

## Duistermaat–Heckman Formulas

In this section, we discuss the Duistermaat–Heckman formula, for the case of isolated fixed points. Let $T$ be a torus, and $(M, \omega)$ a compact Hamiltonian $T$-space, with moment map $\Phi : M \to \mathfrak{t}^*$. Denote by $\omega_T = \omega + \Phi$ the equivariant extension of $\omega$. Assuming isolated fixed points, the localization formula gives, for all integers $k \geq 0$,

$$\int_M (\omega + \langle \Phi, \xi \rangle)^k = (-1)^n \sum_p \frac{\langle \Phi(p), \xi \rangle^k}{\prod_j \langle \mu_j(p), \xi \rangle} \qquad [51]$$

where $n = (1/2) \dim M$. Note that both sides are homogeneous of degree $k - n$ in $\xi$, but the terms on the right-hand side are only rational functions while the left-hand side is a polynomial. For $k = n$, both sides are independent of $\xi$, and compute the integral $\int_M \omega^n$. For $k < n$, the integral [51] is zero, and the cancellation of the terms on the right-hand side gives identities among the weights $\mu_j(p)$. Equation [51] also implies

$$\int_M \mathrm{e}^{\omega + \langle \Phi, \xi \rangle} = (-1)^n \sum_p \frac{\mathrm{e}^{\langle \Phi(p), \xi \rangle}}{\prod_j \langle \mu_j(p), \xi \rangle} \qquad [52]$$

Assume, in particular, that $T = \mathrm{U}(1)$, and let $\xi = t\xi_0$, where $\xi_0$ is the generator of the integral lattice in $\mathfrak{t}$. Identify $\mathfrak{t} \cong \mathbb{R}$ in such a way that $\xi_0$ corresponds to $1 \in \mathbb{R}$. Then $H = \langle \Phi, \xi_0 \rangle$ is a Hamiltonian function with periodic flow. Write $a_j(p) = \langle \mu_j(p), \xi_0 \rangle \in \mathbb{Z}$. Then eqn [52] reads

$$\int_M \mathrm{e}^{tH} \frac{\omega^n}{n!} = \frac{(-1)^n}{t^n} \sum_p \frac{\mathrm{e}^{tH(p)}}{\prod_j a_j(p)} \qquad [53]$$

The right-hand side of eqn [53] is the leading term for the stationary phase approximation of the integral on the left. For this reason, eqn [52] is known as the Duistermaat–Heckman exact stationary phase theorem.

Formula [52] has the following consequence for the push-forward of the Liouville measure under the moment map, the so-called Duistermaat–Heckman measure $H_*(\omega^n/n!)$. Let $\Theta$ be the Heaviside measure (i.e., the characteristic measure of the positive real axis).

**Theorem 39** (Duistermaat–Heckman). *The push-forward $H_*(\omega^n/n!)$ is piecewise polynomial measure of degree $n-1$, with singularities at the set of all $H(p)$ for fixed points $p$ of the action. One has the formula*

$$H_*\left(\frac{\omega^n}{n!}\right) = \sum_p \frac{(\lambda - H(p))^{n-1}}{\prod_j a_j(p)} \Theta(\lambda - H(p)) \qquad [54]$$

**Proof** It is enough to show that the Laplace transforms of the two sides are equal. Multiplying by $\mathrm{e}^{t\lambda}$ and integrating over $\lambda$ (take $t < 0$ to ensure convergence of the integral), the resulting identity is just eqn [53]. □

**Remark 40** The theorem generalizes to Hamiltonian actions of higher-rank tori, and also to nonisolated fixed points. See the paper by Guillemin, Lerman, and Sternberg (1988) for a detailed discussion of this formula and of its "quantum analog."

## Equivariant Index Theory

By definition, the Cartan model consists of equivariant forms $\alpha(\xi)$ with polynomial dependence on the equivariant parameter $\xi$. However, the integration formula holds in much greater generality. For instance, one may consider generalized Cartan complexes (Kumar and Vergne 1993). Here the parameter $\xi$ varies in some invariant open subset of $\mathfrak{g}$, and the polynomial dependence is replaced by smooth dependence. The use of these more general complexes in equivariant index theory was pioneered by Berline and Vergne (1992).

Assume that $M$ is an even-dimensional, compact oriented Riemannian manifold, equipped with a Spin-c structure. According to the Atiyah–Singer theorem, the index of the corresponding Dirac operator $D$ is given by the formula

$$\mathrm{ind}(D) = \int_M \hat{A}(M) \mathrm{e}^{c/2} \qquad [55]$$

Here $c$ is the curvature 2-form of the complex line bundle associated to the Spin-c structure, and $\hat{A}(M)$ is the $\hat{A}$-form. Recall that $\hat{A}(M)$ is obtained by substituting the curvature form in the formal power series expansion of the function $\hat{A}(x) = \det^{1/2}((x/2)/\sinh(x/2))$ on $\mathfrak{so}(n)$.

Suppose now that a compact, connected Lie group $G$ acts on $M$ by isometries, and that the action lifts to the Spin-c bundle. Replacing curvatures with equivariant curvatures, one defines the equivariant form $\hat{A}(M)(\xi)$ and the form $c(\xi)$. Note that $\hat{A}(\xi)$ is only

defined for $\xi$ in a sufficiently small neighborhood of 0, since the function $\hat{A}(x)$ is not analytic for all $x$.

The $G$-index of the equivariant Spin-c Dirac operator is a virtual character $g \mapsto \text{ind}(D)(g)$ of the group $G$. For $g = \exp \xi$ sufficiently small, it is given by the formula

$$\text{ind}(D)(\exp \xi) = \int_M \hat{A}(M)(\xi) e^{c(\xi)/2} \qquad [56]$$

For $\xi$ sufficiently small, the fixed point set of $g$ coincides with the set of zeroes of the vector field $a_\xi$. The localization formula reproduces the Atiyah–Segal formula for $\text{ind}(D)(g)$, as an integral over $M^g$.

Berline and Vergne (1996) gave similar formulas for the equivariant index of any $G$-equivariant elliptic operator, and more generally for operators that are transversally elliptic in the sense of Atiyah.

## Introduction

The ergodic theory was developed from the following Poincaré's work, which served as the starting point in the measure theory of dynamical systems in the sense of the study of the properties of motions that take place at "almost all" initial states of a system: let $(X, \mathcal{B}, \mu)$ be a probability space and a transformation $T: X \to X$ preserve $\mu$ (i.e., $\mu(T^{-1}A) = \mu(A)$ for any $A \in \mathcal{B}$). If $\mu(A) > 0$, then for almost all points $x \in A$ the orbit $\{T^n x\}_{n \geq 0}$ returns to $A$ infinitely more often (the Poincaré–Caratheodory recurrence theorem). The main theme of the ergodic theory is to know whether averages of quantities generated in a stationary manner converge. In the classical situation the stationary is described by a measure-preserving transformation $T$, and one considers averages taken along a sequence $f, fT, fT^2, \ldots$ for integrable $f$. This corresponds to the probabilistic concept of stationarity. Hence, traditionally, the ergodic theory is the qualitative study of iterates of an individual transformation, of one parameter flow of transformations (such as that obtained from the solution of an autonomous ordinary differential equation). We should note that an important purpose behind this theory is to verify significant facts from a statistical point of view (e.g., the law of large numbers, convergence to limit distributions). The oldest branch

of this theory is the study of ergodic theorems. It was started in 1931 by Birkhoff (1931) and von Neumann (1932), having its origins in statistical mechanics. More specifically, the central notion is that of ergodicity, which is intended to capture the idea that a flow is "random" or "chaotic." In dealing with the motion of molecules, Boltzmann and Gibbs made such hypotheses from the beginning. One of the earliest precise definitions of randomness of a dynamical system was "minimality": the orbit of almost every point is dense. In order to describe such phenomena in measure-theoretical setting, von Neumann and Birkhoff required the stronger assumption of ergodicity as follows. Let $(X, \mathcal{B}, \mu)$ be a measure space and $F_t$ a measurable flow on $X$. We call $F_t$ ergodic if the only invariant measurable sets are $\emptyset$ or all of $X$. Here, the invariance of the set $A$ means that $F_t(A) = A$ for all $t \in \boldsymbol{R}$ and we agree to write $A = B$ if $A$ and $B$ differ by a null set with respect to $\mu$. Note that ergodicity implies minimality if we are on a second countable Borel space. A function $f : X \to \boldsymbol{R}$ will be called a "constant of the motion" iff $f \circ F_t = f$ a.e. for each $t \in \boldsymbol{R}$. Then we see that a flow $F_t$ on $X$ is ergodic iff the only constants of the motion are constant a.e. In case of a measurable transformation $T$ on $X$, the invariance of the set $A$ means that $T^{-1}A = A$, and the measurable function $f$ is called invariant if $f \circ T = f$ a.e. Then we call $T$ ergodic provided if $A$ is invariant then either $\mu(A) = 0$ or $\mu(A) = 1$; equivalently, any invariant function is constant a.e. (Cornfeld *et al.* 1982). The most basic example where ergodicity can be verified is the following: if $M$ is a compact Riemannian and has negative sectional curvatures at each point, then the geodesic flow on each sphere bundle is ergodic (Hopf–Hadamard). In general, verifying ergodicity can still be very difficult. In the Hamiltonian case, the first step is to pass to an energy surface. For example, Sinai (1970) shows that one has ergodicity on an energy surface of a classical model for molecular motion, that is, a collection of hard spheres in a box.

## Ergodic Theorems

Koopman (1931) published the following significant observation: if $T$ is an invertible measure-preserving transformation of a measure space $(X, \mathcal{B}, \mu)$, then the operator $U$, defined on $L^2(X, \mathcal{B}, \mu)$ by $Uf(x) := f(Tx)$, is unitary. Thus, the association of $U$ with $T$ replaces a nonlinear finite-dimensional problem with a linear infinite-dimensional one. Then von Neumann (1932) showed an intimate connection between measure-preserving transformations and unitary operators (the mean ergodic theorem): let $U$ be a unitary operator on a Hilbert space $\mathcal{H}$. Denote by $P$ the orthogonal projection onto the subspace $\mathcal{H}_0 := \{f \in \mathcal{H} | Uf = f\}$. For any $f \in \mathcal{H}$, one has

$$\lim_{N\to\infty} \left\| \frac{1}{N} \sum_{n=0}^{N-1} U^n f - Pf \right\|_{\mathcal{H}} = 0$$

As a corollary, one can show that if $T : X \to X$ is an ergodic measure-preserving transformation on a probability space $(X, \mathcal{B}, \mu)$ then, for any $f \in L^1(X, \mathcal{B}, \mu)$,

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} f(T^n x) = \frac{1}{\mu(X)} \int_X f \, d\mu$$

in $L^1$-norm. We also know that $T$ is ergodic if and only if $U$ has 1 as a simple eigenvalue. In the case of a continuous invertible process, the setting is the following. Let $M$ be a manifold and $\Omega$ a volume on $M$, with $\mu_\Omega$ the corresponding measure. If $F_t$ is a volume-preserving flow on $M$, then $F_t$ induces a linear one-parameter group of isometries on $\mathcal{H} = L^2(M, \mu_\Omega)$ by $U_t(f) = f \circ F_{-t}$. Then $U_t$ has 1 as a simple eigenvalue for all $t$ if and only if $F_t$ is ergodic.

On the other hand, Birkhoff (1931) proved the following almost everywhere statement (the pointwise ergodic theorem): for any $f \in L^1(X, \mathcal{B}, \mu)$, there exists a function $\bar{f} \in L^1(X, \mathcal{B}, \mu)$ such that for $\mu$-a.e. $x$, $\bar{f}T(x) = \bar{f}(x)$ and

$$\lim_{N\to\infty} \frac{1}{N} \sum_{n=0}^{N-1} f(T^n x) = \bar{f}(x)$$

In particular, if $T$ is ergodic then $\mu$-a.e. $x, \bar{f}(x) = \int_X f d\mu$. Thus, the Birkhoff theorem allows one to prove the ergodic hypothesis by Boltzmann–Gibbs, that is, the space average of an observable function coincides with its time averages almost everywhere, and guarantees the existence, for almost everywhere, of the mean number of occurrences in any measurable set. On the other hand, physical meanings of the mean ergodic theorem can be explained as follows. We now turn to one-parameter flow of transformations. In order to study continuous averages

$$\frac{1}{t} \int_0^t f(F_s x) ds$$

fix some $s_0 \in \boldsymbol{R}$ and consider the averages of the form

$$\frac{1}{N} \sum_{n=0}^{N-1} f(T^n x)$$

where $T = F_{s_0}$. In reality, the measurements can be done only approximately at times $t = 0, 1, \ldots, N-1$, and it is natural to consider the perturbed averages

$$\frac{1}{N}\sum_{n=0}^{N-1} f(T^{n+\delta_n}x)$$

where $\{\delta_n\}_{n\in N}$ is an independent random sequence in a small interval $(-\epsilon, \epsilon)$. Assuming that $T = F_{s_0}$ is ergodic, we would like to know whether for large $N$, the averages

$$\frac{1}{N}\sum_{n=0}^{N-1} f(T^{n+\delta_n}x)$$

are close to

$$\int_X f(x)\mathrm{d}\mu(x)$$

The answer to this question is satisfactory if one is concerned with norm convergence (see, e.g., Bergelson *et al.* (1994)).

## Induced Transformations and Tower Constructions

Suppose $T$ is a measure-preserving transformation on a probability space $(X, \mathcal{B}, \mu)$ and $A \in \mathcal{B}$ with $\mu(A) > 0$. Let us transform $A$ into a space with normalized measure by choosing the $\sigma$-algebra $\mathcal{B}_A$ consisting of all subsets $E \subset A, E \in \mathcal{B}$ and setting $\mu_A(E) = \mu(A \cap E)/\mu(A)$. Let $R_A : A \to \mathbf{N} \cup \{\infty\}$ be the "first return function," that is, $R_A(x) := \inf\{n \in \mathbf{N} \mid T^n x \in A\}$. Then it follows from the Poincaré reccurrence theorem that $\mu_A(\{x \in A \mid R_A(x) < \infty\} = 1$. Define $T_A : \{x \in A \mid R_A(x) < \infty\} \to A$ by $T_A x := T^{R_A(x)}x$, which is called the "induced transformation" over $A$ (constructed from $T$). For each $n \in \mathbf{N}$ we define $A_n := \{x \in A \mid R_A(x) = n\}$. Then for every $E \in \mathcal{B}_A$ we see that $T_A{}^{-1}E = \bigcup_{n=1}^{\infty} T^{-n}(A_n \cap E)$. Hence, if $T$ is invertible, then we have immediately $\mu_A(T_A{}^{-1}E) = \mu_A(E)$; thus, $\mu_A$ is invariant under $T_A$. Even if $T$ is noninvertible, since for every $k \geq 1$ the equality,

$$\begin{aligned}\mu\left(\bigcup_{j=0}^{k-1} T^{-j}A^{\mathrm{c}} \cap T^{-k}(A \cap E)\right) &= \mu(A_{k+1} \cap T^{-(k+1)}E) \\ &\quad + \mu\left(\bigcup_{j=0}^{k} T^{-j}A^{\mathrm{c}} \cap T^{-(k+1)}(A \cap E)\right)\end{aligned}$$

holds, we have $\mu(E) = \sum_{k=1}^{\infty} \mu(A_k \cap T^{-k}E) = \mu(T_A{}^{-1}E)$, which allows us to see that $T_A$ preserves $\mu_A$. We note that for every $E \in \mathcal{B}_A$ with $\mu(E) > 0$, $\{n \in \mathbf{N} \mid T^n x \in E\} = \{n \in \mathbf{N} \mid T_A{}^n x \in E\}$. Therefore, for a.e. $x \in E$, $\sum_{n=1}^{\infty} 1_E T^n(x) = \sum_{n=1}^{\infty} 1_E T_A{}^n(x)$. This equality allows us to see that if $(T, \mu)$ is ergodic then $(T_A, \mu_A)$ is ergodic. Indeed, suppose $T_A{}^{-1}E = E$ and $\mu(A \cap E^{\mathrm{c}}) > 0$. Then for $x \in A \cap E^{\mathrm{c}}$, we have $\sum_{n=1}^{\infty} 1_E T_A{}^n(x) = 0$. On the other hand, as $E \subset \bigcup_{n=1}^{\infty} T^{-n}E \pmod{\mu}$, $\bigcup_{n=1}^{\infty} T^{-n}E = \bigcup_{n=0}^{\infty} T^{-n}E$ is a $T$-invariant set. Hence, ergodicity of $(T, \mu)$ allows us to see that $\bigcup_{n=1}^{\infty} T^{-n}E = X$ ($\mu$ mod 0), which implies $\sum_{n=1}^{\infty} 1_E T^n(x) = \infty$. In the case when $T$ is invertible, we can write $\int_A R_A \,\mathrm{d}\mu = \mu(\bigcup_{n\geq 0} T^n A)$, so that Kac's formula (Darling and Kac 1957):

$$\int_A R_A \,\mathrm{d}\mu_A = \mu(A)^{-1}$$

is valid when $\bigcup_{n\geq 0} T^n A = X \pmod{\mu}$. In particular, $\mu(\bigcup_{n\geq 0} T^n A) = 1$ if $T$ is ergodic. The key to establish the Kac formula is to show that $T^i A_k (0 \geq i \geq k-1, k \geq 1)$ are pairwise disjoint. This property holds when $T$ is invertible. On the other hand, in the case when $T$ is noninvertible, if $\bigcup_{n=0}^{\infty} T^{-n}A = X(\mu \bmod 0)$ then we can establish, for every $E \in \mathcal{B}$,

$$\mu(E) = \mu(A)\int_A \sum_{h=0}^{R_A(x)-1} 1_E T^h(x)\,\mathrm{d}\mu_A(x) \qquad [1]$$

by noting that the following equality holds for all $n \geq 1$:

$$\begin{aligned}\mu(E) = &\sum_{k=1}^{n} \mu|_A\left(A \cap \bigcap_{h=1}^{k} T^{-h}A^c \cap T^{-k}A\right) \\ &+ \mu|_A(A \cap E) + \mu\left(\left(\bigcup_{j=0}^{n} T^{-j}A\right)^{\mathrm{c}} \cap T^{-n}E\right)\end{aligned}$$

Then choosing $E = X$ allows one to establish the Kac formula. As we have observed in the above, the assumption that $\bigcup_{n=0}^{\infty} T^{-n}A = X(\mu \bmod 0)$ is automatically satisfied if $(T, \mu)$ is ergodic. Conversely, if $(T_A, \mu_A)$ is ergodic and $\bigcup_{n=1}^{\infty} T^{-n}A \pmod{\mu}$ holds, then $(T, \mu)$ is ergodic. We should remark that the formula [1] allows one to obtain a $T$-invariant measure when a $T_A$-invariant measure $\mu_A$ is obtained previously. Even if $R_A$ is nonintegrable, we may have a $\sigma$-finite infinite invariant measure. Then if $\mu_A$ is ergodic, $\mu$ obtained by [1] is still ergodic (i.e., $T^{-1}E = E$ implies that $\mu(E) = 0$ or $\mu(E^c) = 0$) under the assumption that $\bigcup_{n=1}^{\infty} T^{-n}A = X \pmod{\mu}$ (cf. Aaronson (1997)). In particular, the recent progress in the study of nonhyperbolic systems strongly depends on such constructions of induced maps over hyperbolic regions. More specifically, if one can find a subset $A$ over which the induced map possesses an

invariant measure satisfying nice statistical properties, then the formula [1] may give a $\sigma$-finite invariant measure $\mu$ for the original map $T$ which reflects the statistical properties of the induced system. The fundamental problem in the study of nonhyperbolic phenomena arising from complex systems is to clarify how to predict statistical properties of nonhyperbolic systems $(T, \mu)$ by using those of induced systems $(T_A, \mu_A)$ over hyperbolic regions. We should claim that induced maps are well defined over positive-measure sets with respect to a reference measure $\nu$ that is "conservative." Here conservativity of $(T, \nu)$ implies that there are no wandering sets of positive measure with respect to $\nu$. In many cases, the reference measures are physical measures (e.g., Lebesgue measures, conformal measures) which satisfy nonsingularity with respect to $T$. Here nonsingularity of $\nu$ means that $\nu T^{-1} \sim \nu$. Then as long as we obtain a $T_A$-invariant measure $\mu_A$ which is equivalent to $\nu | A$, the formula [1] may give us a $T$-invariant $\sigma$-finite measure which is equivalent to $\nu$.

At the end of this section, we will explain that the folmula [1] can be obtained via Rohlin tower (Kakutani's skyscraper) in the case when $T$ is invertible. This tower construction is a dual construction to the construction of induced transformations. Assuming that we are given an invertible transformation $T$ of the measure space $(X, \mathcal{B}, \mu)$, consider the measurable integer-valued positive function $f \in L^1(X, \mathcal{B}, \mu)$. By using this function, construct a new measure space $X^f$, whose points are of the form $(x, i)$, where $x \in X, 1 \le i \le f(x)$ and $i$ is an integer. The $\sigma$-algebra $\mathcal{B}^f$ of measurable sets in $X^f$ is constructed in an obvious way. The measure $\mu^f$ is defined as follows: for any subset of the form $(A, i), A \in \mathcal{B}$ we put

$$\mu^f((A, i)) := \frac{\mu(A)}{\int_X f \, d\mu}$$

Let

$$T^f(x, i) = \begin{cases} (x, i+1) & \text{if } i+1 \le f(x) \\ (Tx, 1) & \text{if } i+1 > f(x) \end{cases}$$

It is easy to see that $T^f$ preserves $\mu^f$. The space can naturally be visualized as a tower whose foundation is the space $X$ and which has $f(x)$ floors over the point $x \in X$. The space $X$ is identified with the set of points $(x, 1)$. We see that $T = (T^f)_X$ and the construction of $(X^f, T^f)$ is called the Rohlin tower over $X$. Let $T$ be an invertible measure-preserving transformation on a probability space $(X, \mathcal{B}, \mu)$ and $A \in \mathcal{B}$ with $\mu(A) > 0$. Suppose that $X = \bigcup_{n=0}^{\infty} T^n A \pmod{\mu}$. Then $T$ is represented as the Rohlin tower $(A^{R_A}, \mathcal{B}^{R_A}, (\mu_A)^{R_A})$ over $A$ as follows. We define $p : (A^{R_A}, \mathcal{B}^{R_A}, (\mu_A)^{R_A}) \to (X, \mathcal{B}, \mu)$ by $p(x, i) := T^i x$. Then $p$ is an isomorphism satisfying $p(T^{R_A})_A = Tp$ (almost everywhere). Moreover, we can verify that $(\mu_A)^{R_A} p^{-1} = \mu$ by assuming ergodicity of $\mu$. This is because $\forall E \in \mathcal{B}$ we have

$$\begin{aligned} &\left( \bigcup_{n=0}^{\infty} T^n A \right) \cap E \\ &= \bigcup_{n=1}^{\infty} \bigcup_{i=0}^{n-1} p((A_n \cap T^{-i} E) \times \{i\}) \end{aligned}$$

so that

$$\begin{aligned} (\mu_A)^{R_A}(p^{-1}E) &= \sum_{n=1}^{\infty} \sum_{i=0}^{n-1} \frac{\mu_A(A_n \cap T^{-i}E)}{\int_A R_A \, d\mu_A} \\ &= \mu(A) \int_A \sum_{h=0}^{R_A(x)-1} 1_E T^h(x) \, d\mu_A(x) \end{aligned}$$

On the other hand, in the case when $T$ is noninvertible, the formula [1] is not necessarily obtained by any tower construction, except in very special cases. For example, even if $T$ is not invertible, the tower construction is valid if $T|_A$ and $T|_{A^c}$ are one-to-one and $TA = X$.

## Convergence to Equilibrium States and Mixing Properties

Let $T : X \to X$ be a measure-preserving transformation on a probability space $(X, \mathcal{B}, \mu)$. We call $T$ to be "weak mixing" if for any $A, B \in \mathcal{B}$

$$\lim_{N \to \infty} \frac{1}{N} \sum_{n=0}^{N-1} \left| \mu(T^{-n} A \cap B) - \mu(A)\mu(B) \right| = 0$$

The weak-mixing property of $(T, \mu)$ can be represented by; $\forall f, g \in L^2(X, \mathcal{B}, \mu)$

$$\lim_{N \to \infty} \frac{1}{N} \sum_{n=0}^{N-1} \left| \int_X (f T^n) g \, d\mu - \int_X f \, d\mu \int_X g \, d\mu \right| = 0$$

and this is equivalent to the ergodicity of $(T \times T, \mu \times \mu)$. Moreover, $(T, \mu)$ is weak mixing if and only if the unitary operator $U : \mathcal{H} \to \mathcal{H}$ defined by $Uf(x) = f(Tx)$ has no eigenfunctions that are not constants ($\mu$ mod 0). We say that the operator $U$ has continuous spectrum if there are no eigenvectors. If $\mathcal{H}$ is the closure of the linear span of the eigenvectors, then we say that the operator $U$ has pure point spectrum. The weak-mixing property of $(T, \mu)$ just implies that $U$ restricted on the orthonormal subspace of the subspace consisting of

constant functions has continuous spectrum. We recall that if $U$ has one as a simple eigenvalue then $T$ is ergodic. Additionally, if there are no other eigenvalues, then $T$ is weakly mixing. Hence, if $T$ is weak mixing, then it is necessarily ergodic. The next property corresponds to the term "relaxation" in physics literature which is used to describe processes under which the system passes to a certain stationary state independently of its original state. We call $T$ (strong) mixing if for any $A, B \in \mathcal{B}$

$$\lim_{n\to\infty} \mu(T^{-n}A \cap B) = \mu(A)\mu(B)$$

Then $(T, \mu)$ is (strong) mixing if and only if for any $f, g \in L^2(X, \mathcal{B}, \mu)$

$$\lim_{n\to\infty} \int_X (fT^n) g \, \mathrm{d}\mu = \int_X f \, \mathrm{d}\mu \int_X g \, \mathrm{d}\mu$$

and mixing is necessarily weak mixing. Moreover, for any probability measure $\nu$ absolutely continuous with respect to $\mu$, one can show that $\lim_{n\to\infty} \nu(T^{-n}A) = \mu(A)$ for every $A \in \mathcal{B}$. Thus, any nonequilibrium distribution tends to an equilibrium one with time. The mixing property has a significant meaning from a physical point of view, as it implies decay of correlation of observable functions; moreover, limiting distributions of averaged observables are determined by the decay rates of correlation functions for many cases (e.g., hyperbolic systems). For any $f \in L^2(X, \mathcal{B}, \mu)$ we consider the scalar products $s_n = s_n(f) = (U^n f, f), n \geq 0$ and define $s_n := \bar{s}_{-n}$ for $n < 0$. The sequence $\{s_n\}_{n\in\mathbf{Z}}$ is positive definite and so by Bohner's theorem, we can write $s_n(f) = \int_0^1 \exp[2\pi i n\lambda] \, \mathrm{d}\sigma_f(\lambda)$, where $\sigma_f$ is a finite Borel measure on the unit circle $S^1$ and satisfies the condition that $\sigma_f(S^1) = \|f\|^2$. Such a measure is called a spectral measure of $f$. We see that $T$ is mixing iff for any $f \in L^2(X, \mathcal{B}, \mu)$ with $\int_X f \, \mathrm{d}\mu = 0$ the Fourier coefficients $\{s_n\}$ of the spectral measure $\sigma_f$ tend to zero as $|n| \to \infty$. Let $(X, \mathcal{B}, \mu)$ be isomorphic to $([0,1], \mathcal{B}_0, \lambda)$, where $\mathcal{B}_0$ is the Borel $\sigma$-algebra on [0, 1] and $\lambda$ is the normalized Lebesgue measure of [0, 1]. Then we call a measure-preserving transformation $T$ on $(X, \mathcal{B}, \mu)$ an exact endomorphism if $\bigcap_{n=0}^{\infty} T^{-n}\mathcal{B} = \{X, \emptyset\}(\mu \bmod 0)$. We can verify that an exact endomorphism is (strong) mixing (Rohlin 1964). Moreover, $\mu$ is exact if for any positive-measure set $A \in \mathcal{B}$ with $T^n A \in \mathcal{B}(\forall n \geq 0) \lim_{n\to\infty} \mu(T^n A) = 1$ holds. Let $T$ be a nonsingular transformation on $(X, \mathcal{B}, \nu)$, that is, $\nu T^{-1} \sim \nu$. Then we can define the transfer (Perron–Frobenius) operator $\mathcal{L}_\nu : L^1(X, \nu) \to L^1(X, \nu)$ by $\mathcal{L}_\nu f := \mathrm{d}(f\nu)T^{-1}/\mathrm{d}\nu$, which satisfies

$$\int_X (\mathcal{L}_\nu f) g \, \mathrm{d}\nu = \int_X f(gT) \mathrm{d}\nu \quad (\forall g \in L^\infty(X, \nu))$$

We say that a nonsingular measure $\nu$ is exact if $A \in \bigcap_{n=0}^{\infty} T^{-n}\mathcal{B}$ implies $\nu(A)\nu(A^c) = 0$. By Lin's theorem (Lin 1971) the exactness of $\nu$ can be described as follows; $\forall f \in L^1(X, \nu)$ with $\int_X f \, \mathrm{d}\nu = 0$, $\lim_{n\to\infty} \|\mathcal{L}_\nu{}^n f\|_1 = 0$. Let $\mu = h\nu$ be an exact $T$-invariant probability measure equivalent to $\nu$. Then the upper bounds of mixing rates of the exact measure $\mu = h\nu$ are determined by the speed of $L^1$-convergence of the iterated transfer operators $\{\mathcal{L}_\nu{}^n\}$. This is because $\mathcal{L}_\nu h = h$ and for every $f \in L^1(X, \nu)$ with $\int_X f \, \mathrm{d}\nu = 1$, $\lim_{n\to\infty} \|\mathcal{L}_\nu{}^n f - h\|_1 = 0$. Hence, the property $\mathcal{L}_\mu f = h^{-1}\mathcal{L}_\nu(hf)$ allows one to see that for every $f, g \in L^\infty(X, \mu)$ the correlation function

$$C_{f,g}(n) := \left| \int_X (fT^n) g \, \mathrm{d}\mu - \int_X f \, \mathrm{d}\mu \int_X g \, \mathrm{d}\mu \right|$$

is bounded from above by

$$\begin{aligned} &\|f\|_\infty \|\mathcal{L}_\mu^n g - \int_X g \, \mathrm{d}\mu\|_1 \\ &\quad = \|f\|_\infty \|h^{-1}\{\mathcal{L}_\nu{}^n(gh) - P(gh)\}\|_1 \end{aligned}$$

where $P : L^1(X, \nu) \to L^1(X, \nu)$ is a linear operator defined by $Pf := h \int_X f \, \mathrm{d}\nu$. The operator $P$ is the one-dimensional projection operator associated to the eigenvalue 1 (which is maximal in many cases) of $\mathcal{L}_\nu$ satisfying $P^2 = P$ and $P\mathcal{L}_\nu = \mathcal{L}_\nu P = P$. Moreover, since $\mathcal{L}_\nu{}^n - P = (\mathcal{L}_\nu - P)^n$, the exponential decay of mixing rates follows from the spectral gap of $\mathcal{L}_\nu$, that is, 1 is the simple isolated maximal eigenvalue of $\mathcal{L}_\nu$.

## Entropy and Reversibility

We recall one of the fundamental problems of ergodic theory, namely deciding when two automorphisms $T_1, T_2$ of probability spaces $(X_1, \mathcal{B}_1, \mu_1)$ and $(X_2, \mathcal{B}_2, \mu_2)$ are equivalent. The approach developed for this problem involved the study of spectral properties of the associated isometric operators $U_i : L^2(X_i, \mu_i) \to L^2(X_i, \mu_i)(i = 1, 2)$ and is based on the concept of the entropy of automorphism $T$, introduced by Kolmogorov (1958). The entropy is a non-negative number, which is the same for equivalent automorphisms. For example, the entropy of the Bernoulli shift $\sigma : \Pi_{n\in\mathbf{Z}}\{1, 2, \ldots, d\} \to \Pi_{n\in\mathbf{Z}}\{1, 2, \ldots, d\}$ with probability vector $(p_1, p_2, \ldots, p_d)$ is equal to $-\sum_{k=1}^{d} p_k \log p_k$. A remarkable theorem of Ornstein (1970) states that Bernoulli shifts with the same entropy are equivalent. On the other hand, Shannon (1948) introduced a notion of entropy in his work information theory, which is essentially the same as Kolmogorov's. Let $T : X \to X$ be a measure-preserving transformation on a probability space $(X, \mathcal{B}, \mu)$. We define the entropy of a measurable partition $\alpha$ of $X$ by

$H_\mu(\alpha) = -\sum_{A\in\mathcal{A}} \mu(A)\log\mu(A)$ and define the entropy of $T$ with respect to $\alpha$ by

$$h_\mu(T,\alpha) := \lim_{n\to\infty}\frac{1}{n}H_\mu\left(\bigvee_{i=0}^{n-1}T^{-i}\alpha\right)$$

Then the (measure-theoretic) entropy of $T$ is defined by

$$h_\mu(T) = \sup_{\alpha:H_\mu(\alpha)<\infty} h_\mu(T,\alpha)$$

The next Abramov theorem gives an important method of practical computation: let $\{\alpha_n\}_{n\geq 1}$ be an increasing sequence of partitions with $H_\mu(\alpha_n) < \infty (\forall n \geq 1)$ and such that $\bigcup_{n\geq 1}\alpha_n$ generates the $\sigma$-algebra $\mathcal{B}$. Then $h_\mu(T) = \lim_{n\to\infty} h_\mu(T,\alpha_n)$. We say that a partition $\alpha$ is called a generator for a noninvertible measure-preserving transformation $T$ on a probability space $(X,\mathcal{B},\mu)$ if $\bigvee_{i=0}^{\infty}T^{-i}\alpha$ generates $\mathcal{B}$. If $T$ is invertible then a partition $\alpha$ is called a generator if $\bigvee_{i=-\infty}^{\infty}T^{-i}\alpha$ generates $\mathcal{B}$. In the case when $\alpha$ is a generator with $H_\mu(\alpha) < \infty$, by the Kolmogorov–Sinai theorem we have $h_\mu(T) = h_\mu(T,\alpha)$. Let $\alpha_n(x)$ denote an element of $\bigvee_{i=0}^{n-1}T^{-i}\alpha$ containg $x \in X$. By the Shannon–McMillan–Breiman theorem, if $T$ is a measure-preserving transformation of the probability space $(X,\mathcal{B},\mu)$ and $\alpha$ is a partition of $X$ with $H_\mu(\alpha) < \infty$, then $-(1/n)\mu(\alpha_n(x))$ converges $\mu$-a.e. and in $L^1(X,\mu)$ as $n\to\infty$. If $T$ is ergodic, then the limit coincides with $h_\mu(T,\alpha)$. Now we can apply these results to piecewise expanding transitive (countable) Markov transformations $T$ of $X \subset \boldsymbol{R}^d$. More specifically, let $\nu$ be the normalized Lebesgue measure of $X$. It is well known that under certain conditions there exists the unique ergodic invariant probability measure $\mu$ equivalent to $\nu$. Then we can establish the Rohlin's entropy formula (Rohlin 1964):

$$h_\mu(T) = \int_X \log|\det DT|\,\mathrm{d}\mu$$

under the assumptions that $H_\nu(\alpha) < \infty$ and $\log|\det DT| \in L^1(X,\nu)$. In particular, if $\alpha$ is a finite partition and $\phi = -\log|\det DT|$ is piecewise Hölder continuous, then the entropy formula just implies that $\mu$ is an equilibrium state for the potential $\phi$ in the following sense:

$$h_\mu(T) + \int_X \phi\,\mathrm{d}\mu = \sup\{h_m(T) + \int_X \phi\,\mathrm{d}m | m$$

is a $T$-invariant Borel probability measure on $X\}$, where the right-hand side is called the pressure for $\phi$ (Walters 1981).

We now turn our attention to results which relate entropy to Lyapunov exponent in the context of smooth invertible systems. Let $T$ be a diffeomorphism of a compact manifold $M$. We say that $x \in M$ is a regular point of $T$ if there exist numbers $\lambda_1(x) > \lambda_2(x) > \cdots > \lambda_d(x)$ and a decomposition $T_xM = E_1(x) + E_2(x) + \cdots + E_d(x)$ such that

$$\lim_{n\to\infty}\frac{1}{n}\log\|DT^n(x)u\| = \lambda_j(x)$$

for every $0 \neq u \in E_j(x)$ and every $1 \leq j \leq d$. Let $\Lambda$ be the set of regular points of $T$. Then we define a function

$$\chi(x) := \sum_{\lambda_j(x)\geq 0}\lambda_j(x)\dim E_j(x)$$

In the case when all Lyapunov exponents at $x$ are negative, we put $\chi(x) = 0$. Then for every $T$-invariant Borel probability measure $\mu$ on $(X,\mathcal{B})$, it holds that $h_\mu(T) \leq \int_X \chi\,\mathrm{d}\mu$ (Ruelle 1978). Moreover, the equality holds whenever $T$ is $C^1$-Hölder and $\mu$ is absolutely continuous with respect to the Lebesgue measure of $X$ (Pesin 1977). Let $T$ be a transitive $C^1$-Hölder Anosov diffeomorphism. $E^{\mathrm{s}}, E^{\mathrm{u}}$ denote the stable and unstable fiber bundles of $T$. Suppose that $\mu_+$ is the unique $T$-invariant probability measure which satisfies

$$\int_M f\,\mathrm{d}\mu_+ = \lim_{n\to\infty}\frac{1}{n}\sum_{k=0}^{n-1}fT^k(x)$$

for every continuous function $f : M \to \boldsymbol{R}$ and almost everywhere $x \in M$ with respect to the Lebesgue measure. The probability measure is the so-called Sinai–Ruelle–Bowen (SRB) measure. Then we have

$$h_{\mu_+}(T) = \int_M \log|\det DT(x)|_{E_x^u}|\mathrm{d}\mu_+(x)$$

On the other hand, we have

$$h_{\mu_+}(T) = \int_M \log|\det DT^{-1}(x)|_{E_x^s}|\mathrm{d}\mu_+(x) + \int_M \log|\det DT(x)|\mathrm{d}\mu_+(x)$$

We also define unti-SRB measure $\mu_-$ by replacing $T$ by $T^{-1}$. Then the SRB measure $\mu_+$ is absolutely continuous with respect to the Lebesgue measure of $M$ iff $\mu_+$ coincides with the unti-SRB measure $\mu_-$ (Bowen 1975). Hence, the SRB measure is absolutely continuous iff $\int_M \log|\det DT(x)|\mathrm{d}\mu_+(x) = 0$. This property is sometimes explained as "zero entropy production" and also as "reversibility" in the context of non-equilibrium statistical mechanics (Ruelle 1997).

# Euclidean Field Theory

**F Guerra**, Università di Roma "La Sapienza," Rome, Italy

## Introduction

In this article, we consider Euclidean field theory as a formulation of quantum field theory which lives in some Euclidean space, and is expressed in probabilistic terms. Methods arising from Euclidean field theory have been introduced in a very successful way in the study of concrete models of constructive quantum field theory.

Euclidean field theory was initiated by Schwinger (1958) and Nakano (1959), who proposed to study the vacuum expectation values of field products analytically continued into the Euclidean region (Schwinger functions), where the first three (spatial) coordinates of a world point are real and the last one (time) is purely imaginary (Schwinger points). The possibility of introducing Schwinger functions, and their invariance under the Euclidean group are immediate consequences of the now classic formulation of quantum field theory in terms of vacuum expectation values given by Wightman (Streater and Wightman 1964). The convenience of dealing with the Euclidean group, with its positive-definite scalar product, instead of the Lorentz group, is evident, and has been exploited by several authors, in different contexts.

The next step was made by Symanzik (1966), who realized that Schwinger functions for boson fields have a remarkable positivity property, allowing to introduce Euclidean fields on their own sake. Symanzik also pointed out an analogy between Euclidean field theory and classical statistical mechanics, at least for some interactions (Symanzik 1969).

This analogy was successfully extended, with a different interpretation, to all boson interactions by Guerra *et al.* (1975), with the purpose of using rigorous results of modern statistical mechanics for

the study of constructive quantum field theory, within the program advocated by Wightman (1967), and further pursued by Glimm and Jaffe (see Glimm and Jaffe (1981) for an overall presentation).

The most dramatic advance of Euclidean theory was due to Nelson (1973a, b). He was able to isolate a crucial property of Euclidean fields (the Markov property) and gave a set of conditions for these fields, which allow us to derive all properties of relativistic quantum fields satisfying Wightman axioms. The Nelson theory is very deep and rich in new ideas. Even after so many years since the basic papers were published, we lack a complete understanding of the radical departure from the conventional theory afforded by Nelson's ideas, especially about their possible further developments.

By using the Nelson scheme, in particular a very peculiar symmetry property, it was very easy to prove (Guerra 1972) the convergence of the ground-state energy density, and the van Hove phenomenon in the infinite-volume limit for two-dimensional boson theories. A subsequent analysis (Guerra *et al.* 1972) gave other properties of the infinite-volume limit of the theory, and allowed a remarkable simplification in the proof of a very important regularity property for fields, previously established by Glimm and Jaffe.

Since then, all work on constructive quantum field theory has exploited in different ways ideas coming from Euclidean field theory. Moreover, a very important reconstruction theorem has been established by Osterwalder and Schrader (1973), allowing a reconstruction of relativistic quantum fields from the Euclidean Schwinger functions, and avoiding the previously mentioned Nelson reconstruction theorem, which is technically more difficult to handle.

This article is intended to be an introduction to the general structure of Euclidean quantum field theory, and to some of the applications to constructive quantum field theory. Our purpose is to show that, 50 years after its introduction, the Euclidean theory is still interesting, both from the point of view of technical applications and physical interpretation.

The article is organized as follows. In the next section, by considering simple systems made of a single spinless relativistic particle, we introduce the relevant structures in both Euclidean and Minkowski worlds. In particular, a kind of (pre)Markov property is introduced already at the one-particle level.

Next we present a description of the procedure of second quantization on the one-particle structure. The free Markov field is introduced, and its crucial Markov property explained. Following Nelson, we use probabilistic concepts and methods, whose relevance for constructive quantum field theory became immediately more and more apparent. The very structure of classical statistical mechanics for Euclidean fields is firmly based on these probabilistic methods. This is followed by an introduction of interaction, and we show the connection between the Markov theory and the Hamiltonian theory, for two-dimensional space-cutoff interacting scalar fields. In particular, we present the Feynman–Kac–Nelson formula that gives an explicit expression of the semigroup generated by the space-cutoff Hamiltonian in $\Phi o \kappa$ space. We also deal with some applications to constructive quantum field theory. This is followed by a short discussion about the physical interpretation of the theory. In particular, we discuss the Osterwalder–Schrader reconstruction theorem on Euclidean Schwinger functions, and the Nelson reconstruction theorem on Euclidean fields. For the sake of completeness, we sketch the main ideas of a proposal, advanced in Guerra and Ruggiero (1973), according to which the Euclidean field theory can be interpreted as a stochastic field theory in the physical Minkowski spacetime.

Our treatment will be as simple as possible, by relying on the basic structural properties, and by describing methods of presumably very long lasting power. The emphasis given to probabilistic methods, and to the statistical mechanics analogy, is a result of the historical development. Our opinion is that not all possibilities of Euclidean field theory have been fully exploited yet, both from technical and physical points of view.

## One-Particle Systems

A system made of only one relativistic scalar particle, of mass $m > 0$, has a quantum state space represented by the positive-frequency solutions of the Klein–Gordon equation. In momentum space, with points $p_\mu, \mu = 0, 1, 2, 3$, let us introduce the upper mass hyperboloid, characterized by the constraints $p^2 \equiv p_0^2 - \sum_{i=1}^{3} p_i^2 = m^2, p_0 \geq m$, and the relativistic invariant measure on it, formally given by $\mathrm{d}\mu(p) = \theta(p_0)\delta(p^2 - m^2)\,\mathrm{d}p$, where $\theta$ is the step function $\theta(x) = 1$ if $x \geq 0$, and $\theta(x) = 0$ otherwise, and $\mathrm{d}p$ is the four-dimensional Lebesgue measure. The Hilbert space of quantum states $F$ is given by the square-integrable functions on the mass hyperboloid equipped with the invariant measure $\mathrm{d}\mu(p)$. Since in some reference frame the mass hyperboloid is uniquely characterized by the space values of the momentum $\boldsymbol{p}$, with the energy given by $p_0 \equiv \omega(\boldsymbol{p}) = \sqrt{\boldsymbol{p}^2 + m^2}$, the Hilbert space $F$ of the states is, in fact, made of those complex-valued tempered distributions $f$ in the configuration space $R^3$ whose Fourier transforms, $\tilde{f}(\boldsymbol{p})$, are square-integrable functions in momentum space with respect to the image of the relativistic invariant measure $\mathrm{d}\boldsymbol{p}/2\omega(\boldsymbol{p})$, where

d$\boldsymbol{p}$ is the Lebesgue measure in momentum space. The scalar product on $F$ is defined by

$$\langle f,g\rangle_F=(2\pi)^3\int\tilde{f}^*(\boldsymbol{p})\tilde{g}(\boldsymbol{p})\frac{\mathrm{d}\boldsymbol{p}}{2\omega(\boldsymbol{p})}$$

where we have normalized the Fourier transform in such a way that

$$f(\boldsymbol{x})=\int\exp(\mathrm{i}\boldsymbol{p}.\boldsymbol{x})\tilde{f}(\boldsymbol{p})\,\mathrm{d}\boldsymbol{p}$$

$$\tilde{f}(\boldsymbol{p})=(2\pi)^{-3}\int\exp(-\mathrm{i}\boldsymbol{p}.\boldsymbol{x})\tilde{f}(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}$$

$$\int\exp(\mathrm{i}\boldsymbol{p}.\boldsymbol{x})\,\mathrm{d}\boldsymbol{p}=(2\pi)^3\delta(\boldsymbol{x})$$

The scalar product on $F$ can also be expressed in the form

$$\langle f,g\rangle_F=\iint f(\boldsymbol{x}')^*W(\boldsymbol{x}'-\boldsymbol{x})g(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}'\,\mathrm{d}\boldsymbol{x}$$

where we have introduced the two-point Wightman function at fixed time, defined by

$$W(\boldsymbol{x}'-\boldsymbol{x})=(2\pi)^{-3}\int\exp(\mathrm{i}\boldsymbol{p}.(\boldsymbol{x}'-\boldsymbol{x}))\frac{\mathrm{d}\boldsymbol{p}}{2\omega(\boldsymbol{p})}$$

A unitary irreducible representation of the Poincaré group can be defined on $F$ in the obvious way. In particular, the generators of space translations are given by multiplication by the components of $\boldsymbol{p}$ in momentum space, and the generator of time translations (the energy of the particle) is given by $\omega(\boldsymbol{p})$.

For the scalar product of time-evolved wave functions, we can write

$$\begin{aligned}&\langle\exp(-\mathrm{i}t')f,\exp(-\mathrm{i}t)g\rangle_F\\&=\iint f(\boldsymbol{x}')^*W(t'-t,\boldsymbol{x}'-\boldsymbol{x})g(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}'\mathrm{d}\boldsymbol{x}\end{aligned}$$

where we have introduced the two-point Wightman function, defined by

$$\begin{aligned}&W(t'-t,\boldsymbol{x}'-\boldsymbol{x})\\&=(2\pi)^{-3}\int\exp(-\mathrm{i}(t-t'))\exp(\mathrm{i}\boldsymbol{p}.(\boldsymbol{x}'-\boldsymbol{x}))\frac{\mathrm{d}\boldsymbol{p}}{2\omega(\boldsymbol{p})}\end{aligned}$$

To the physical single-particle system living in Minkowski spacetime, we associate a kind of mathematical image, living in Euclidean space, from which all properties of the physical system can be easily derived. We start from the two-point Schwinger function

$$S(x)=\frac{1}{(2\pi)^4}\int\frac{\exp(\mathrm{i}p\cdot x)}{\sqrt{p^2+m^2}}\,\mathrm{d}p$$

which is the analytic continuation of the previously given two-point Wightman function into the Schwinger points. Here $x,p\in R^4$, and $p\cdot x=\sum_{i=1}^4 x_ip_i$. Here d$p$ and d$x$ are the Lebesgue measures in the $R^4$ momentum and configuration spaces, respectively. The function $S(x)$ is positive and analytic for $x\neq 0$, decreases as $\exp(-m\|x\|)$ as $x\to\infty$, and satisfies the equation

$$(-\Delta+m^2)S(x)=\delta(x)$$

where $\Delta=\sum_{i=1}^4\partial^2/\partial x_i^2$ is the Laplacian in four dimensions.

The mathematical image we are looking for is described by the Hilbert space $N$ of those tempered distributions in four-dimensional configuration space $R^4$ whose Fourier transforms are square integrable with respect to the measure $\mathrm{d}p/\sqrt{p^2+m^2}$. The scalar product on $N$ is defined by

$$\langle f,g\rangle_N=(2\pi)^4\int\tilde{f}^*(p)\tilde{g}(p)\frac{\mathrm{d}p}{\sqrt{p^2+m^2}}$$

Four-dimensional Fourier transforms are normalized as follows:

$$f(x)=\int\exp(\mathrm{i}p.x)\tilde{f}(p)\,\mathrm{d}p$$

$$\tilde{f}(p)=(2\pi)^{-4}\int\exp(-\mathrm{i}p.x)\tilde{f}(x)\,\mathrm{d}x$$

$$\int\exp(\mathrm{i}p.x)\,\mathrm{d}p=(2\pi)^4\delta(x)$$

We also write

$$\begin{aligned}\langle f,g\rangle_N&=\iint f^*(x)S(x-y)g(y)\,\mathrm{d}x\,\mathrm{d}y\\&=\left\langle f,(-\Delta+m^2)^{-1}g\right\rangle\end{aligned}$$

where $\langle\,,\rangle$ is the ordinary Lebesgue product defined on Fourier transforms and, in momentum space, $(-\Delta+m^2)^{-1}$ amounts to a multiplication by $(p^2+m^2)^{-1}$. The Schwinger function $S(x-y)$ is formally the kernel of the operator $(-\Delta+m^2)^{-1}$. The Hilbert space $N$ is the carrier space of a unitary (nonirreducible) representation of the four-dimensional Euclidean group $E(4)$. In fact, let $(a,R)$ be an element of $E(4)$

$$\begin{aligned}(a,R):R^4&\to R^4\\x&\to Rx+a\end{aligned}$$

where $a\in R^4$, and $R$ is an orthogonal matrix, $RR^{\mathrm{T}}=R^{\mathrm{T}}R=1_4$. Then the transformation $u(a,R)$ defined by

$$\begin{aligned}&u(a,R):N\to N\\&\quad f(x)\to(u(a,R)f)(x)=f(R^{-1}(x-a))\end{aligned}$$

provides the representation. In particular, we consider the reflection $r_0$ with respect to the hyperplane

$x_4 = 0$, and the translations $u(t)$ in the $x_4$-direction. Then we have $r_0 u(t) r_0 = u(-t)$, and analogously for other hyperplanes.

Now we introduce a local structure on $N$ by considering, for any closed region $A$ of $R^4$, the subspace $N_A$ of $N$ made by distributions in $N$ with support on $A$. We call $e_A$ the orthogonal projection on $N_A$. It is obvious that if $A \in B$ then $N_A \in N_B$ and $e_A e_B = e_B e_A = e_A$. A kind of (pre)Markov property for one-particle systems is introduced as follows. Consider a closed three-dimensional piecewise smooth manifold $\sigma$, which divides $R^4$ in two closed regions $A$ and $B$, having $\sigma$ in common. Therefore, $\sigma \in A, \sigma \in B, A \cap B = \sigma, A \cup B = R^4$. Let $N_A, N_B, N_\sigma$, and $e_A, e_B, e_\sigma$ be the associated subspaces and projections, respectively. Then $N_\sigma \subset N_A, N_\sigma \subset N_B$, and $e_\sigma e_A = e_A e_\sigma = e_\sigma, e_\sigma e_B = e_B e_\sigma = e_\sigma$. It is very simple to prove the following:

**Theorem 1** *Let $e_A, e_B, e_\sigma$ be defined as above, then $e_A e_B = e_B e_A = e_\sigma$.*

Clearly, it is enough to show that for any $f \in N$ we have $e_A e_B f \in N_\sigma$. In that case, $e_\sigma e_A e_B f = e_A e_B f$, from which the theorem easily follows. Since $e_A e_B f$ has support on $A$, we must show that for any $C_0^\infty$ function $g$ with support on $A_\sigma$ we have $\langle g, e_A e_B f \rangle = 0$. Then $e_A e_B f$ has support on $\sigma$, and the proof is complete. Now we have

$$\begin{aligned}\langle g, e_A e_B f\rangle &= \langle(-\Delta + m^2)g, e_A e_B f\rangle_N \\ &= \langle e_A(-\Delta + m^2)g, e_B f\rangle_N \\ &= \langle(-\Delta + m^2)g, e_B f\rangle_N \\ &= \langle g, e_B f\rangle = 0\end{aligned}$$

where we have used the definition of $\langle\,\rangle_N$ in terms of $\langle\,\rangle$, the fact that $e_A(-\Delta + m^2)g = (-\Delta + m^2)g$, since $(-\Delta + m^2)g$ has support on $A_\sigma$, and the fact that $e_B f$ has support on $B$. This ends the proof of the (pre)Markov property for one-particle systems.

A very important role in the theory is played by subspaces of $N$ associated to hyperplanes in $R^4$. To fix ideas, consider the hyperplane $x_4 = 0$ and the associated subspace $N_0$. A tempered distribution in $N$ with support on $x_4 = 0$ has necessarily the form $(f \otimes \delta_0)(x) \equiv f(\mathbf{x})\delta(x_4)$, with $f \in F$. By using the basic magic formula, for $x \geq 0$ and $M > 0$,

$$\int_{-\infty}^{+\infty} \frac{\exp(ipx)}{p^2 + M^2}\,dp = \frac{\pi}{M}\exp(-Mx)$$

it is immediate to verify that $\|f \otimes \delta_0\|_N = \|f\|_F$. Therefore, we have an isomorphic and isometric identification of the two Hilbert spaces $F$ and $N_0$. Obviously, similar considerations hold for any hyperplane. In particular, we consider the hyperplanes $x_4 = t$ and the associated subspaces $N_t$. Let us introduce injection operators $j_t$ defined by

$$\begin{aligned} j_t : F &\to N \\ f &\to f \otimes \delta_t \end{aligned}$$

where $f$ is a generic element of $F$, with values $f(\mathbf{x})$, and $(f \otimes \delta_t)(x) = f(\mathbf{x})\delta(x_4 - t)$. It is immediate to verify the following properties for $j_t$ and its adjoint $j_t^*$: the range of $j_t$ is $N_t$; moreover, $j_t$ is an isometry, so that $j_t^* j_t = 1_F, j_t j_t^* = e_t$, where $1_F$ is the identity on $F$, and $e_t$ is the projection on $N_t$. Moreover, $e_t j_t = j_t$ and $j_t^* = j_t^* e_t$.

If we introduce translations $u(t)$ along the $x_4$-direction and the reflection $r_0$ with respect to $x_4 = 0$, then we also have the covariance property $u(t) j_s = j_{t+s}$, and the reflexivity property $r_0 j_0 = j_0$, $j_0^* r_0 = j_0^*$. The reflexivity property is very important. It tells us that $r_0$ leaves $N_0$ pointwise invariant, and it is an immediate consequence of the fact that $\delta(x_4) = \delta(-x_4)$.

Therefore, if we start from $N$ we can obtain $F$, by taking the projection $j_\pi$ with respect to some hyperplane $\pi$, in particular $x_4 = 0$. It is also obvious that we can induce on $F$ a representation of $E(3)$ by taking those elements of $E(4)$ that leave $\pi$ invariant.

Let us now see how we can define the Hamiltonian on $F$ starting from the properties of $N$. Since we are considering the simple case of the one-particle system, we could just perform the following construction explicitly by hand, through a simple application of the basic magic formula given earlier. But we prefer to follow a route that emphasizes Markov property and can be immediately generalized to more complicated cases.

Let us introduce the operator $p(t)$ on $F$ defined by the dilation $p(t) = j_0^* j_t = j_0^* u(t) j_0, t \geq 0$. Then we prove the following:

**Theorem 2** *The operator $p(t)$ is bounded and self-adjoint. The family $\{p(t)\}$, for $t \geq 0$, is a norm-continuous semigroup.*

**Proof** Boundedness and continuity are obvious. Self-adjointness is a consequence of reflexivity. In fact,

$$p^*(t) = j_0^* u(-t) j_0 = j_0^* r_0 u(t) r_0 j_0 = j_0^* u(t) j_0 = p(t)$$

The semigroup property is a consequence of the Markov property. In fact, let us introduce $N_+, N_0, N_-$ as subspaces of $N$ made by distributions with support in the regions $x_4 \geq 0, x_4 = 0, x_4 \leq 0$, respectively, and call $e_+, e_0, e_-$ the respective projections. By Markov property, we have $e_0 = e_- e_+$. Now write, for $s, t \geq 0$,

$$p(t)p(s) = j_0^* u(t) j_0 j_0^* u(s) j_0 = j_0^* u(t) e_0 u(s) j_0$$

If $e_0$ could be cancelled, then the semigroup property would follow from the group property of the translations $u(t)u(s) = u(t+s)$ (a miracle of the dilations!). For this, consider the matrix element

$$\langle f, p(t)p(s)g\rangle_F = \langle u(-t)j_0 f, e_0 u(s) j_0\, g\rangle_N$$

recall $e_0 = e_- e_+$, and use $u(s)j_0 g \in N_+$ and $u(-t)j_0 f \in N_-$.

Let us call $h$ the generator of $p(t)$, so that $p(t) = \exp(-th)$, for $t \geq 0$. By definition, $h$ is the Hamiltonian of the physical system. A simple explicit calculation shows that $h$ is just the energy $\omega$ introduced earlier. Starting from the representation of the Euclidean group $E(3)$ already given and from the Hamiltonian, we immediately get a representation of the full Poincaré group on $F$. Therefore, all physical properties of the one-particle system have been reconstructed from its Euclidean image on the Hilbert space $N$.

As a last remark of this section, let us note that we can consider the real Hilbert spaces $N_r$ and $F_r$, made of real elements (in configuration space) in $N$ and $F$. The operators $u(a,t), u(t), r_0, j_\pi, j_\pi^*, e_A$ are all reality preserving, that is, they map real spaces into real spaces.

This completes our discussion about the one-particle system. For more details we refer to Guerra *et al.* (1975) and Simon (1974). We have introduced the Euclidean image, discussed its main properties, and shown how we can derive all properties of the physical system from its Euclidean image. In the next sections, we will show how this kind of construction carries through the second-quantized case and the interacting case.

## Second Quantization and Free Fields

We begin this section with a short review about the procedure of second quantization based on probabilistic methods, by following mainly Nelson (1973b); see also Guerra *et al.* (1975) and Simon (1974). Probabilistic methods are particularly useful in the framework of the Euclidean theory.

Let $\mathcal{H}$ be a real Hilbert space with symmetric scalar product $\langle\,,\rangle$. Let $\phi(u)$ be the elements of a family of centered Gaussian random variables indexed by $u \in \mathcal{H}$, uniquely defined by the expectation values $E(\phi(u)) = 0, E(\phi(u)\phi(v)) = \langle u, v\rangle$. Since $\phi$ is Gaussian, we also have

$$E(\exp(\lambda\phi(u))) = \exp\left(\tfrac{1}{2}\lambda^2\langle u,u\rangle\right)$$

and

$$E(\phi(u_1)\phi(u_2)\cdots\phi(u_n)) = [u_1 u_2 \cdots u_n]$$

Here $[\ldots]$ is the Hafnian of elements $[u_i u_j] = \langle u_i, u_j\rangle$, defined to be zero for odd $n$, and for even $n$ given by the recursive formula

$$[u_1 u_2 \cdots u_n] = \sum_{i=2}^{n} [u_1 u_i][u_1 u_2 \cdots u_n]'$$

where in $[\ldots]'$ the terms $u_1$ and $u_i$ are suppressed. Hafnians, from the Latin name of Copenhagen, the first seat of the theoretical group of CERN, were introduced in quantum field theory by Caianiello (1973), as a useful tool when dealing with Bose statistics.

Let $(Q, \Sigma, \mu)$ be the underlying probability space where $\phi$ are defined as random variables. Here $Q$ is a compact space, $\Sigma$ a $\sigma$-algebra of subsets of $Q$, and $\mu$ a regular, countable additive probability measure on $\Sigma$, normalized to $\mu(Q) = \int_Q d\mu = 1$.

The fields $\phi(u)$ are represented by measurable functions on $Q$. The probability space is uniquely defined, but for trivial isomorphisms, if we assume that $\Sigma$ is the smallest $\sigma$-algebra with respect to which all fields $\phi(u)$, with $u \in \mathcal{H}$, are measurable. Since $\phi(u)$ are Gaussian, they are represented by $L^p(Q, \Sigma, \mu)$ functions, for any $p$ with $1 \leq p < \infty$, and the expectations will be given by

$$E(\phi(u_1)\phi(u_2)\cdots\phi(u_n)) = \int_Q \phi(u_1)\phi(u_2)\cdots\phi(u_n)\, d\mu$$

where, by a mild abuse of notation, $\phi(u_i)$ on the right-hand side denote the $Q$ space functions which represent the random variables $\phi(u_i)$. We call the complex Hilbert space $\mathcal{F} = \Gamma(\mathcal{H}) = L^2(Q, \Sigma, \mu)$ the Фок space constructed on $\mathcal{H}$, and the function $\Omega_0 \equiv 1$ on $Q$ the Фок vacuum.

In order to introduce the concept of second quantization of operators, we must introduce subspaces of $\mathcal{F}$ with a "fixed number of particles." Call $\mathcal{F}_{(0)} = \{\lambda\Omega_0\}$, where $\lambda$ is any complex number. Define $\mathcal{F}_{(\leq n)}$ as the subspace of $\mathcal{F}$ generated by complex linear combinations of monomials of the type $\phi(u_1)\cdots\phi(u_j)$, with $u_i \in \mathcal{H}$, and $j \leq n$. Then $\mathcal{F}_{(\leq n-1)}$ is a subspace of $\mathcal{F}_{(\leq n)}$. We define $\mathcal{F}_{(n)}$, the $n$-particle subspace, as the orthogonal complement of $\mathcal{F}_{(\leq n-1)}$ in $\mathcal{F}_{(\leq n)}$, so that

$$\mathcal{F}_{(\leq n)} = \mathcal{F}_{(n)} \oplus \mathcal{F}_{(\leq n-1)}$$

By construction, the $\mathcal{F}_{(n)}$ are orthogonal, and it is not difficult to verify that

$$\mathcal{F} = \bigoplus_{n=0}^{\infty} \mathcal{F}_{(n)}$$

Let us now introduce the Wick normal products by the definition

$$:\phi(u_1)\phi(u_2)\cdots\phi(u_n):=E_{(n)}\phi(u_1)\phi(u_2)\cdots\phi(u_n)$$

where $E_{(n)}$ is the projection on $\mathcal{F}_{(n)}$. It is not difficult to prove the usual Wick theorem (see, e.g., Guerra *et al.* (1975), and its inversion given by Caianiello (1973).

It is interesting to remark that, in the framework of the second quantization performed with probabilistic methods, it is not necessary to introduce creation and destruction operators as in the usual treatment. However, the two procedures are completely equivalent, as shown, for example, in Simon (1974).

Given an operator $A$ from the real Hilbert space $\mathcal{H}_1$ to the real Hilbert space $\mathcal{H}_2$, we define its second-quantized operator $\Gamma(A)$ through the following definitions:

$$\Gamma(A)\Omega_{01}=\Omega_{02}$$

$$\Gamma(A):\phi_1(u_1)\phi_1(u_2)\ldots\phi_1(u_n):\\ =:\phi_2(Au_1)\phi_2(Au_2)\cdots\phi_2(Au_n):$$

where we have introduced the probability spaces $Q_1$ and $Q_2$, their vacua $\Omega_{01}$ and $\Omega_{02}$, and the random variables $\phi_1$ and $\phi_2$, associated to $\mathcal{H}_1$ and $\mathcal{H}_2$, respectively. The following remarkable theorem by Nelson (1973b) gives a full characterization of $\Gamma(A)$, very useful in the applications.

**Theorem 3** *Let $A$ be a contraction from the real Hilbert space $\mathcal{H}_1$ to the real Hilbert space $\mathcal{H}_2$. Then $\Gamma(A)$ is an operator from $L^1_{(1)}$ to $L^1_{(2)}$ which is positivity preserving, $\Gamma(A)u\geq 0$ if $u\geq 0$, and such that $E(\Gamma(A)u)=E(u)$. Moreover, $\Gamma(A)$ is a contraction from $L^p_{(1)}$ to $L^p_{(2)}$ for any $p$, $1\leq p<\infty$. Finally, $\Gamma(A)$ is also a contraction from $L^p_{(1)}$ to $L^q_{(2)}$, with $q\geq p$, if $\|A\|^2\leq(p-1)/(q-1)$.*

We have indicated with $L^p_{(1)}, L^p_{(2)}$ the $L^p$ spaces associated to $\mathcal{H}_1$ and $\mathcal{H}_2$, respectively. This is the celebrated best hypercontractive estimate given by Nelson. For the proof, we refer to the original paper of Nelson (1973b); see also Simon (1974).

This completes our short review on the theory of second quantization based on probabilistic methods.

The usual time-zero quantum field $\bar{\phi}(u), u\in F_r$, in the Фок representation, can be obtained through second quantization starting from $F_r$. We call $(\bar{Q},\bar{\Sigma},\bar{\mu})$ the underlying probability space, and $\mathcal{F}=\Gamma(F_r)=L^2(\bar{Q},\bar{\Sigma},\bar{\mu})$ the Hilbert Фок space of the free physical particles.

Now we introduce the free Markov field $\phi(f), f\in N_r$, by taking $N_r$ as the starting point. We call $(Q,\Sigma,\mu)$ the associated probability space. We introduce the Hilbert space $\mathcal{N}=\Gamma(N_r)=L^2(Q,\Sigma,\mu)$, and the operators $U(a,R)=\Gamma(u(a,R))$, $R_0=\Gamma(r_0)$, $U(t)=\Gamma(u(t))$, $E_A=\Gamma(e_A)$, and so on, for which the previous Nelson theorem holds (take $\mathcal{H}_1=\mathcal{H}_2=N_r$).

Since in general $\Gamma(AB)=\Gamma(A)\Gamma(B)$, we have immediately the following expression of the Markov property $E_\sigma=E_AE_B$, where the closed regions $A,B,\sigma$ of the Euclidean space have the same properties as explained earlier in the proof of the (pre)Markov property for one-particle systems.

It is obvious that $E_A$ can also be understood as conditional expectation with respect to the sub-$\sigma$-algebra $\Sigma_A$ generated by the field $\phi(f)$ with $f\in N_r$ and the support of $f$ on $A$.

The relation, previously pointed out, between $N_t$ subspaces and $F$ are also valid for their real parts $N_{rt}$ and $F_r$. Therefore, they carry out through the second quantization procedure. We introduce $J_t=\Gamma(j_t)$ and $J_t^*=\Gamma(j_t^*)$; then the following properties hold. $J_t$ is an isometric injection of $L^p(\bar{Q},\bar{\Sigma},\bar{\mu})$ into $L^p(Q,\Sigma,\mu)$; the range of $J_t$ as an operator $L^2\to L^2$ is obviously $\mathcal{N}_t=\Gamma(N_{rt})$; moreover, $J_tJ_t^*=E_t$. The free Hamiltonian $H_0$ is given for $t\geq 0$ by

$$J_0^*J_t=\exp(-tH_0)=\Gamma(\exp(-t\omega))$$

Moreover, we have the covariance property $U(t)J_0=J_t$, and the reflexivity $R_0J_0=J_0, J_0^*R_0=J_0^*$.

These relations allow a very simple expression for the matrix elements of the Hamiltonian semigroup in terms of Markov quantities. In fact, for $u,v\in\mathcal{F}$ we have

$$\langle u,\exp(-tH_0)v\rangle=\int_Q (J_tu)^*J_0v\,\mathrm{d}\mu$$

In the next section, we will generalize this representation to the interacting case.

Finally, let us derive the hypercontractive property of the free Hamiltonian semigroup.

Since $\|\exp(-t\omega)\|\leq\exp(-tm)$, where $m$ is the mass of the particle, we have immediately, by a simple application of Nelson theorem,

$$\|\exp(-tH_0)\|_{p,q}\leq 1$$

provided $q-1\leq(p-1)\exp(2tm)$, where $\|\ldots\|_{p,q}$ denotes the norm of an operator from $L^p$ to $L^q$ spaces.

## Interacting Fields

The discussion of the previous sections was limited to free fields both in Minkowski and Euclidean spaces. Now we must introduce interaction in order to get nontrivial theories.

First, as a general motivation, we will proceed quite formally and then we will resort to precise statements.

Let us recall that in standard quantum field theory, for scalar self-coupled fields, the time-ordered products of quantum fields in Minkowski spacetime can be expressed formally through the formula

$$\frac{\langle T(\phi(x_1)\cdots\phi(x_n)\exp(\mathrm{i}\int\mathcal{L}\,\mathrm{d}x))\rangle}{\langle T\exp(\mathrm{i}\int\mathcal{L}\,\mathrm{d}x)\rangle}$$

where $T$ denotes time ordering, $\phi$ are free fields in Minkowski spacetime, $\mathcal{L}$ is the interaction Lagrangian, and $\langle\ldots\rangle$ are vacuum averages. As is well known, this expression can be put, for example, at the basis of perturbative expansions, giving rise to terms expressed through Feynman graphs. The appropriately chosen normalization provides automatic cancelation of the vacuum to vacuum graphs.

Now we can introduce a formal analytic continuation to the Schwinger points, as previously done for the one-particle system, and obtain the following expression for the analytic continuation of the field time-ordered products, now called Schwinger functions,

$$S(x_1,\ldots,x_n)=\frac{\langle\phi(x_1)\cdots\phi(x_n)\exp U\rangle}{\langle\exp U\rangle}$$

Here $x_1,\ldots,x_n$ denote points in Euclidean space, $\phi$ are the Euclidean fields introduced earlier. The chronological time ordering disappears, because the fields $\phi$ are commutative, and there is no distinguished "time" direction in Euclidean space. Here the symbol $\langle\ldots\rangle$ denotes the expectation values represented by $\int\ldots\mathrm{d}\mu$, as explained earlier, and $U$ is the Euclidean "action" of the system formally given by the integral on Euclidean space

$$U=-\int P(\phi(x))\,\mathrm{d}x$$

if the field self-interaction is produced by the polynomial $P$.

Therefore, these formal considerations suggest that the passage from the free Euclidean theory to the fully interacting one is obtained through a change of the free probability measure $\mathrm{d}\mu$ to the interacting measure

$$\exp U\,\mathrm{d}\mu\Big/\int_Q\exp U\,\mathrm{d}\mu$$

The analogy with classical statistical mechanics is evident. The expression exp $U$ acts as *Boltzmannfaktor*, and $Z=\int_Q\exp U\,\mathrm{d}\mu$ is the partition function.

Our task will be to make these statements precise from a mathematical point of view. We will be obliged to introduce cutoffs, and then be involved in their careful removal.

For the sake of convenience, we make the substantial simplification of considering only two-dimensional theories (one space, one time dimension in the Minkowski region) for which the well-known ultraviolet problem of quantum field theory gives no trouble. There is no difficulty in translating the contents of the previous sections to the two-dimensional case.

Let $P$ be a real polynomial, bounded below and normalized to $P(0)=0$. We introduce approximations $h$ to the Dirac $\delta$ function at the origin of the two-dimensional Euclidean space $R^2$, with $h\in N_{\mathrm{r}}$. Let $h_x$ be the translate of $h$ by $x$, with $x\in R^2$. The introduction of $h$, equivalent to some ultraviolet cutoff, is necessary, because local fields, of the formal type $\phi(x)$, have no rigorous meaning, and some smearing is necessary.

For some compact region $\Lambda$ in $R^2$, acting as space cutoff (infrared cutoff), introduce the $Q$ space function

$$U_\Lambda^{(h)}=-\int_\Lambda :P(\phi(h_x)):\,\mathrm{d}x$$

where $\mathrm{d}x$ is the Lebesgue measure in $R^2$. It is immediate to verify that $U_\Lambda^{(h)}$ is well defined, bounded below and belongs to $L^p(Q,\Sigma,\mu)$, for any $p$, $1\le p<\infty$. This is the infrared and ultraviolet cutoff action. Notice the presence of the Wick normal products in its definition. They provide a kind of automatic introduction of counterterms, in the framework of renormalization theory.

The following theorem allows us to remove the ultraviolet cutoff.

**Theorem 4** *Let $h\to\delta$, in the sense that the Fourier transforms $\tilde{h}$ are uniformly bounded and converge pointwise in momentum space to the Fourier transform of the $\delta$-function given by $(2\pi)^{-2}$. Then $U_\Lambda^{(h)}$ is $L^p$-convergent for any $p, 1\le p<\infty$, as $h\to\delta$. Call $U_\Lambda$ the $L^p$-limit, then $U_\Lambda$, $\exp U_\Lambda\in L^p(Q,\Sigma_\Lambda,\mu)$, for $1\le p<\infty$.*

The proof uses standard methods of probability theory, and originates from pioneering work of Nelson in (1966). It can be found for example in Guerra *et al.* (1975), and Simon (1974).

Since $U_\Lambda$ is defined with normal products, and the interaction polynomial $P$ is normalized to $P(0)=0$, an elementary application of Jensen inequality gives

$$\int_Q\exp U_\Lambda\,\mathrm{d}\mu\ge\exp.\int_Q U_\Lambda\,\mathrm{d}\mu=1$$

Therefore, we can rigorously define the new space cutoff measure in $Q$ space:

$$d\mu_\Lambda = \exp U_\Lambda \, d\mu \Big/ \int_Q \exp U_\Lambda \, d\mu$$

The space-cutoff interacting Euclidean theory is defined by the same fields on $Q$ space, but with a change in the measure and, therefore, in the expectation values. The correlations for the interacting fields $\bar{\phi}$ are the cutoff Schwinger functions

$$\begin{aligned} S_\Lambda(x_1, \ldots, x_n) &= \langle \bar{\phi}(x_1) \cdots \bar{\phi}(x_n) \rangle \\ &= Z_\Lambda^{-1} \langle \phi(x_1) \cdots \phi(x_n) \exp U_\Lambda \rangle \end{aligned}$$

where the partition function is

$$Z_\Lambda = \langle \exp U_\Lambda \rangle$$

We see that the analogy with statistical mechanics is complete here. Of course, the introduction of the space cutoff $\Lambda$ destroys translation invariance. The full Euclidean covariant theory must be recovered by taking the infinite-volume limit $\Lambda \to R^2$ on field correlations. For the removal of the space cutoff, all methods of statistical mechanics are available. In particular, correlation inequalities of ferromagnetic type can be easily exploited, as shown, for example, in Guerra *et al.* (1975) and Simon (1974).

We would like to conclude this section by giving the connection between the space-cutoff Euclidean theory and the space-cutoff Hamiltonian theory in the physical Фок space.

For $\ell \geq 0, t \geq 0$, consider the rectangle in $R^2$,

$$\Lambda(\ell, t) = \left\{ (x_1, x_2) \colon -\frac{\ell}{2} \leq x_1 \leq \frac{\ell}{2}, 0 \leq x_2 \leq t \right\}$$

and define the operator in the physical Фок space

$$P_\ell(t) = J_0^* \exp U_\Lambda(\ell, t) J_t$$

where $J_0$ and $J_t$ are injections relative to the lines $x_2 = 0$ and $x_2 = t$, respectively. Then the following theorem, largely due to Nelson, holds.

**Theorem 5** *The operator $P_\ell(t)$ is bounded and self-adjoint. The family $\{P_\ell(t)\}$, for $\ell$ fixed and $t \geq 0$, is a strongly continuous semigroup. Let $H_\ell$ be its lower bounded self-adjoint generator, so that $P_\ell(t) = \exp(-tH_\ell)$. On the physical Фок space, there is a core $\mathcal{D}$ for $H_\ell$ such that on $\mathcal{D}$ the equality $H_\ell = H_0 + V_\ell$ holds, where $H_0$ is the free Hamiltonian introduced earlier and $V_\ell$ is the volume-cutoff interaction given by*

$$V_\ell = \lim \int_{-\ell/2}^{\ell/2} : P(\bar{\phi}(h_{x_1})) : dx_1$$

*where $h_{x_1}$ are the translates of approximations to the $\delta$-function at the origin on the $x_1$-space, and the limit is taken in $L^p$, in analogy to what has been explained for the two-dimensional case in the definition of $U_\Lambda$.*

While we refer to Guerra *et al.* (1975) and Simon (1974) for a full proof, we mention here that boundedness is related to hypercontractivity of the free Hamiltonian, self-adjointness is a consequence of reflexivity, and the semigroup property follows from Markov property. This theorem is remarkable, because it expresses the cutoff interacting Hamiltonian semigroup in an explicit form in the Euclidean theory through probabilistic expectations. In fact, we have

$$\langle u, \exp(-tH_\ell)v \rangle = \int_Q (J_t u)^* J_0 v \exp U_\Lambda(\ell, t) \, d\mu$$

We could call this expression as the Feynman–Kac–Nelson formula, in fact it is nothing but a path integral expressed in stochastic terms, and adapted to the Hamiltonian semigroup.

By comparison with the analogous formula given for the free Hamiltonian semigroup, we see that the introduction of the interaction inserts the *Boltzmannfaktor* under the integral.

As an immediate consequence of the Feynman–Kac–Nelson formula, together with Euclidean covariance, we have the following astonishing Nelson symmetry:

$$\langle \Omega_0, \exp(-tH_\ell)\Omega_0 \rangle = \langle \Omega_0, \exp(-\ell H_t)\Omega_0 \rangle$$

which was at the basis of Guerra (1972) and Guerra *et al.* (1972), and played some role in showing the effectiveness of Euclidean methods in constructive quantum field theory.

It is easy to establish, through simple probabilistic reasoning, that $H_\ell$ has a unique ground state $\Omega_\ell$ of lowest energy $E_\ell$. For a convenient choice of normalization and phase factor, one has $\|\Omega_\ell\|_2 = 1$, and $\Omega_\ell > 0$ almost everywhere on $Q$ space (for bosonic systems, ground states have no nodes in configuration space!). Moreover, $\Omega_\ell \in L^p$, for any $1 \leq p < \infty$. If $\ell > 0$ and the interaction is not trivial, then $\Omega_\ell \neq \Omega_0, E_\ell < 0$, and $\|\Omega_\ell\|_1 < 1$. Obviously, $\|\exp(-tH_\ell)\|_{2,2} = \exp(-tE_\ell)$.

The general structure of Euclidean field theory, as explained in this section, has been at the basis of all applications in constructive quantum field theory. These applications include the proof of the existence of the infinite-volume limit, with the establishment of all Wightman axioms, for two- and three-dimensional theories. Moreover, the existence of phase transitions and symmetry breaking has been firmly established.

Extensions have also been given to theories involving Fermions, and to gauge field theory. Due to the scope of this review, limited to a description of the general structure of Euclidean field theory, we cannot give a detailed treatment of these applications. Therefore, we refer to recent general reviews on constructive quantum field theory for a complete description of all results (see, e.g., Jaffe (2000)). For recent applications of Euclidean field theory to quantum fields on curved spacetime manifolds we refer, for example, to Schlingemann (1999).

## The Physical Interpretation of Euclidean Field Theory

Euclidean field theory has been considered by most researchers as a very useful tool for the study of quantum field theory. In particular, it is quite easy, for example, to obtain the fully interacting Schwinger functions in the infinite-volume limit in two-dimensional spacetime. At this point, there arises the problem of connecting these Schwinger functions with observable physical quantities in Minkowski spacetime. A very deep result of Osterwalder and Schrader (1973) gives a very natural interpretation of the resulting limiting theory. In fact, the Euclidean theory, as has been shown earlier, arises from an analytic continuation from the physical Minkowski spacetime to the Schwinger points, through a kind of analytic continuation in time (also called Wick rotation, because Wick exploited this trick in the study of the Bethe–Salpeter equation). Therefore, having obtained the Schwinger functions for the full covariant theory, after all cutoff removal, it is very natural to try to reproduce the inverse analytic continuation in order to recover the Wightman functions in Minkowski spacetime. Therefore, Osterwalder and Schrader have been able to identify a set of conditions, quite easy to verify, wich allow us to recover Wightman functions from Schwinger functions. A key role in this reconstruction theorem is played by the so-called reflection positivity for Schwinger functions, a property quite easy to verify. In this way, a fully satisfactory solution for the physical interpretation of Euclidean field theory is achieved.

From a historical point of view, an alternate route is possible. In fact, at the beginning of the exploitation of Euclidean methods in constructive quantum field theory, Nelson was able to isolate a set of axioms for the Euclidean *fields* (Nelson 1973a), allowing the reconstruction of the physical theory. Of course, Nelson axioms are more difficult to verify, since they also involve properties of the Euclidean fields and not only of the Schwinger functions. However, it is still very interesting to investigate whether the Euclidean fields play only an auxiliary role in the construction of the physical content of relativistic theories, or if they have a more fundamental meaning.

From a physical point of view, the following considerations could also lead to further developments along this line. By its very structure, the Euclidean theory contains the fixed-time quantum correlations in the vacuum. In elementary quantum mechanics, it is possible to derive all physical content of the theory from the simple knowledge of the ground state wave function, including scattering data. Therefore, at least in principle, it should be possible to derive all physical content of the theory directly from the Euclidean theory, without any analytic continuation.

We conclude this short section on the physical interpretation of the Euclidean theory with a mention of a quite surprising result (Guerra and Ruggiero 1973) obtained by submitting classical field theory to the procedure of stochastic quantization in the sense of Nelson (1985). The procedure of stochastic quantization associates a stochastic process to each quantum state. In this case, in a fixed reference frame, the procedure of stochastic quantization, applied to interacting fields, produces, for the ground state, a process in the physical spacetime that has the same correlations as Euclidean field theory. This opens the way to a possible interpretation of Euclidean field theory directly in Minkowski spacetime. However, a consistent development along this line requires a new formulation of representations of the Poincaré group in the form of measure-preserving transformations in the probability space where the Euclidean fields are defined. This difficult task has not been accomplished as yet.

# Evolution Equations: Linear and Nonlinear

**J Escher**, Universität Hannover, Hannover, Germany

## Introduction

In this article we present the semigroup approach to linear and nonlinear evolution equations in general Banach spaces. In the first part we introduce the general frame and we explain the cornerstones of the widely developed theory of linear evolution equations. Besides the classical approach to linear evolution equations based on $C_0$-semigroups, we also give a brief introduction to the more recent theory of maximal regularity. The entire linear theory is not only important on its own (which we prove by discussing applications to the heat equation, Schrödinger equation, wave equation, and Maxwell equations) but it is also the indispensable basis for the theory of nonlinear evolution equation, which we present in the second part.

## Linear Evolution Equations

Let $E_0$ be a Banach space, $T > 0$, and assume that $\mathcal{A} := \{A(t); t \in [0, T]\}$ is a family of closed linear operators in $E_0$. By this we mean that, given $t \in [0, T]$, there is a linear subspace $D(A(t))$ of $E_0$ and linear mapping $A(t) : D(A(t)) \subset E_0 \to E_0$ such that the graph $\{(x, A(t)x); x \in D(A(t))\}$ of $A(t)$ is a closed subspace of $E_0 \times E_0$. Given a mapping $f : [0, T] \to E_0$ and a vector $u_0 \in E_0$, we study the following initial-value problem for $(\mathcal{A}, f, u_0)$: find a function $u \in C^1((0, T], E_0)$ such that $u(t) \in D(A(t))$ for $t \in (0, T]$ and

$$u'(t) = A(t)u(t) + f(t), \quad t \in (0, T], \quad u(0) = u_0 \qquad [1]$$

Sometimes we call [1] also the Cauchy problem of the linear evolution equation $u'(t) = A(t)u(t) + f(t)$. In the following, we will specify different conditions on $(\mathcal{A}, f, u_0)$ which guarantee the well-posedness of [1], and we shall discuss several examples of equations of type [1] which are relevant in mathematical physics.

### Autonomous Homogeneous Equations

As in the case of ordinary differential equations in finite-dimensional spaces, it is convenient to consider first the autonomous version of [1], that is, we assume that $\mathcal{A}$ is trivial in the sense that $T = \infty$ and that $A(0) = A(t)$ for all $t \geq 0$. In order to simplify our notation, we set $A := A(0)$. We consider first the homogeneous problem

$$u'(t) = Au(t), \quad t \in (0, \infty), \quad u(0) = u_0 \qquad [2]$$

where $u_0 \in E_0$ is given. The question of the well-posedness of [2] is closely tied to the notion of a $C_0$-semigroup in $E_0$. Let $\mathcal{L}(E_0)$ denote the Banach space of all bounded linear operators on $E_0$, endowed with the usual operator norm. A one-parameter family $\mathcal{T} = \{T(t) \in \mathcal{L}(E_0); t \geq 0\}$ is called "$C_0$-semigroup" in $\mathcal{L}(E_0)$ iff

1. $T(0) = \mathrm{id}_{E_0}$ (normalization),
2. $T(s+t) = T(s)T(t)$ for all $s, t \geq 0$ (semigroup property), and
3. $\lim_{t\to 0} T(t)x = x$ for all $x \in E_0$ (strong continuity at 0).

Given a $C_0$-semigroup $\mathcal{T}$, we define its (infinitesimal) generator $B$ by setting

$$\mathrm{dom}(B) := \left\{ x \in E_0; \lim_{t\to 0} \frac{T(t)x - x}{t} \text{ exists in } E_0 \right\}$$

and by defining

$$Bx := \lim_{t\to 0} \frac{T(t)x - x}{t} \quad \text{for } x \in \mathrm{dom}(B)$$

This clearly defines a linear operator in $E_0$ and it is well known that $B$ is closed and densely defined. Moreover, we have

**Theorem 1** *Assume that $A : D(A) \subset E_0 \to E_0$ is the generator of a $C_0$-semigroup $\{T(t); t \geq 0\}$. Then, given $u_0 \in D(A)$, problem [2] possesses a unique solution $u$ in $C^1([0,\infty), E_0)$, which is given by $u(t) = T(t)u_0$.*

Under suitable additional assumptions it can be shown that the converse of Theorem 1 also holds true. However, we shall not go into these details but we prefer to present the following characterization of generators of $C_0$-semigroups:

**Theorem 2** (Hille–Yosida). *The operator $A : D(A) \subset E_0 \to E_0$ generates a $C_0$-semigroup iff it is closed, densely defined, and there exists $\omega$, $M \in \mathbb{R}$ such that the resolvent set $\rho(A)$ of $A$ contains the ray $(\omega, \infty)$ and such that $\|(\lambda - \omega)^n (\lambda - A)^{-n}\| \leq M$ for all $\lambda > \omega$ and all $n \in \mathbb{N}$.*

In applications, it is in general rather difficult to derive a uniform estimate of powers of the resolvent of an unbounded operator. Luckily, generators of $C_0$-semigroups of contractions (i.e., $\|T(t)\|_{\mathcal{L}(E_0)} \leq 1$ for all $t \geq 0$) can be characterized in a rather useful way. To formulate this result we call an operator $B : D(B) \subset E_0 \to E_0$ "dissipative" iff for any $x \in D(B)$ there is an $x' \in E_0'$ with $\langle x', x\rangle = \|x\|^2_{E_0} = \|x'\|^2_{E_0'}$ such that $\mathrm{Re}\langle x', Bx\rangle \leq 0$. Here $\langle\cdot,\cdot\rangle$ denotes the duality pairing between $E_0'$ and $E_0$. The operator $B$ is called "$m$-dissipative" if it is dissipative and $im(\lambda_0 - A) = E_0$ for some $\lambda_0 > 0$.

**Theorem 3** (Lumer–Phillips). *Let $A : D(A) \subset E_0 \to E_0$ be a closed and densely defined operator. Then $A$ generates a $C_0$-semigroup of contractions in $\mathcal{L}(E_0)$ iff $A$ is $m$-dissipative.*

Before we shall discuss examples of $C_0$-semigroups and their infinitesimal generators, let us introduce the following definition: given $\alpha \in (0, \pi]$, let $\Sigma_\alpha := \{z \in \mathbb{C}; |\arg(z)| < \alpha\}$ denote the sector in $\mathbb{C}$ of angle $2\alpha$. A family of operators $\mathcal{T} = \{T(z) \in \mathcal{L}(E_0); z \in \Sigma_\alpha\}$ is called a "holomorphic $C_0$-semigroup" in $\mathcal{L}(E_0)$ iff

1. $[z \mapsto T(z)] : \Sigma_\alpha \to \mathcal{L}(E_0)$ is holomorphic,
2. $T(0) = \mathrm{id}_{E_0}$ and $\lim_{z\to 0} T(z)x = x$ for all $x \in E_0$, and
3. $T(w+z) = T(w)T(z)$ for all $w, z \in \Sigma_\alpha$.

Generators of holomorphic $C_0$-semigroups can be characterized in the following way:

**Theorem 4** *A densely defined closed linear operator $A : D(A) \subset E_0 \to E_0$ generates a holomorphic $C_0$-semigroup iff there exist $M > 0$ and $\omega_0 \geq 0$ such that $\lambda \in \rho(A)$ and $\|\lambda(\lambda - A)^{-1}\| \leq M$ for all $\lambda \in \mathbb{C}$ with $\mathrm{Re}\,\lambda > \omega_0$.*

**Examples 5**

(i) *Self-adjoint generators*. Let $E_0$ be a Hilbert space and assume that $A$ is self-adjoint and that there exists an $\alpha_0 \in \mathbb{R}$ such that $A \leq \alpha_0$. Then $A$ generates a holomorphic $C_0$-semigroup $\{T(t); t \geq 0\}$. If $\{E_A(\lambda); \lambda \in \mathbb{R}\}$ denotes the spectral resolution of $A$, then $T(t) = \int_{\mathbb{R}} \exp(t\lambda)\, \mathrm{d}E_A(\lambda)$ for $t \geq 0$.

(ii) *Dissipative operators in Hilbert spaces*. Assume again that $E_0$ is a Hilbert space. Then, by Riesz' representation formula, an operator $A$ is dissipative iff $\mathrm{Re}(u|Au) \leq 0$ for all $u \in D(A)$.

(iii) *The heat semigroup*. Let $M$ be either a smooth compact closed Riemannian manifold or $\mathbb{R}^m$ with the Euclidean metric and write $\Delta$ for the Laplace–Beltrami operator on $M$. Then it is known that $\Delta \in \mathcal{L}(\mathcal{D}'(M))$, where $\mathcal{D}'(M)$ is the space of all distributions on $M$. Given $1 \leq p < \infty$, let

$$D(\Delta_p) := \{u \in L_p(M); \Delta u \in L_p(M)\}$$

and set $\Delta_p u = \Delta u$ for $u \in D(\Delta_p)$. Then $\Delta_p$ generates a holomorphic $C_0$-semigroup on $L_p(M)$, the so-called "diffusion" or "heat semigroup" on $M$. If $1 < p < \infty$, then it can be shown that $D(\Delta_p) = W_p^2(M)$, where $W_p^k(M)$ denotes the Sobolev space of order $k \in \mathbb{N}$, built over $L_p(M)$.

If $M = \mathbb{R}^m$ then the operators $T(t)$ of the semigroup generated by $\Delta_{\mathbb{R}^m}$ are given by

$$T(t)u(x) = \frac{1}{(4\pi t)^{m/2}} \int_{\mathbb{R}^m} \exp\left(\frac{-|x-y|^2}{4t}\right) u(y)\, \mathrm{d}y$$

for all $t > 0$ and almost all $x \in \mathbb{R}^m$.

Observe that the case $L_\infty(M)$ is excluded here. In fact, it is known that if a linear operator $A$ generates a $C_0$-semigroup on $L_\infty(M)$, then $A$ must be bounded. However, it can be shown that suitable realizations of the Laplace–Beltrami operator on spaces of continuous and Hölder continuous functions generate holomorphic semigroups. For more details on that topic the reader is referred to the "Further reading" section.

(iv) *Stone's theorem and the Schrödinger equation*. Let $E_0$ be a Hilbert space and assume that $A$ is self-adjoint. Then Theorem 3 and Remark (ii) imply that i$A$ generates a $C_0$-group $\{U(t); t \in \mathbb{R}\}$ of unitary operators. In fact, Stone's theorem ensures that every generator of a $C_0$-group of unitary operators is of the form i$A$ with a self-adjoint operator $A$. As an example of particular interest, let us consider the Schrödinger equation

$$\frac{1}{\mathrm{i}}\frac{\partial u}{\partial t} = \Delta u - Vu \qquad [3]$$

with a bounded potential $V: \mathbb{R}^m \to \mathbb{R}$. Letting $D(A) := H^2(\mathbb{R}^m)$ and $Au := \Delta u - Vu$, it follows that $A$ is self-adjoint in $L_2(\mathbb{R}^m)$. Hence, the evolution of [3] is governed by the group of unitary operators generated by i$A$. Of course, the assumption that $V$ be bounded is rather restrictive. In fact, there are numerous contributions which show that this assumption can be weakened considerably. Again reader is referred to the "Further reading" section for more details in this direction.

(v) *The wave equation*. Let us consider the following initial-value problem

$$\begin{aligned} \Box u(t,x) &= 0, \quad x \in \mathbb{R}^m, \quad t > 0 \\ u(0,x) &= \varphi_1(x), \quad \partial u/\partial t(0,x) \\ &= \varphi_2(x), \quad x \in \mathbb{R}^m \end{aligned} \qquad [4]$$

for the d'Alembert operator $\Box = \partial^2 u/\partial t^2 - \Delta_{\mathbb{R}^m}$ in $m+1$ dimensions. In order to associate with [4] a semigroup, let us formally re-express [4] as the following first-order system:

$$\frac{\mathrm{d}U}{\mathrm{d}t} = AU, \quad t > 0, \quad U(0) = \Phi$$

where

$$U = (u, u'), \quad A = \begin{pmatrix} 0 & \mathrm{id} \\ \Delta & 0 \end{pmatrix}, \ \Phi = (\varphi_1, \varphi_2)$$

Letting now $E_0 := H^1(\mathbb{R}^m) \times L_2(\mathbb{R}^m)$ and $D(A) := H^2(\mathbb{R}^m) \times H^1(\mathbb{R}^m)$, it can be shown that $A$ generates a $C_0$-group of linear operators in $\mathcal{L}(E_0)$. Hence, given any initial datum $(\varphi_1, \varphi_2) \in H^2(\mathbb{R}^m) \times H^1(\mathbb{R}^m)$, there exists a unique solution $u \in C^1([0,\infty), L_2(\mathbb{R}^m))$ to the initial-value problem [4]. It can be shown that this solution possesses the following additional regularity:

$$u \in C^2([0,\infty), L_2(\mathbb{R}^m)) \cap C([0,\infty), H^2(\mathbb{R}^m))$$

Hence, eqns [4] are satisfied for all $t \in [0, \infty)$ and for almost all $x \in \mathbb{R}^m$.

(vi) *Maxwell equations*. Let $\boldsymbol{E}$ and $\boldsymbol{H}$ denote the electric and magnetic field vector, respectively, $\varepsilon$ and $\mu$ the electrical permittivity and magnetic permeability, respectively, and consider the initial-value problem for Maxwell equations in vacuum and without charges and currents: given sufficiently smooth vector fields $(\boldsymbol{E}_0, \boldsymbol{H}_0)$ find a pair $(\boldsymbol{E}, \boldsymbol{H})$ such that

$$\begin{aligned} &\varepsilon\frac{\partial \boldsymbol{E}}{\partial t} - \operatorname{rot}\boldsymbol{H} = 0 \quad \text{in } (0,\infty)\times\mathbb{R}^3 \\ &\mu\frac{\partial \boldsymbol{H}}{\partial t} + \operatorname{rot}\boldsymbol{E} = 0 \quad \text{in } (0,\infty)\times\mathbb{R}^3 \\ &\boldsymbol{E}(0,\cdot) = \boldsymbol{E}_0, \quad \boldsymbol{H}(0,\cdot) = \boldsymbol{H}_0 \quad \text{in } \mathbb{R}^3 \end{aligned} \qquad [5]$$

We assume that $\varepsilon$ and $\mu$ belong to $L_\infty(\mathbb{R}^3, \mathcal{L}_{\mathrm{sym}}(\mathbb{R}^3))$ and are uniformly positive definite, that is, we assume that there are $\varepsilon_0 > 0$ and $\mu_0 > 0$ such that

$$(\varepsilon(x)y|y) \geq \varepsilon_0|y|^2, \quad (\mu(x)y|y) \geq \mu_0|y|^2$$

for all $x, y \in \mathbb{R}^3$. Based on these assumptions we endow the space $L_2(\mathbb{R}^3) \times L_2(\mathbb{R}^3)$ with the inner product

$$((u_1,\, u_2)|(v_1,\, v_2)) := (\varepsilon u_1|v_1)_{L_2} + (\mu u_2|v_2)_{L_2}$$

for $(u_1, u_2), (v_1, v_2) \in L_2(\mathbb{R}^3) \times L_2(\mathbb{R}^3)$, and call this Hilbert space $E_0$. We further set

$$E_1 := \{(u_1, u_2) \in E_0; (\operatorname{rot} u_1, \operatorname{rot} u_2) \in E_0\}$$

Finally, given $\boldsymbol{u} = (u_1, u_2) \in E_1$, let

$$Au := \left(\varepsilon^{-1}\operatorname{rot} u_2, -\mu^{-1}\operatorname{rot} u_1\right)$$

It can be shown that i$A$ is self-adjoint in $E_0$. Hence, Stone's theorem ensures that $A$ generates a $C_0$-group of unitary operators in $\mathcal{L}(E_0)$. Therefore, given $(\boldsymbol{E}_0, \boldsymbol{H}_0) \in E_1$, there exists a unique solution $(\boldsymbol{E}(\cdot), \boldsymbol{H}(\cdot))$ of [5]. For this solution, the energy functional

$$E(t) = \frac{1}{2}\int_{\mathbb{R}^3}\left[(\varepsilon\boldsymbol{E}(t)|\boldsymbol{E}(t))_{\mathbb{R}^3} + (\mu\boldsymbol{H}(t)|\boldsymbol{H}(t))_{\mathbb{R}^3}\right]\mathrm{d}x$$

is constant on $[0, \infty)$.

### Autonomous Inhomogeneous Equations

Next, we study problem [1] in the case $A(t) = A$ for all $t \in [0, T)$. Throughout this section we assume that the following minimal hypotheses

1. $A$ generates a $C_0$-semigroup in $\mathcal{L}(E_0)$,
2. $f \in L_1((0,T), E_0)$, and
3. $u_0 \in E_0$

are satisfied. Later on we shall discuss several more restrictive assumptions on $(A, f, u_0)$. A function $u:[0,T] \to E_0$ is called a "(classical) solution" of

$$u'(t) = Au(t) + f(t), \quad t \in (0,T], \quad u(0) = u_0 \qquad [6]$$

iff $u \in C([0,T], E_0) \cap C^1((0,T], E_0)$, $u(t) \in D(A)$ for all $t \in (0,T]$, and $u$ satisfies [6] pointwise on $[0,T]$. It can be shown that [6] has at most one solution. If it has a solution, this solution is represented by the following variation-of-constant-formula:

$$u(t) = T(t)u_0 + \int_0^t T(t-s)f(s)\,\mathrm{d}s, \quad t \in [0,T] \qquad [7]$$

where $\{T(t); t \geq 0\}$ denotes the semigroup generated by $A$. Observe that the function $u:[0,T] \to E_0$, defined by [7], is continuous, but in general not differentiable on $(0,T]$. For this reason one calls [7] the "mild solution" of [6].

It is not difficult to see that if $u_0 \in D(A)$ and $f \in C^1([0,T], E_0)$, then the mild solution is a classical solution, that is, [6] is uniquely solvable in the classical sense. In application to nonlinear problems, the assumption $f \in C^1([0,T], E_0)$ is often too restrictive. Fortunately, in the case of generators of holomorphic semigroups, this assumption on $f$ can be weakened in two different directions. Let $\|x\|_A := \|x\|_{E_0} + \|Ax\|_{E_0}$ denote the graph norm on $D(A)$. Then the closedness of $A$ implies that $(D(A); \|\cdot\|_A)$ is a Banach space. In the following, we call this Banach space $E_1$. Moreover, given $\alpha \in (0,1)$, we write $E_\alpha = (E_0, E_1)_\alpha$ for the complex interpolation space between $E_0$ and $E_1$. Then we have the following result.

**Theorem 6** *Let $A$ generate a holomorphic $C_0$-semigroup in $\mathcal{L}(E_0)$ and assume that there is a constant $\alpha \in (0,1)$ such that*

$$f \in C^\alpha([0,T], E_0) + C([0,T], E_\alpha)$$

*Then, given $u_0 \in E_0$, the Cauchy problem [6] possesses a unique classical solution. It is given by*

$$u(t) = T(t)u_0 + \int_0^t T(t-s)f(s)\,\mathrm{d}s, \quad t \in [0,T]$$

*where $\{T(t); t \geq 0\}$ stands for the semigroup generated by $A$.*

In the following, we discuss an alternative approach to the Cauchy problem [6], which is based on the so-called theory of maximal regularity. There are several different types of results on maximal regularity, which we cannot discuss in full detail here. We decided to give a brief introduction to the theory of the so-called "maximal $L_p$-regularity." For further results on maximal regularity, we again draw the reader's attention to the "Further reading" section.

The Banach space $E_0$ is called an unconditionality of martingale "differences" (UMD) space if the Hilbert transform is bounded on $L_q(\mathbb{R}, E_0)$ for some $q \in (1,\infty)$. It is known that Hilbert spaces, the Lebesgue spaces $L_p(X, \mathrm{d}\mu)$ with $1 < p < \infty$ and with a $\sigma$-finite measure space $(X,\mu)$, and closed subspaces of UMD spaces are UMD spaces. Furthermore, UMD spaces are without exception reflexive. Thus, the spaces $L_1(X, \mathrm{d}\mu)$, $L_\infty(X, \mathrm{d}\mu)$, and spaces of continuous or Hölder continuous functions are not UMD spaces.

Next, assume that $-A$ generates a holomorphic $C_0$-semigroup in $\mathcal{L}(E_0)$ and that $[0,\infty) \subset \rho(-A)$. Then, it is known that, given $z \in \mathbb{C}$, the fractional power $A^z$ of $A$ is a densely defined closed operator in $E_0$. We say that $A$ has bounded imaginary powers (BIP) of angle $\theta \geq 0$ if there exist positive constants $M$ and $\varepsilon$ such that

$$A^{it} \in \mathcal{L}(E_0) \quad \text{and} \quad \|A^{it}\|_{\mathcal{L}(E_0)} \leq M \exp(\theta|t|) \quad t \in (-\varepsilon, \varepsilon) \qquad [8]$$

In order to have a neat notation, we write $A \in \mathrm{BIP}(\theta)$ if [8] holds true.

**Remarks 7** In the following, we assume that $-A$ generates a holomorphic $C_0$-semigroup in $\mathcal{L}(E_0)$ and that $[0,\infty) \subset \rho(-A)$.

(i) If $\mathrm{Re}\, z < 0$, then $A^z$ is bounded on $E_0$.
(ii) There are several representation formulas for the fractional powers of $A$. Among them we picked the following: if $\mathrm{Re}\, z \in (-1,1)$ and $x \in D(A)$, then

$$A^z x = \frac{\sin(\pi z)}{\pi z} \int_0^\infty s^z (s+A)^{-2} Ax\,\mathrm{d}s$$

(iii) Assume that $E_0$ is a Hilbert space, that $A$ is self-adjoint, and that there is a positive constant $\alpha$ such that $A \geq \alpha$. Further, let $\{E_A(\lambda) \in \mathbb{R}\}$ be the spectral resolution of $A$; then

$$A^z := \int_0^\infty \lambda^z\,\mathrm{d}E_A(\lambda), \quad z \in \mathbb{C}$$

Moreover, $A \in \mathrm{BIP}(0)$.
(iv) Let again $E_0$ be a Hilbert space and assume that $-A$ is $m$-dissipative and satisfies $0 \in \rho(A)$. Then $A \in \mathrm{BIP}(\pi/2)$.

Given $p \in (1,\infty)$, Sobolev's embedding theorem ensures that $W_p^1((0,T), E_0)$ is continuously injected into $C([0,T], E_0)$. Consequently, given any function $u \in W_p^1((0,T), E_0)$ and $t \in [0,T]$, the pointwise

evaluation $u(t)$ is well defined. In particular, the trace at 0 with respect to time

$$\mathrm{tr}: W_p^1((0,T),E_0) \to E_0, \quad u \mapsto u(0)$$

is a well-defined and bounded linear operator. In order to formulate the next result, let $E_{s,p} = (E_0, E_1)_{s,p}$, with $p \in (1,\infty)$ and $s \in (0,1)$, denote the real interpolation space between the basic space $E_0$ and $E_1$, the domain $D(A)$ of $A$, endowed with the graph norm. Furthermore, we set

$$\mathbb{E}_0 := L_p((0,T),E_0)$$
$$\mathbb{E}_1 := L_p((0,T),E_1) \cap W_p^1((0,T),E_0)$$

and we write $\mathrm{Isom}(E,F)$ for the set of all topological isomorphisms mapping the Banach space $E$ onto the Banach space $F$.

**Theorem 8** (Dore and Venni). *Suppose that $E_0$ is a UMD space and that $A \in \mathrm{BIP}(\theta)$ for some $\theta \in [0,\pi/2)$. Then, given $p \in (1,\infty)$, we have*

$$(\partial_t + A, \mathrm{tr}) \in \mathrm{Isom}(\mathbb{E}_1, \mathbb{E}_0 \times E_{1-1/p,p})$$

*This means that, given $(f,u_0) \in L_p((0,T),E_0) \times E_{1-1/p,p}$, there exists a unique solution $u \in L_p((0,T),E_1) \cap W_p^1((0,T),E_0)$ of the Cauchy problem [6]. Moreover, $u$ depends continuously on $(f,u_0)$ and fulfills the following* a priori *estimate*:

$$\|u\|_{\mathbb{E}_1} \le c(\|f\|_{\mathbb{E}_0} + \|u_0\|_{E_{1-1/p,p}})$$

*where* $c := \|(\partial_t + A, \mathrm{tr})^{-1}\|_{\mathcal{L}(\mathbb{E}_0 \times E_{1-1/p,p}, \mathbb{E}_1)}$.

## Nonautonomous Equations of Hyperbolic Type

According to Theorem 1 and the corresponding remark, it is reasonable to impose in the study of the Cauchy problem [1] the minimal hypothesis that, given $s \in [0,T]$, each individual operator $A(s)$ be the generator of a $C_0$-semigroup $\{T_s(t); t \ge 0\}$ in $\mathcal{L}(E_0)$. If this semigroup is holomorphic, we call [1] of "parabolic type." Otherwise the evolution equation [1] is said to be of "hyperbolic type."

A family $\{A(t); t \in [0,T]\}$ of generators of $C_0$-semigroups in $\mathcal{L}(E_0)$ is called "stable" iff there exist positive constants $M$ and $\omega$ such that $(\omega,\infty) \subset \rho(A(t))$ for all $\in [0,T]$ and such that

$$\left\| \prod_{j=1}^{k} (\lambda - A(t_j))^{-1} \right\| \le M(\lambda - \omega)^{-k} \quad \text{for } \lambda > \omega$$

and every finite sequence $0 \le t_1 \le t_2 \le \cdots t_k \le T$ with $k \in \mathbb{N}$. Observe that the resolvent operators $(\lambda - A(t_j))^{-1}$ do not commute in general. Therefore, the order of the terms on the left-hand side of the above estimate has to be obeyed. Assume that $\mathcal{A} = \{A(t); t \in [0,T]\}$ is a family of $m$-dissipative operators. Then, $\mathcal{A}$ is stable, since any $m$-dissipative operator $B$ satisfies the estimate $\|(\lambda - B)^{-1}\| \le 1/\lambda$ for all $\lambda > 0$.

It turns out that the stability of a family of generators is not sufficient to construct a solution of [1] even in the case $f \equiv 0$. We also need a certain time regularity of the mapping $t \mapsto A(t)$. For this we say that the family $\{A(t); t \in [0,T]\}$ has a common domain $D$ iff $D$ is a dense subspace of $E_0$ such that $D(A(t)) = D$ for all $t \in [0,T]$. The family $\{A(t); t \in [0,T]\}$ is called "strongly differentiable" iff it has a common domain $D$ and, given $v \in D$, the function $t \mapsto A(t)v$ belongs to $C^1([0,T],E_0)$.

We are now prepared to formulate the following result.

**Theorem 9** (Kato). *Let $\{A(t); t \in [0,T]\}$ be a stable and strongly differentiable family of generators of $C_0$-semigroups with common domain $D$. If $f \in C^1([0,T],E_0)$ and $u_0 \in D$ then [1] possesses a unique classical solution.*

The above result is based on the construction of an evolution operator $U(t,s)$, which can be considered as the generalization of the notion of a $C_0$-semigroup for autonomous equations to the case evolution equations of the form

$$u'(t) = A(t)u(t), \quad t \in (s,T], \quad u(s) = v$$

for fixed $s \in [0,T)$. Once an evolution operator is available, the solution of [1] is given by

$$u(t) = U(t,0)u_0 + \int_0^t U(t,s)f(s)\,\mathrm{d}s, \quad t \in [0,T]$$

Of course, this generalizes [7] and if $A(t)$ is independent of $t$, then $U(t,s) = T(t-s)$, where $\{T(t); t \ge 0\}$ is the semigroup generated by $A(0)$.

Furthermore, there are several extensions of the Kato's result. Among them the most interesting contributions are concerned to weaken the time regularity of $f$ and to weaken the assumption that $\{A(t); t \in [0,T]\}$ be strongly differentiable. In particular, it is possible to study [1] for families without a common domain.

For the construction of evolution operators as well as generalizations of Theorem 9, the reader is again referred to the "Further reading" section.

## Nonautonomous Equations of Parabolic Type

Throughout this section we assume that $E_0$ and $E_1$ are Banach spaces such that $E_1$ is dense and continuously injected in $E_0$. In the study of parabolic evolution equations, the class of all operators in $\mathcal{L}(E_1,E_0)$, considered as unbounded operators in $E_0$ with common domain $E_1$, which generate holomorphic $C_0$-semigroups in $\mathcal{L}(E_0)$ has turned out to

be very useful. In the following, we call this class $\mathcal{H}(E_1, E_0)$. It is known that $A \in \mathcal{H}(E_1, E_0)$ iff there exist constants $\omega > 0$ and $\kappa \geq 1$ such that $\omega - A \in \mathrm{Isom}(E_1, E_0)$ and such that

$$\kappa^{-1} \leq \frac{\|(\lambda - A)x\|_0}{|\lambda|\|x\|_0 + \|x\|_1} \leq \kappa$$
$$x \in E_1 \backslash \{0\}, \quad \mathrm{Re}\,\lambda \geq \omega$$

where $\|\cdot\|_j$ denotes the norm of $E_j$. Using the above characterization, it can be shown that $\mathcal{H}(E_1, E_0)$ is an open subset of $\mathcal{L}(E_1, E_0)$. In the following, we always endow $\mathcal{H}(E_1, E_0)$ with the topology induced by the norm of $\mathcal{L}(E_1, E_0)$. As a consequence of this convention it is meaningful to consider, for example, continuous mappings from $[0, T]$ into $\mathcal{H}(E_1, E_0)$. Observe that if $A \in C([0, T], \mathcal{H}(E_1, E_0))$, then $\mathcal{A} = \{A(t); t \in [0, T]\}$ is a family of generators of holomorphic semigroups with the common domain $E_1$. Then we have the following result.

**Theorem 10** (Sobolevskii, Tanabe). *Assume that there is a* $\rho \in (0, 1)$ *such that*

$$(A, f) \in C^\rho([0, T], \mathcal{H}(E_1, E_0) \times E_0)$$

*Then, given* $u_0 \in E_0$, *the Cauchy problem* [1] *possesses a unique classical solution u. This solution has the additional regularity*

$$u \in C^\rho((0, T], E_1) \cap C^{1+\rho}((0, T], E_0)$$

*Finally, if* $u_0 \in E_1$, *then* $u \in C^1([0, T], E_0)$.

As in the hyperbolic case, the proof of Theorem 10 is based on the evolution operator $U(t, s)$ for the homogeneous problem, although the constructions of the corresponding evolution operators are completely different.

In addition, there are several extensions and generalizations of Theorem 10. In particular, the assumption that the family $\{A(t); t \in [0, T]\}$ possesses a common domain can be weakened considerably. Furthermore, it is possible to look at parabolic evolution equations in the so-called interpolation and extrapolation scales. This offers a great flexibility in the study of nonlinear problems. Further details in this direction can be found in the "Further reading" section.

## Nonlinear Evolution Equations

Let $E_0, E_1$ be Banach spaces such that $E_1$ is dense and continuously embedded in $E_0$. Assume further that $u_0 \in E_1$ and that we are given a nonlinear operator $F \in C([0, T] \times V, E_0)$, where $V$ is an open neighborhood of $u_0$ in $E_1$. In this section, we will discuss the well-posedness of the Cauchy problem for the following nonlinear evolution equation

$$u'(t) = F(t, u(t)), \quad t \in (0, T], \quad u(0) = u_0 \qquad [9]$$

in the Banach space $E_0$. We will always assume that the nonlinear operator $F$ either carries a quasilinear structure or is of fully nonlinear parabolic type. By a "quasilinear structure," we mean that there is mapping $A \in C([0, T] \times V, \mathcal{L}(E_1, E_0))$ and a suitable "lower-order term" $f \in C([0, T] \times V, E_0)$ such that

$$F(t, v) = A(t, v)v + f(t, v)$$
$$\text{for all } (t, v) \in [0, T] \times V$$

Problem [9] is of fully nonlinear parabolic type if $F \in C^1([0, T] \times V, E_0)$ and if the Fréchet derivative $D_2F(0, u_0)$ of $F$ with respect to $v$ at $(0, u_0)$ belongs to the class $\mathcal{H}(E_1, E_0)$.

### Quasilinear Evolution Equations of Hyperbolic Type

Assume that $E_0$ is a reflexive Banach space and let $u_0 \in V \subset E_1$ be chosen as above. We consider the following abstract quasilinear evolution equation of hyperbolic type:

$$\begin{aligned} &u'(t) = A(t, u(t))u(t) + f(t, u(t)), \ t \in (0, T] \\ &u(0) = u_0 \end{aligned} \qquad [10]$$

and assume that the following hypotheses are satisfied:

$(H_1)$ $A \in C([0, T] \times V, \mathcal{L}(E_1, E_0))$ is bounded on bounded subsets of $V$ and, given $(t, v) \in [0, T] \times V$, the operator $A(t, v)$ is $m$-dissipative and there is a constant $\mu_A$ such that

$$\|A(t, v) - A(t, w)\|_{\mathcal{L}(E_1, E_0)} \leq \mu_A \|v - w\|_{E_0}$$

for all $t \in [0, T]$ and all $v, w \in V$.

$(H_2)$ There is a $Q \in \mathrm{Isom}(E_1, E_0)$ such that $QA(t, v)Q^{-1} = A(t, v) + B(t, v)$, where $B(t, v) \in \mathcal{L}(E_0)$ is bounded, uniformly on bounded subsets of $V$. Moreover,

$$\|B(t, v) - B(t, w)\|_{\mathcal{L}(E_0)} \leq \mu_B \|v - w\|_{E_1}$$

for all $t \in [0, T]$ and all $v, w \in V$.

$(H_3)$ $f \in C([0, T] \times V, E_1)$ is bounded on bounded subsets of $V$ and there are $\mu_0$ and $\mu_1$ such that

$$\|f(t, v) - f(t, w)\|_{E_j} \leq \mu_j \|v - w\|_{E_j}$$
$$\text{for all } v, w \in V, j \in \{0, 1\}$$

Then we have the following result.

**Theorem 11** (Kato). *Assume that* $(H_1)$, $(H_2)$, *and* $(H_3)$ *are satisfied. Then there is a maximal*

$t^+ \in (0, T]$, *depending only on* $\|u_0\|_{E_1}$, *and a unique solution* $u$ *to*[10] *such that*

$$u = u(\cdot, u_0) \in C([0, t^+), V) \cap C^1([0, t^+), E_0)$$

*Moreover, the mapping* $u_0 \mapsto u(\cdot, u_0)$ *is continuous from* $V$ *to* $C([0, t^+), V) \cap C^1([0, t^+), E_0)$.

There are many applications of Theorem 11 to different concrete partial differential equations (PDEs), including symmetric hyperbolic first-order systems, the Korteweg–de Vries equation, nonlinear elastodynamics, quasilinear wave equations, Navier–Stokes and Euler equations, and coupled Maxwell–Dirac equations. We decided to explain in some detail an application to the so-called periodic Camassa–Holm equation:

$$\begin{aligned} &u_t - u_{xxt} + 3uu_x = 2u_x u_{xx} + uu_{xxx} \\ &t > 0,\ x \in \mathbb{S}^1 \end{aligned} \qquad [11]$$

where $\mathbb{S}^1$ stands for the unit circle. In the above model, the function $u$ is the height of a unilinear water wave over a flat bottom.

Set $X := L_2(\mathbb{S}^1), V := H^1(\mathbb{S}^1)$, and $Q := (I - \partial_x^2)^{1/2}$. With $y := u - u_{xx}$, eqn [11] can be re-expressed as

$$y_t + (Q^{-2})y_x = -2y(Q^{-2}y)_x \quad \text{in } L_2(\mathbb{S}^1)$$

which is of type [10] with

$$A(y) = (Q^{-2}y)\partial_x, \quad f(y) = -2y(Q^{-2}y)_x, \quad y \in V$$

where $\mathrm{dom}(A(y)) := \{v \in L_2(\mathbb{S}^1); (Q^{-2}y)v \in H^1(\mathbb{S}^1)\}$.

### Quasilinear Evolution Equations of Parabolic Type

Assume that $E_0$ and $E_1$ are Banach spaces such that $E_1$ is dense and continuously injected in $E_0$. Moreover, let $(\cdot, \cdot)_0$ for each $\theta \in (0, 1)$ be an admissible interpolation functor (e.g., the real or complex interpolation functor) and set $E_\theta := (E_0, E_1)_\theta$ for $\theta \in (0, 1)$. Given a subset $X \subset E_\theta$ for some $\theta \in (0, 1)$, we set $X_\eta := X \cap E_\eta$ for $\eta \in [0, 1]$, equipped with the topology induced by $E_\eta$. Finally, we write $C^{1-}(M, N)$ for the class of all locally Lipschitz continuous functions mapping the metric space $M$ into the metric space $N$.

**Theorem 12** (Amann). *Suppose that* $0 < \gamma \le \beta < \alpha < 1$, *that* $X_\beta$ *is open in* $E_\beta$, *and that*

$$(A, f) \in C^{1-}([0, T] \times X_\beta, \mathcal{H}(E_1, E_0) \times E_\gamma)$$

*Then, given* $u_0 \in X_\alpha$, *there exists a unique maximal* $t^+ \in (0, T]$, *such that the quasilinear parabolic Cauchy problem*

$$u'(t) = A(t, u(t))u(t) + f(t, u(t)), \quad t \in (0, T], u(0) = u_0$$

*possesses a unique classical solution*

$$u := u(\cdot, u_0) \in C([0, t^+), X_\alpha) \cap C^1((0, t^+), E_0)$$

*Assume* $A$ *and* $f$ *are independent of* $t$ *and let* $u(\cdot, u_0)$ *be the solution to corresponding autonomous problem*

$$u'(t) = A(u(t))u(t) + f(u(t)), \quad t \in (0, \infty), u(0) = u_0$$

*Then the mapping* $(t, u_0) \mapsto u(t, u_0)$ *is a semiflow on* $X_\alpha$.

Due to its clarity and flexibility, Theorem 12 has found a plethora of applications, which we cannot discuss in detail here. Let us at least mention the following: reaction–diffusion systems, population dynamics, phase transition models, flows through porous media, Stefan problems, and nonlinear and dynamic boundary conditions in boundary-value problems. In addition, many geometric evolution equations fall into the scope of Theorem 12. Consider, for example, the volume-preserving gradient flow of the area functional of a compact hypersurface $M$ in $\mathbb{R}^{m+1}$ with respect to $L_2(M)$ and $W_2^{-1}(M)$, respectively. These flows are known as the averaged mean curvature flow and the surface diffusion flow, respectively, and have been investigated on the basis of Theorem 12.

### Fully Nonlinear Evolution Equations of Parabolic Type

Based on the theory of maximal regularity for linear evolution equations, it is possible to investigate abstract fully nonlinear parabolic problems of type [9]. As there are different techniques of maximal regularity, there are also different approaches to [9]. We present here a result which uses maximal regularity properties in singular Hölder spaces $C_\beta^\beta$. Let $E_0$ and $E_1$ be Banach spaces such that $E_1$ is continuously embedded into $E_0$ (density of $E_1$ in $E_0$ is not needed here). As before, $V$ is an open subset of $E_1$ and $D_2F$ stands for the Fréchet derivative of $F(t, v)$ with respect to the second variable.

**Theorem 13** (Lunardi). *Assume that* $F \in C^2([0, T] \times V, E_0)$ *such that* $D_2F \in C^1([0, T] \times V, \mathcal{H}(E_1, E_0))$. *Then, given* $u_0 \in V$, *there is a maximal* $t^+ \in (0, T]$ *such that problem* [9] *has a solution* $u \in C([0, t^+), E_1) \cap C^1([0, t^+), E_0)$. *This solution is unique in the class*

$$\bigcup_{0<\beta<1} C_\beta^\beta((0, t^+ - \varepsilon], E_1) \cap C([0, t^+ - \varepsilon], E_1)$$

*for each* $\varepsilon \in (0, t^+)$.

Theorem 13 has important applications to problems for which the hypotheses of Theorem 12 (in particular the assumption on the quasilinear structure) are not

satisfied. We mention here fully nonlinear second-order boundary-value problems, Hele–Shaw models, models from combustion theory, and Bellman equations.

# Exact Renormalization Group

**P K Mitter**, Université de Montpellier 2, Montpellier, France

## Introduction

The renormalization group (RG) in its modern form was invented by K G Wilson in the context of statistical mechanics and Euclidean quantum field theory (EQFT). It offers the deepest understanding of renormalization in quantum field theory (QFT) by connecting EQFT with the the theory of second-order phase transition and associated critical phenomena. Thermodynamic functions of many statistical mechanical models (the prototype being the Ising model in two or more dimensions) exhibit power-like singularities as the temperature approaches a critical value. One of the major triumphs of the Wilson RG was the prediction of the exponents (known as critical exponents) associated to these singularities. Wilson's fundamental contribution was to realize that many length scales begin to cooperate as one approaches criticality and that one should disentangle them and treat them one at a time. This leads to an iterative procedure known as the "renormalization group." Singularities and critical exponents then arise from a limiting process. Ultraviolet singularities of field theory can also be understood in the same way. Wilson reviews this (Wilson and Kogut 1974) and gives the historical genesis of his ideas (Wilson 1983).

The early work in the subject was heuristic, in the sense that clever but uncontrolled approximations were made to the exact equations often with much success. Subsequently, authors with mathematical bent began to use the underlying ideas to prove theorems. Benfatto, Cassandro, Gallavotti, Nicolo, Olivieri *et al.* pioneered the rigorous use of Wilson's renormalization group in the construction of super-renormalizable QFTs, (see Benfatto and Gallavotti (1995) and references therein). The subject saw further mathematical development in the work of Gawedzki and Kupiainen (1984, 1986) and that of Bałaban (1982), and references therein. Bałaban in a series of papers ending in Bałaban (1989) proved a basic result on the continuum limit of Wilson's lattice gauge theory. Brydges and Yau (1990) simplified the mathematical treatment of the renormalization group for a class of models and this has led to further systemization and simplification in the work of Brydges *et al.* (1998, 2003). Another method which has been intensely developed during the same historical period is based on phase cell expansions: Feldman, Magnen, Rivasseau, and Sénéor developed the early phase cell ideas of

Glimm and Jaffe and were able to prove independently many of the results cited earlier (see Rivasseau (1991) and references therein). Although these methods share many features of the Wilson RG, they are different in methodology and thus remain outside of the purview of the present exposition.

A somewhat different line of development has been the use of the RG to give simple proofs of perturbative renormalizability of various QFTs: Gallavotti and Nicolo, via iterative methods (see Benfatto and Gallavotti (1995) and references therein), and Polchinski (1984), who exploited a continuous version of the RG for which Wilson (1974) had derived a nonlinear differential equation. These early works were devoted to the standard $(\phi^4)_4$ scalar field theory, but subsequently Polchinski's work has been extended to a large class of models, including four-dimensional nonabelian gauge theories (*see* Kopper and Muller (2000) and references therein).

Finally, it should be mentioned that apart from QFT and statistical mechanics, the RG method has proved fruitful in other domains. An example is the study of interacting fermion systems in condensed matter physics (*see* Fermionic Systems and Renormalization: Statistical Mechanics and Condensed Matter). In the rest of this article, our focus will be on EQFT and statistical mechanics.

## The RG as a Discrete Semigroup

We will first define a discrete version of the RG and consider its continuous version later. As we will see, the RG is really a semigroup, so calling it a group is a misnomer.

Let $\phi$ be a Gaussian random field (see, e.g., Gelfand and Vilenkin (1964) for a discussion of random fields) in $\mathbf{R}^d$. Associated to it there is a positive-definite function which is identified as its covariance. In QFT one is interested in the covariance

$$E(\phi(x)\phi(y)) = \text{const.}\, |x-y|^{-2[\phi]} = \int_{\mathbf{R}^d} \mathrm{d}p\, \mathrm{e}^{ip.(x-y)} \frac{1}{|p|^{d-2[\phi]}} \qquad [1]$$

Here $[\phi] > 0$ is the (canonical) dimension of the field, which for the standard massless free field is $[\phi] = (d-2)/2$. The latter is positive for $d > 2$. However, other choices are possible but in EQFT they are restricted by the Osterwalder–Schrader positivity. It is assured if $[\phi] = (d-\alpha)/2$, with $0 < \alpha \leq 2$. If $\alpha < 2$, we get a generalized free field.

Observe that the covariance is singular for $x = y$ and this singularity is responsible for the ultraviolet divergences of QFT. This singularity has to be initially cut off and there are many ways to do this. A simple way is as follows. Let $u(x)$ be a smooth, rotationally invariant, positive-definite function of fast decrease. Examples of such functions are legion. Observe that

$$|x-y|^{-2\phi} = \text{const.}\int_0^\infty \frac{\mathrm{d}l}{l} l^{-2[\phi]}\, u\left(\frac{x-y}{l}\right) \qquad [2]$$

as can be seen by scaling in $l$. We define the unit ultraviolet cutoff covariance $C$ by cutting off at the lower end point of the $l$ integration (responsible for the singularity at $x = y$) at $l = 1$,

$$C(x-y) = \int_1^\infty \frac{\mathrm{d}l}{l} l^{-2[\phi]}\, u\left(\frac{x-y}{l}\right) \qquad [3]$$

$C(x-y)$ is positive-definite and everywhere smooth. Being positive-definite, it qualifies as the covariance of a Gaussian probability measure denoted $\mu_C$ on a function space $\Omega$ (which it is not necessary to specify any further). The covariance $C$ being smooth implies that the sample fields of the measure are $\mu_C$ almost everywhere sufficiently differentiable.

**Remark** Note that, more generally, we could have cut off the lower end point singularity in [1] at any $\epsilon > 0$. The $\epsilon$-cutoff covariance is related to the unit cutoff covariance by a scale transformation (defined below) and we will exploit this relation later.

Let $L > 1$ be any real number. We define a scale transformation $S_L$ on fields $\phi$ by

$$S_L\phi(x) = L^{-[\phi]}\,\phi\left(\frac{x}{L}\right) \qquad [4]$$

on covariances by

$$S_L C(x-y) = L^{-2[\phi]} C\left(\frac{x-y}{L}\right) \qquad [5]$$

and on functions of fields $F(\phi)$ by

$$S_L F(\phi) = F(S_L\phi) \qquad [6]$$

The scale transformations form a multiplicative group: $S_L^n = S_{L^n}$.

Now define a fluctuation covariance $\Gamma_L$:

$$\Gamma_L(x-y) = \int_1^L \frac{\mathrm{d}l}{l} l^{-2[\phi]}\, u\left(\frac{x-y}{l}\right) \qquad [7]$$

$\Gamma_L(x-y)$ is smooth, positive-definite and of fast decrease on scale $L$. It generates a key scaling decomposition

$$C(x-y) = \Gamma_L(x-y) + S_L C(x-y) \qquad [8]$$

Iterating this, we get

$$C(x-y) = \sum_{n=0}^{\infty} \Gamma_n(x-y) \qquad [9]$$

where

$$\Gamma_n(x-y) = S_{L^n}\Gamma_L(x-y) = L^{-2n[\phi]}\Gamma_L\left(\frac{x-y}{L^n}\right) \quad [10]$$

The functions $\Gamma_n(x-y)$ are of fast decrease on scale $L^{n+1}$.

Thus, [9] achieves the decomposition into a sum over increasing length scales as desired. Being positive definite, $\Gamma_n$ qualify as covariances of Gaussian probability measures, and therefore $\mu_C = \bigotimes_{n=0}^{\infty}\mu_{\Gamma_n}$. Correspondingly introduce a family of independent Gaussian random fields $\zeta_n$, called fluctuation fields, distributed according to $\mu_{\Gamma_n}$. Then

$$\phi = \sum_{n=0}^{\infty}\zeta_n \quad [11]$$

Note that the fluctuation fields $\zeta_n$ are slowly varying over length scales $L^n$. In fact, an easy estimate using a Tchebycheff inequality shows that, for any $\gamma > 0$,

$$|x-y| \le L^n \\ \Rightarrow \mu_C(|\zeta_n(x) - \zeta_n(y)| \ge \gamma) \le \text{const.}\,\gamma^{-2} \quad [12]$$

which reveals the slowly varying nature of $\zeta_n$ on scale $L^n$. Equation [11] is an example of a multiscale decomposition of a Gaussian random field.

The above implies that the $\mu_C$ integral of a function can be written as a multiple integral over the fields $\zeta_n$. We calculate it by integrating out the fluctuation fields $\zeta_n$ step by step, going from shorter to longer length scales. This can be accomplished by the iteration of a single transformation $T_L$, a renormalization group transformation, as follows. Let $F(\phi)$ be a function of fields. Then we define a RG transformation $F \to T_L F$ by

$$(T_L F)(\phi) = S_L\mu_{\Gamma_L} * F(\phi) \\ = \int d\mu_{\Gamma_L}(\zeta)\,F(\zeta + S_L\phi) \quad [13]$$

Thus the renormalization group transformation consists of a convolution with the fluctuation measure followed by a rescaling.

### Semigroup Property

The discrete RG transformations form a semigroup:

$$T_L T_{L^n} = T_{L^{n+1}} \quad \text{for all } n \ge 0 \quad [14]$$

To prove this, we must first see how scaling commutes with convolution with a measure. We have the property

$$\mu_{\Gamma_L} * S_L F = S_L\mu_{S_L\Gamma_L} * F \quad [15]$$

To see this, observe first that if $\zeta$ is a Gaussian random field distributed with covariance $\Gamma_L$ then the Gaussian field $S_L\zeta$ is distributed according to $S_L\Gamma_L$. This can be checked by computing the covariance of $S_L\zeta$. Now the left-hand side of [15] is just the integral of $F(S_L\zeta + S_L\phi)$ with respect to $d\mu_{\Gamma_L}(\zeta)$. By the previous observation, this is the integral of $F(\zeta + S_L\phi)$ with respect to $d\mu_{S_L\Gamma_L}(\zeta)$, and the latter is the right-hand side of [15]. Now we can check the semigroup property trivially:

$$\begin{aligned} T_L T_{L^n} F &= S_L\mu_{\Gamma_L} * S_{L^n}\mu_{\Gamma_{L^n}} * F \\ &= S_L S_{L^n}\mu_{S_{L^n}\Gamma_L} * \mu_{\Gamma_{L^n}} * F \\ &= S_{L^{n+1}}\mu_{\Gamma_{L^n}+S_{L^n}\Gamma_L} * F \\ &= S_{L^{n+1}}\mu_{\Gamma_{L^{n+1}}} * F \\ &= T_{L^{n+1}}F \end{aligned} \quad [16]$$

We have used the fact that $\Gamma_{L^n} + S_{L^n}\Gamma_L = \Gamma_{L^{n+1}}$. This is because $S_{L^n}\Gamma_L$ has the representation [7] with integration interval changed to $[L^n, L^{n+1}]$.

We note some properties of $T_L$. $T_L$ has an unique invariant measure, namely $\mu_C$: for any bounded function $F$,

$$\int d\mu_C\,T_L F = \int d\mu_C\,F \quad [17]$$

To understand [17], recall the earlier observation that if $\phi$ is distributed according to the covariance $C$, then $S_L\phi$ is distributed according to $S_L C$. By [8], $\Gamma_L + S_L C = C$. Therefore,

$$\begin{aligned} \int d\mu_C T_L F &= \int d\mu_C S_L\mu_{\Gamma_L} * F \\ &= \int d\mu_{S_L C}\mu_{\Gamma_L} * F \\ &= \int d\mu_C F \end{aligned} \quad [18]$$

The uniqueness of the invariant measure follows from the fact that the semigroup $T_L$ is realized by a convolution with a probability measure and, therefore, is positivity improving:

$$F \ge 0, \mu_C \text{ a.e.} \;\Rightarrow\; T_L F > 0, \mu_C \text{ a.e.}$$

Finally, note that $T_L$ is a contraction semigroup on $L^p(d\mu_C)$ for $1 \le p < \infty$. To see this, note that since $T_L$ is a convolution with a probability measure $T_L F = \mu_{S_{L^{-1}}\Gamma_L} * S_L F$, we have, via Hölder's inequality, $|T_L F|^p \le T_L|F|^p$. Then use the fact that $\mu_C$ is an invariant measure.

### Eigenfunctions

Let $:p_{n,m}:(\phi(x))$ be a $C$ Wick-ordered local monomial of $m$ fields with $n$ derivatives. Define

$$P_{n,m}(X) = \int_X dx : p_{n,m} :_C (x)$$

The functions $P_{n,m}(X)$ play the role of eigenfunctions of the RG transformation $T_L$ up to a scaling of volume:

$$T_L P_{n,m}(X) = L^{d-m[\phi]-n} P_{n,m}(L^{-1}X) \qquad [19]$$

Because of the scaling in volume, $P_{n,m}(X)$ are not true eigenfunctions. Nevertheless, they are very useful because they play an important role in the analysis of the evolution of the dynamical system which we will later associate with $T_L$. They are classified as expanding (relevant), contracting (irrelevant) or central (marginal), depending on whether the exponent of $L$ on the right-hand side of [19] is positive, negative, or zero, respectively. This depends, of course, on the space dimension $d$ and the field dimension $[\phi]$.

Gaussian measures are of limited interest. But we can create new measures by perturbing the Gaussian measure $\mu_C$ with local interactions. We cannot study directly the situation where the interactions are in infinite volume. Instead, we put them in a very large volume which will eventually go to infinity. We have a ratio of two length scales, one from the size of the diameter of the volume and the other from the ultraviolet cutoff in $\mu_C$, and this ratio is enormous. The RG is useful whenever there are two length scales whose ratio is very large. It permits us to do a scale-by-scale analysis and at each step the volume is reduced at the cost of changing the interactions. The largeness of the ratio is reflected in the large number of steps to be accomplished, this number tending eventually to infinity. This large number of steps has to be controlled mathematically.

### Perturbation of the Gaussian Measure

Let $\Lambda_N = [-L^N/2, L^N/2]^d \subset \mathbf{R}^d$ be a large cube in $\mathbf{R}^d$. For any $X \subset \Lambda_N$, let $V_0(X,\phi)$ be a local semibounded function where the fields are restricted to the set $X$. Here "local" means that if $X, Y$ are sets with disjoint interiors then $V_0(X \cup Y, \phi) = V_0(X) + V_0(Y)$. Consider the integral (known as the partition function in QFT and statistical mechanics)

$$Z(\Lambda_N) = \int \mathrm{d}\mu_C(\phi) z_0(\Lambda_N, \phi) \qquad [20]$$

where

$$z_0(X,\phi) = \mathrm{e}^{-V_0(X,\phi)} \qquad [21]$$

and

$$\mathrm{d}\mu^{(0)}(\Lambda_N,\phi) = \frac{1}{Z(\Lambda_N)} \mathrm{d}\mu_C(\phi) \mathrm{e}^{-V_0(\Lambda_N,\phi)} \qquad [22]$$

is the corresponding probability measure. $V_0$ is typically not quadratic in the fields and therefore leads to a non-Gaussian perturbation. For example,

$$V_0(X,\phi) = \int_X \mathrm{d}x (\xi |\nabla\phi(x)|^2 + g_0\phi^4(x) + \mu_0\phi^2(x)) \qquad [23]$$

where we take $g_0 > 0$. The integral [20] is well defined because the sample fields are smooth.

We now proceed to the scale-by-scale analysis mentioned earlier. Because $\mu_C$ is an invariant measure of $T_L$, we have the partition function $Z(\Lambda_N)$ in the volume $\Lambda_N$ as

$$Z(\Lambda_N) = \int \mathrm{d}\mu_C(\phi) z_0(\Lambda_N,\phi) = \int \mathrm{d}\mu_C(\phi) T_L z_0(\Lambda_N,\phi) \qquad [24]$$

The integrand on the right-hand side is a new function of fields which, because of the final scaling, live in the smaller volume $\Lambda_{N-1}$. This leads to the following definition:

$$z_1(\Lambda_{N-1},\phi) = T_L z_0(\Lambda_N,\phi) \qquad [25]$$

Because $V_0$ is local, $z_0$ has a factorization property for unions of sets with disjoint interiors. This is no longer the case for $z_1$. Wilson noted that, nevertheless, the integral is well approximated by an integrand which does, but the approximator has new coupling constants. The phrase "well approximated" is what all the rigorous work is about and this was not evident in the early Wilson era. The idea is to extract out a local part and also consider the remainder. The local part leads to a flow of coupling constants and the (unexponentiated) remainder is an irrelevant term. This operation and its mathematical control is an essential feature of RG analysis.

Iterating the above transformation, we get, for all $0 \le n \le N$,

$$z_{n+1}(\Lambda_{N-n-1},\phi) = T_L z_n(\Lambda_{N-n},\phi) \qquad [26]$$

After $N$ iterations, we get

$$Z(\Lambda_N) = \int \mathrm{d}\mu_C(\phi) z_N(\Lambda_0,\phi) \qquad [27]$$

where $\Lambda_0$ is the unit cube. To take the limit as $N \to \infty$, we have to control the infinite sequence of iterations. We cannot hope to control the infinite sequence at the level of the entire partition function. Instead, one chooses representative coordinates for which the infinite sequence has a chance of having a meaning. The coordinates are provided by the coupling constants of the extracted local part and the irrelevant terms (an

approximate calculation of the flow of coupling constants is given in the next section). The existence of a global trajectory for such coordinates helps us to control the limit for moments of the probability measure (correlation functions). The question of coordinates and the representation of the irrelevant terms will be taken up in the section "Rigorous RG analysis."

### Ultraviolet Cutoff Removal

The next issue is ultraviolet cutoff removal in field theory. This problem can be put into the earlier framework as follows. Let $\epsilon_N$ be a sequence of positive numbers which tend to 0 as $N \to \infty$. Following the remark after [3], we replace the unit cutoff covariance $C$ by the covariance $C_{\epsilon_N}$ defined by taking $\epsilon_N$ (instead of 1) as the lower end point in the integral [3]. Thus, $\epsilon_N$ acts as a short-distance or ultraviolet cutoff. It is easy to see that

$$C_{\epsilon_N}(x-y) = S_{\epsilon_N} C(x-y) \qquad [28]$$

Consider the partition function $Z_{\epsilon_N}(\Lambda)$ in a cube $\Lambda = [-R/2, R/2]^d$:

$$Z_{\epsilon_N}(\Lambda) = \int \mathrm{d}\mu_{C_{\epsilon_N}}(\phi) \mathrm{e}^{-V_0(\Lambda, \phi, \tilde{\xi}_N, \tilde{g}_N, \tilde{\mu}_N)} \qquad [29]$$

where $V_0$ is given by [23] with $g_0, \mu_0$ replaced by $\tilde{g}_N, \tilde{\mu}_N$, respectively. By dimensional analysis we can write

$$\begin{aligned} \tilde{\xi}_N &= \epsilon_N^{(2[\phi]-d+2)} \xi, \quad \tilde{g}_N = \epsilon_N^{(4[\phi]-d)} g, \\ \tilde{\mu}_N &= \epsilon_N^{(2[\phi]-d)} \mu \end{aligned} \qquad [30]$$

where $g, \xi, \mu$ are dimensionless parameters. Now $\phi$ distributed according to $C_{\epsilon_N}$ equals in distribution $S_{\epsilon_N}\phi$ distributed according to $C$. Therefore, choosing $\epsilon_N = L^{-N}$, we get

$$\begin{aligned} Z_{\epsilon_N}(\Lambda) &= \int \mathrm{d}\mu_C(\phi) \mathrm{e}^{-V_0(\Lambda, S_{\epsilon_N}\phi, \tilde{\xi}_N, \tilde{g}_N, \tilde{\mu}_N)} \\ &= \int \mathrm{d}\mu_C(\phi) \mathrm{e}^{-V_0(\Lambda_N, \phi, \xi g, \mu)} \end{aligned} \qquad [31]$$

where $\Lambda_N = [-L^N R/2, L^N R/2]^d$. Thus, the field theory problem of removing the ultraviolet cutoff, that is, taking the limit $\epsilon_N \to 0$, has been reduced to the study of a statistical mechanical model in a very large volume. The latter has to be analyzed via RG iterations as before.

### Critical Field Theories

As mentioned earlier, we have to study the flow of local interactions as well as that of irrelevant terms. Together they constitute the RG trajectory and we have to prove that it exists globally. In general, the trajectory will tend to explode after a large number of iterations due to growing relevant terms (characterized in terms of the expanding Wick monomials mentioned earlier). Wilson pointed out that the saving factor is to exploit fixed points and their invariant manifolds by tuning the initial interaction so that the RG has a global trajectory. This leads to the notion of a critical manifold which can be defined as follows. A fixed point will have contracting and/or marginal attractive directions besides the expanding ones. In the language of dynamical systems, the critical manifold is the stable or center stable manifold of the fixed point in question. This is determined by a detailed study of the discrete flow. In the examples above, it amounts to fixing the initial "mass" parameter $\mu_0 = \mu_c(g_0)$ with a suitable function $\mu_c$ such that the flow remains bounded in an invariant set. The critical manifold is then the graph of a function from the space of contracting and marginal variables to the space of $\mu$'s which remains invariant under the flow. Restricted to it the flow will now converge to a fixed point. All references to initial coupling constants have disappeared. The result is known as a critical theory.

Critical theories have been rigorously constructed in a number of cases. Take the standard $\phi^4$ in $d$ dimensions. Then $[\phi] = (d-2)/2$. For $d > 5$ the $\phi^4$ interaction is irrelevant and the Gaussian fixed point is attractive with one unstable direction (corresponding to $\mu$). In this case one can prove that the interactions converge exponentially fast to the Gaussian fixed point on the critical manifold. For $d = 4$ the interaction is marginal and the Gaussian fixed point attractive for $g > 0$. The critical theory has been constructed by Gawedzki and Kupainen (1984) starting with a sufficiently small coupling constant. The fixed point is Gaussian (interactions vanish in the limit) and the convergence rate is logarithmic. This is thus a mean-field theory with logarithmic corrections, as expected on heuristic grounds. The mathematical construction of the critical theory in $d = 3$ is an open problem. (It is expected to exist with a non-Gaussian fixed point, and this is indicated by the perturbative $\epsilon$ expansion of Wilson and Fisher in $4 - \epsilon$ dimensions.) However, the critical theory for $d = 3$ for $[\phi] = (3 - \epsilon)/4$ for $\epsilon > 0$ held very small has been rigorously constructed by Brydges *et al.* (2003). This theory has a nontrivial hyperbolic fixed point of $O(\epsilon)$. The stable manifold is constructed in a small neighborhood of the fixed point. Note that the covariance without cutoff is Osterwalder–Schrader positive and thus this is a candidate for a nontrivial EQFT. For $\epsilon = 1$ we have the standard situation in $d = 3$, and

this remains open, as mentioned earlier. A very simplified picture of the above is furnished by the perturbative computation in the next section.

### Unstable Fixed Points

We may attempt to construct field theories around unstable fixed points. In this case the initial parameters have to be adjusted as functions of the cutoff in such a way as to stabilize the flow in the neighborhood of the fixed point. This may be called a genuine renormalization. A famous example of this is pure Yang–Mills theory in $d=4$, where the Gaussian fixed point has only marginal unstable directions. Bałaban in a series of papers ending in Bałaban (1989) considered Wilson's lattice cutoff version of Yang–Mills theory in $d=4$ with initial coupling fixed by the two-loop asymptotic freedom formula. He proved, by lattice RG iterations, that in the weak-coupling regime the free energy per unit volume is bounded above and below by constants independent of the lattice spacing. Instability of the flow is expected to lead to mass generation for observables but this is a famous open problem. Another example is the standard nonlinear sigma model for $d=2$. Here too the flow is unstable around the Gaussian fixed point and we can set the initial coupling constant by the two-loop asymptotic freedom formula. Although much is known via approximation methods (as well as by methods based on integrable systems) this theory remains to be rigorously constructed as an EQFT.

Let us now consider a relatively simpler example, that of constructing a massive super-renormalizable scalar field theory. This has been studied in $d=3$, with $[\phi]=(d-2)/2=1/2$. We get $\xi=\tilde{\xi}, g=L^{-N}\tilde{g}, \mu=L^{-2N}\tilde{\mu}$, and $\tilde{g}$ is taken to be small. $\xi$ is marginal, whereas $g, \mu$ are relevant parameters and grow with the iterations. After $N$ iterations, they are brought up to $\tilde{g}, \tilde{\mu}$ together with remainders. This realizes the so-called massive continuum $\phi^4$ theory in $d=3$, and this has been mathematically controlled in the exact RG framework. This was proved by Brydges, Dimock, and Hurd and earlier by Benfatto, Cassandro, Gallavotti, and others, (see the references in Brydges *et al.* (1998) and Benfatto and Gallavotti (1995)).

## The Exact RG as a Continuous Semigroup

The discrete semigroup defined in [13] of the previous section has a natural continuous counterpart. Just take $L$ to be a continuous parameter, $L=e^t, t\geq 0$, and write by abuse of notation $T_t, S_t, \Gamma_t$ instead of $T_{e^t}$, etc. The continuous transformations $T_t$,

$$T_t F = S_t \mu_{\Gamma_t} * F \qquad [32]$$

give a semigroup

$$T_t T_s = T_{t+s} \qquad [33]$$

of contractions on $L^2(d\mu_C)$ with $\mu_C$ as invariant measure. One can show that $T_t$ is strongly continuous and, therefore, has a generator which we will call $\mathcal{L}$. This is defined by

$$\mathcal{L}F = \lim_{t\to 0^+} \frac{T_t - 1}{t} F \qquad [34]$$

whenever this limit exists. This restricts $F$ to a suitable subspace $\mathcal{D}(\mathcal{L}) \subset L^2(d\mu_C)$. $\mathcal{D}(\mathcal{L})$ contains, for example, polynomials in fields as well as twice-differentiable bounded cylindrical functions. The generator $\mathcal{L}$ can be easily computed. To state it, we need some definitions. Define $(D^n F)(\phi; f_1, \ldots, f_n)$ as the $n$th tangent map at $\phi$ along directions $f_1, \ldots, f_n$. The functional Laplacian $\Delta_{\dot{\Gamma}}$ is defined by

$$\Delta_{\dot{\Gamma}} F(\phi) = \int d\mu_{\dot{\Gamma}}(\zeta)(D^2F)(\phi;\zeta,\zeta) \qquad [35]$$

where $\dot{\Gamma}=u$. Define an infinitesimal dilatation operator

$$\mathcal{D}\phi(x) = x\cdot\nabla\phi(x) \qquad [36]$$

and a vector field $\mathcal{X}$,

$$\mathcal{X}F = -[\phi](DF)(\phi;\phi) - (DF)(\phi;\mathcal{D}\phi) \qquad [37]$$

Then, an easy computation gives

$$\mathcal{L} = \tfrac{1}{2}\Delta_{\dot{\Gamma}} + \mathcal{X} \qquad [38]$$

$T_t$ is a semigroup with $\mathcal{L}$ as generator. Therefore, $T_t = e^{t\mathcal{L}}$. Let $F_t(\phi)=T_tF(\phi)$. Then $F_t$ satisfies the linear PDE

$$\frac{\partial F_t}{\partial t} = \mathcal{L}F_t \qquad [39]$$

with the initial condition $F_0=F$. This evolution equation assumes a more familiar form if we write $F_t = e^{-V_t}$, $V_t$ being known as the effective potential. We get

$$\frac{\partial V_t}{\partial t} = \mathcal{L}V_t - \frac{1}{2}(V_t)_\phi\cdot(V_t)_\phi \qquad [40]$$

where

$$(V_t(\phi))_\phi\cdot(V_t(\phi))_\phi = \int d\mu_{\dot{\Gamma}}(\zeta)((DV_t)(\phi;\zeta))^2 \qquad [41]$$

and $V_0=V$. This infinite-dimensional nonlinear PDE is a version of Wilson's flow equation. Note that the linear semigroup $T_t$ acting on

functions induces a semigroup $\mathcal{R}_t$ acting nonlinearly on effective potentials giving a trajectory $V_t = \mathcal{R}_t V_0$.

Equations like the above are notoriously difficult to control rigorously, especially for large times. However, they may be solved in formal perturbation theory when the initial $V_0$ is small via the presence of small parameters. In particular, they give rise easily to perturbative flow equations for coupling constants. They can be obtained to any order but then there is the remainder. It is hard to control the remainder from the flow equation for effective potentials in bosonic field theories. They require other methods based on the discrete RG. Nevertheless, these approximate perturbative flows are very useful for getting a preliminary view of the flow. Moreover, their discrete versions figure as an input in further nonperturbative analysis.

### Perturbative Flow

It is instructive to see this in second-order perturbation theory. We will simplify by working in infinite volume (no infrared divergences can arise because $\dot{\Gamma}(x-y)$ is of fast decrease). Now suppose that we are in standard $\phi^4$ theory with $[\phi] = (d-2)/2$ and $d > 2$. We want to show that

$$V_t = \int \mathrm{d}x \Big( \xi_t : |\nabla\phi(x)|^2 : + g_t : \phi(x)^4 : + \mu_t : \phi(x)^2 : \Big) \qquad [42]$$

satisfies the flow equation in second order modulo irrelevant terms provided the parameters flow correctly. We will ignore field-independent terms. The Wick ordering is with respect to the covariance $C$ of the invariant measure. The reader will notice that we have ignored a $\phi^6$ term which is actually relevant in $d=3$ for the above choice of $[\phi]$. This is because we will only discuss the $d=3$ case for the model discussed at the end of this section and for this case the $\phi^6$ term is irrelevant. We will assume that $\xi_t, \mu_t$ are of order $O(g^2)$. Plug in the above in the flow equation. The quantity $\lambda_t^{n,m}{:}P_{n,m}{:}$ represents one of the terms above with $m$ fields and $n$ derivatives. Because $\mathcal{L}$ is the generator of the semigroup $T_t$ we have

$$\left(\frac{\partial}{\partial t} - \mathcal{L}\right)\lambda_t^{n,m} : P_{n,m} : = \left(\frac{\mathrm{d}\lambda_t^{n,m}}{\mathrm{d}t} - (d - m[\phi] - n)\lambda_t^{n,m}\right) : P_{n,m} : \qquad [43]$$

Next turn to the nonlinear term in the flow equation and insert the $\phi^4$ term (the others are already of order $O(g^2)$). This produces a double integral of $\dot{\Gamma}(x-y){:}\phi(x)^3{:}{:}\phi(y)^3{:}$, which after complete Wick ordering, gives

$$-\frac{g_t^2}{2} 16 \int \mathrm{d}x\,\mathrm{d}y\,\dot{\Gamma}(x-y)\Big( : \phi(x)^3\phi(y)^3 : + 9C(x-y) : \phi(x)^2\phi(y)^2 : + 36C(x-y) : \phi(x)\phi(y) : + 6C(x-y)^2 \Big) \qquad [44]$$

Consider the nonlocal $\phi^4$ term. We can localize it by writing

$$: \phi(x)^2\phi(y)^2 : = \tfrac{1}{2} : \Big( \phi(x)^4 + \phi(y)^4 - \big(\phi(x)^2 - \phi(y)^2\big)^2 \Big) : \qquad [45]$$

The local part gives a $\phi^4$ contribution and the last term above gives rise to an irrelevant contribution because it produces additional derivatives. The coefficients are well defined because $C, \dot{\Gamma}$ are smooth and $\dot{\Gamma}(x-y)$ is of fast decrease. Now the nonlocal $\phi^2$ term is similarly localized. It gives a relevant local $\phi^2$ contribution as well as a marginal $|\nabla\phi|^2$ contribution. Finally, the same principle applies to the nonlocal $\phi^6$ contribution and gives rise to further irrelevant terms. Then it is easy to see by matching that the flow equation is satisfied in second order up to irrelevant terms (these would have to be compensated by adding additional terms in $V_t$) provided

$$\begin{aligned} \frac{\mathrm{d}g_t}{\mathrm{d}t} &= (4-d)g_t - a g_t^2 + O\big(g_t^3\big) \\ \frac{\mathrm{d}\mu_t}{\mathrm{d}t} &= 2\mu_t - b g_t^2 + O\big(g_t^3\big) \\ \frac{\mathrm{d}\xi_t}{\mathrm{d}t} &= c g_t^2 + O\big(g_t^3\big) \end{aligned} \qquad [46]$$

where $a, b, c$ are positive constants. We see from the above formulas that, up to second order in $g^2$, as $t \to \infty, g_t \to 0$ for $d \geq 4$. In fact, for $d \geq 5$ the decay rate is $O(\mathrm{e}^{-t})$ and for $d=4$ the rate is $O(t^{-1})$. However, to see if $V_t$ converges, we also have to discuss the $\mu_t, \xi_t$ flows. It is clear that in general the $\mu_t$ flow will diverge. This is fixed by choosing the initial $\mu_0$ to be the bare critical mass. This is obtained by integrating up to time $t$ and then expressing $\mu_0$ as a function of the entire $g$ trajectory up to time $t$. Assume that $\mu_t$ is uniformly bounded and take $t \to \infty$. This gives the critical mass as

$$\mu_0 = b\int_0^\infty \mathrm{d}s\, \mathrm{e}^{-2s} g_s^2 = \mu_c(g_0) \qquad [47]$$

This integral converges for all cases discussed above. With this choice of $\mu_0$ we get

$$\mu_t = b\int_0^\infty \mathrm{d}s\, \mathrm{e}^{-2s} g_{s+t}^2 \qquad [48]$$

and this exists for all $t$ and converges as $t \to \infty$. Now consider the perturbative $\xi$ flow. It is easy to see from the above that for $d \geq 4, \xi_t$ converges as $t \to \infty$.

We have not discussed the $d=3$ case because the perturbative $g$ fixed point is of order $O(1)$. But suppose we take, in the $d=3$ case, $[\phi]=(3-\epsilon)/4$ with $\epsilon > 0$ held small as in Brydges *et al.* (2003). Then the above perturbative flow equations are easily modified (by taking account of [43]) and we get, to second order, an attractive fixed point $g_* = O(\epsilon)$ of the $g$ flow. The critical bare mass $\mu_0$ can be determined as before and the $\xi_t$ flow converges. The qualitative picture obtained above has a rigorous justification.

## Rigorous RG Analysis

We will give a brief introduction to rigorous RG analysis in the discrete setup in the section "The RG as a Discrete Semigroup" concentrating on the principal problems encountered and how one attempts to solve them. Our approach is borrowed from Brydges *et al.* (2003). It is a simplification of the methods initiated by Brydges and Yau in (1990) and developed further by Brydges *et al.* (1998). The reader will find other approaches to rigorous RG methods in the selected references, such as those of Bałaban, Gawedzki and Kupiainen, Gallavotti, and others. We will take as a concrete example the scalar field model introduced earlier.

At the core of the analysis is the choice of good coordinates for the partition function density, $z$, of the section "The RG as a Discrete Semigroup". This is provided by a polymer representation (defined below) which parametrizes $z$ by a couple $(V, K)$, where $V$ is a local potential and $K$ is a set function also depending on the fields. Then the RG transformation $T_L$ maps $(V, K)$ to a new $(V, K)$. $(V, K)$ remain good coordinates as the volume tends to $\infty$, whereas $z$(volume) diverges. There exist norms which are suited to the fixed-point analysis of $(V, K)$ to new $(V, K)$. Now comes the important point: $z$ does not uniquely specify the representation $(V, K)$. Therefore, we can take advantage of this nonuniqueness to keep $K$ small in norm and let most of the action of $T_L$ reside in $V$. This process is called extraction in Brydges *et al.* (2003). It makes sure that $K$ is an irrelevant term, whereas the local flow of $V$ gives rise to discrete flow equations in coupling constants. We will not discuss extraction any further. In the following, we introduce the polymer representation and explain how the RG transformation acts on it.

To proceed further, we first introduce a simplification in the setup used in the section "The RG as a Discrete Semigroup." Recall that the function $u$ introduced in [3] was smooth, positive definite, and of rapid decrease. We will simplify further by imposing the stronger property that it is actually of finite range: $u(x)=0$ for $|x| \geq 1$. We say that $u$ is of finite range 1. It is easy to construct such functions. For example, if $g$ is any smooth function of finite range 1/2, then $u = g * g$ is a smooth positive-definite function of finite range 1. This implies that the fluctuation covariance $\Gamma_L$ of [7] has finite range $L$. As a result, $\Gamma_n$ in [10] has finite range $L^{n+1}$ and the corresponding fluctuation fields $\zeta_n(x)$ and $\zeta_n(y)$ are independent when $|x-y| \geq L^{n+1}$.

### Polymer Representation

Pave $\mathbf{R}^d$ with closed cubes of side length 1 called 1-blocks or unit blocks denoted by $\Delta$, and suppose that $\Lambda$ is a large cube consisting of unit blocks. A connected polymer $X \subset \Lambda$ is a closed connected subset of these unit blocks. A polymer activity $K(X, \phi)$ is a map $X, \phi \to \mathbf{R}$ where the fields $\phi$ depend only on the points of $X$. We will set $K(X, \phi)=0$ if $X$ is not connected. A generic form of the partition function density $z(\Lambda, \phi)$ after a certain number of RG iterations is

$$z(\Lambda) = \sum_{N=0}^{\infty} \frac{1}{N!} \sum_{X_1, \ldots, X_N} e^{-V(X_c)} \prod_{j=1}^{N} K(X_j) \qquad [49]$$

Here $X_j \subset \Lambda$ are disjoint polymers, $X = \bigcup X_j$, and $X_c = \Lambda \backslash X$. $V$ is a local potential of the form [23] with parameters $\xi, g, \mu$. We have suppressed the $\phi$-dependence. Initially, the activities $K_j = 0$, but they will arise under RG iterations and the form [49] remains stable, as we will see. The partition function density is thus parametrized as a couple $(V, K)$.

### Norms for Polymer Activities

Polymer activities $K(X, \phi)$ are endowed with a norm $\|K(X)\|$, which must satisfy two properties:

$$\dot{X} \cap \dot{Y} = 0 \Rightarrow \|K_1(X) K_2(Y)\| \leq \|K_1(X)\| \, \|K_1(Y)\|$$
$$\|T_L K(X)\| \leq c^{|X|} \|K(X)\| \qquad [50]$$

where $\dot{X}$ is the interior of $X$ and $|X|$ is the number of blocks in $X$. $c$ is a constant of order $O(1)$. The norm measures (Fréchét) differentiability properties of the activity $K(X, \phi)$ with respect to the field $\phi$ as well as its admissible growth in $\phi$. The growth is admissible if it is $\mu_C$ integrable. The second property above ensures the stability of the norm under RG iteration. For a fixed polymer $X$, the norm is such that it gives rise to a Banach

space of activities $K(X)$. The final norm $\|\cdot\|_{\mathcal{A}}$ incorporates the previous one and washes out the set dependence,

$$\|K\|_{\mathcal{A}} = \sup_{\Delta} \sum_{X \supset \Delta} A(X) \, \|K(X)\| \qquad [51]$$

where $A(X) = L^{(d+2)|X|}$. This norm essentially ensures that large polymers have small activities. The details of the above norms can be found in Brydges *et al.* (2003).

The RG operation map $f$ is a composition of two maps. The RG iteration map $z \to T_L z$ induces a map $V \to \tilde{V}'_L$ and a nonlinear map $\tilde{T}_L : K \to \tilde{K} = \tilde{T}_L(K)$. We then compose this with a (nonlinear) extraction map $\mathcal{E}$ which takes out the expanding (relevant) parts of $\tilde{K} \to \mathcal{E}(\tilde{K}) = K'$ and compensates the local potential $\tilde{V}'_L \to V'$ such that $T_L z$ remains invariant. We denote by $f$ the composition of these two maps with

$$V \to V' = f_V(V, K), \quad K \to K' = f_K(V, K) \qquad [52]$$

### The Map $\tilde{T}_L$

Consider applying the RG map $T_L$ to [49]. The map consists of a convolution $\mu_{\Gamma_L} *$ followed by the rescaling $S_L$. In the integration over the fluctuation field $\zeta$, we will exploit the independence of $\zeta(x)$ and $\zeta(y)$ when $|x - y| \geq L$. To do this, we pave $\Lambda$ by closed blocks of side $L$, called $L$-blocks, so that each $L$-block is a union of 1-blocks. Let $\bar{X}^L$ be the $L$-closure of a set $X$, namely the smallest union of $L$-blocks containing $X$. The polymers will be combined into $L$-polymers which are, by definition, connected unions of $L$ blocks. The combination is performed in such a way that the new polymers are associated to independent functionals of $\zeta$.

Let $\tilde{V}(X, \phi))$, to be chosen later, be a local potential independent of $\zeta$. For a coupling constant sufficiently small, there is a bound

$$\|e^{-V(Y)}\| \leq 2^{|Y|} \qquad [53]$$

We assume that $\tilde{V}$ is so chosen that the same bound holds when $V$ is replaced by $\tilde{V}$. Define

$$P(\Delta, \zeta, \phi) = e^{-V(\Delta, \zeta+\phi)} - e^{-\tilde{V}(\Delta, \phi)} \qquad [54]$$

Then we have

$$\begin{aligned} e^{-V(X_c, \zeta+\phi)} &= e^{-V(\bar{X}_c, \zeta+\phi)} \\ &= \prod_{\Delta \subset \bar{X}_c} (e^{-\tilde{V}(\Delta, \phi)} + P(\Delta, \zeta, \phi)) \end{aligned} \qquad [55]$$

where $\bar{X}_c$ is the closure of $X_c$. Expand out the product and insert into the representation [49] for $z(\Lambda, \zeta + \phi))$. We then rewrite the resulting sum in terms of $L$-polymers. The sum splits into a sum over connected components. Define, for every connected $L$-polymer $Y$,

$$\begin{aligned} \mathcal{B}K(Y) = &\sum_{N+M \geq 1} \frac{1}{N!M!} \\ &\times \sum_{(X_j),(\Delta_i) \to Y} e^{-\tilde{V}(X_0)} \prod_{j=1}^{N} K(X_j) \prod_{i=1}^{M} P(\Delta_i) \end{aligned} \qquad [56]$$

where $X_0 = Y \backslash (\cup X_j) \cup (\cup \Delta_j)$ and the sum over the distinct $\Delta_i$, and disjoint 1-polymers $X_j$ is such that their $L$-closure is $Y$. Equation [49] now becomes

$$z(\Lambda) = \sum \frac{1}{N!} \sum_{Y_1, \ldots, Y_N} e^{-\tilde{V}(Y_c)} \prod_{j=1}^{N} \mathcal{B}K(Y_j) \qquad [57]$$

where the sum is over disjoint, connected closed $L$-polymers. We now perform the fluctuation integration over $\zeta$ followed by the rescaling. Now $\tilde{V}(Y_c)$ is independent of $\zeta$. The $\zeta$-integration sails through and then factorizes because the $Y_j$, being disjoint closed $L$-polymers, are separated from each other by a distance $\geq L$. The rescaling brings us back to 1-polymers and reduces the volume from $\Lambda$ to $L^{-1}\Lambda$. Therefore,

$$\begin{aligned} z'(L^{-1}\Lambda) &= T_L z(\Lambda) \\ &= \sum \frac{1}{N!} \sum_{X_1, \ldots, X_N} e^{-\tilde{V}_L(X_c)} \prod_{j=1}^{N} (T_L \mathcal{B}K)(X_j) \end{aligned} \qquad [58]$$

where the sum is over disjoint 1-polymers, $X_c = L^{-1}\Lambda \backslash X$. By definition $\tilde{V}_L(\Delta) = S_L \tilde{V}(L\Delta)$ and $(T_L \mathcal{B}K)(Z) = S_L \mu_{\Gamma_L} * \mathcal{B}K(LZ)$. This shows that the representation [49] is stable under iteration and, furthermore, gives us the map

$$\begin{aligned} &V \to \tilde{V}_L \\ &K \to \tilde{K} = \tilde{T}_L(K) = T_L \mathcal{B}K \end{aligned} \qquad [59]$$

The norm boundedness of $K$ implies that $\tilde{T}_L(K)$ is norm bounded. We see from the above that a variation in the choice of $\tilde{V}$ is reflected in the corresponding variation of $\tilde{K}$. The extraction map $\mathcal{E}$ now takes out from $\tilde{K}$ the expanding parts and then compensates it by a change of $\tilde{V}_L$ in such a way that the representation [58] is left invariant by the simultaneous replacement $\tilde{V}_L \to V', \tilde{K} \to K' = \mathcal{E}(\tilde{K})$. The extraction map is nonlinear. Its linearization is a subtraction operation and this dominates in norm the nonlinearities, (Brydges *et al.* 1998).

The map $V \to \tilde{V}_L \to V'$ leads to a discrete flow of the coupling constants in $V$. It is convenient to write $K = K^{\mathrm{pert}} + R$, where $R$ is the remainder. Then the coupling constant flow is a discrete version of the

continuous flows encountered in the last section, together with remainders which are controlled by the size of $R$. In addition, we have the flow of $K$. The discrete flow of the pair (coupling constants, $K$) can be studied in a Banach space norm. Once one proves that the nonlinear parts satisfy a Lipshitz property, the discrete flow can be analyzed by the methods of stable-manifold theory of dynamical systems in a Banach space context. The reader is referred to the article by Brydges *et al.* (2003) for details of the extraction map and the application of stable-manifold theory in the construction of a global RG trajectory.

## Further Topics

### Lattice RG Methods

Statistical mechanical systems are often defined on a lattice. Moreover, the lattice provides an ultraviolet cutoff for Euclidean field theory compatible with Osterwalder–Schrader positivity. The standard lattice RG is based on Kadanoff–Wilson block spins. Its mathematical theory and applications have been developed by Bałaban, and Gawedzki and Kupiainen (see Gawedzki and Kupiainen (1986) and references therein). This leads to multiscale decompositions of the Gaussian lattice field as a sum of independent fluctuation fields on increasing length scales. Brydges *et al.* (2004) have shown that standard Gaussian lattice fields have multiscale decompositions as a sum of independent fluctuation fields with the finite-range property introduced in the last section. This permits the development of rigorous lattice RG theory in the spirit of the continuum framework of the previous section.

### Fermionic Field Theories

Field theories of interacting fermions are often simpler to handle than bosonic field theories. Because of statistics, fermion fields are bounded and perturbation series converges in finite volume in the presence of an ultraviolet cutoff. The notion of studying the RG flow at the level of effective potentials makes sense. At any given scale, there is always an ultraviolet cutoff and the fluctuation covariance being of fast decrease provides an infrared cutoff. This is illustrated by the work of Gawedzki and Kupiainen (1985), who gave a nonperturbative construction in the weak effective coupling regime of the RG trajectory for the Gross–Neveu model in two dimensions. This is an example of a model with an unstable Gaussian fixed point where the initial coupling has to be adjusted as a function of the ultraviolet cutoff consistent with ultraviolet asymptotic freedom so as to stabilize the flow.

## Falicov–Kimball Model

**Ch Gruber**, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland
**D Ueltschi**, University of Arizona, Tucson, AZ, USA

### A Brief History

The "Falicov–Kimball model" was first considered by Hubbard and Gutzwiller during 1963–65 as a simplification of the Hubbard model. In 1969, Falicov and Kimball introduced a model that included a few extra complications, in order to investigate metal–insulator phase transitions in rare-earth materials and transition-metal compounds (Falicov and Kimball 1969). Experimental data suggested that this transition is due to the interactions between electrons in two electronic states: nonlocalized states (itinerant electrons), and states that are localized around the sites corresponding to the metallic ions of the crystal (static electrons).

A tight-binding approximation leads to a model defined on a lattice (the crystal) and two species of particles are considered. The first species consists of spinless quantum fermions (we refer to them as "electrons"), and the second species consists of localized holes or electrons ("classical particles"). Electrons hop between nearest-neighbor sites but classical particles do not. Both species obey Fermi statistics (in particular, the Pauli exclusion principle prevents more than one particle of a given species to occupy the same site). Interactions are on-site and thus involve particles of different species; they can be repulsive or attractive.

The very simplicity of the model allows for a broad range of applications. It was studied in the context of mixed valence systems, binary alloys, and crystal formation. Adding a magnetic field yields the flux phase problem. The Falicov–Kimball model can also be viewed as the simplest model where quantum particles interact with classical fields.

The fifteen years following the introduction of the model saw studies based on approximate methods, such as Green's function techniques, that gave rise to a lot of confusion. A breakthrough occurred in 1986 when Brandt and Schmidt, and Kennedy and Lieb, proposed the first rigorous results. In particular, Kennedy and Lieb showed in their beautiful paper that the electrons create an effective interaction between the classical particles and that a phase transition takes place for any value of the coupling constant, provided the temperature is low enough.

Many studies by mathematical physicists followed and several results are presented in this short survey. Recent years have seen an increasing interest from condensed matter physicists. We encourage interested readers to consult the reviews by Freericks and Zlatić (2003), Gruber and Macris (1996), and Jędrzejewski and Lemánski (2001).

### Mathematical Setting

#### Definitions

Let $\Lambda \subset \mathbb{Z}^d$ denote a finite cubic box. The configuration space for the classical particles is

$$\Omega_\Lambda = \{0,1\}^\Lambda = \{\omega = (\omega_x) : x \in \Lambda, \text{ and } \omega_x = 0,1\}$$

where $\omega_x = 0$ or 1 denotes the absence or presence of a classical particle at the site $x$. The total number of classical particles is $N_c(\omega) = \sum_{x\in\Lambda} \omega_x$. The Hilbert space for the spinless quantum particles ("electrons") is the usual fermionic Fock space

$$\mathcal{F}_\Lambda = \bigoplus_{N=0}^{|\Lambda|} \mathcal{H}_{\Lambda,N}$$

where $\mathcal{H}_{\Lambda,N}$ is the Hilbert space of square summable, antisymmetric, complex functions $\Psi = \Psi(x_1, \ldots, x_N)$ of $N$ variables $x_i \in \Lambda$. Let $a_x^\dagger$ and $a_x$ denote the standard creation and annihilation operators of an electron at $x$; recall that they satisfy the anticommutation relations

$$\{a_x, a_y\} = 0, \qquad \{a_x^\dagger, a_y^\dagger\} = 0, \qquad \{a_x, a_y^\dagger\} = \delta_{xy}$$

The Hamiltonian for the Falicov–Kimball model is an operator on $\mathcal{F}_\Lambda$ that depends on the configurations of classical particles. Namely, for $\omega \in \Omega_\Lambda$, we define

$$H_\Lambda(\omega) = -\sum_{\substack{x,y\in\Lambda \\ |x-y|=1}} a_x^\dagger a_y - U \sum_{x\in\Lambda} \omega_x a_x^\dagger a_x$$

The first term represents the kinetic energy of the electrons. The second term represents the on-site attraction ($U > 0$) or repulsion ($U < 0$) between electrons and classical particles.

The Falicov–Kimball Hamiltonian can be written with the help of a one-body Hamiltonian $h_\Lambda$, which is an operator on the Hilbert space for a single electron $\ell^2(\Lambda)$. Indeed, we have

$$H_\Lambda(\omega) = \sum_{x,y\in\Lambda} h_{xy}(\omega) a_x^\dagger a_y$$

The matrix $h_\Lambda(\omega) = (h_{xy}(\omega))$ is the sum of a hopping matrix (adjacency matrix) $t_\Lambda$, and of a matrix $v_\Lambda(\omega)$ that represents an external potential due to the classical particles. Namely, we have

$$h_{xy}(\omega) = -t_{xy} - U\omega_x\delta_{xy}$$

where $t_{xy}$ is one if $x$ and $y$ are nearest neighbors, and is zero otherwise. The spectrum of $t_\Lambda$ lies in $(-2d, 2d)$, and the eigenvalues of $v_\Lambda(\omega)$ are $-U$ (with degeneracy $N_c(\omega)$) and 0 (with degeneracy $|\Lambda| - N_c(\omega)$). Denoting $\lambda_j(A)$ the eigenvalues of a matrix $A$, it follows from the minimax principle that

$$\lambda_j(A) - \|B\| \le \lambda_j(A+B) \le \lambda_j(A) + \|B\|$$

Let $\lambda_1(\omega) \le \lambda_2(\omega) \le \cdots \le \lambda_{|\Lambda|}(\omega)$ be the eigenvalues of $h_\Lambda(\omega)$. Choosing $A = v_\Lambda(\omega)$ and $B = t_\Lambda$ in the inequality above, we find that for $U > 0$,

$$-U - 2d < \lambda_j(\omega) < -U + 2d \quad \text{for } j = 1, \ldots, N_c(\omega)$$
$$-2d < \lambda_j(\omega) < 2d \quad \text{for } j = N_c(\omega) + 1, \ldots, |\Lambda|$$

In particular, for any configuration $\omega$ and any $\Lambda$,

$$\operatorname{Spec} h_\Lambda(\omega) \subset (-U - 2d, -U + 2d) \cup (-2d, 2d)$$

Thus, for $U > 4d$, the spectrum of $h_\Lambda(\omega)$ has the "universal" gap $(-U + 2d, -2d)$. A similar property holds for $U < -4d$.

## Canonical Ensemble

A fruitful approach towards understanding the behavior of the Falicov–Kimball model is to first fix the configuration of the classical particles, and then to introduce the ground-state energy $E_\Lambda(N_e, \omega)$ as the lowest eigenvalue of $H_\Lambda(\omega)$ in the subspace $\mathcal{H}_{\Lambda, N_e}$:

$$E_\Lambda(N_e, \omega) = \inf_{\Psi\in\mathcal{H}_{\Lambda,N_e}, \|\Psi\|=1} \langle\Psi|H_\Lambda(\omega)|\Psi\rangle = \sum_{j=1}^{N_e} \lambda_j(\omega)$$

A typical problem is to find the set of ground-state configurations, that is, the set of configurations that minimize $E_\Lambda(N_e, \omega)$ for given $N_e$ and $N_c = N_c(\omega)$.

In the case $U > 4d$ and $N_e = N_c(\omega)$, the ground-state energy $E_\Lambda(N_c(\omega), \omega)$ has a convergent expansion in powers of $U^{-1}$:

$$E_\Lambda(N_c(\omega), \omega) = -UN_c(\omega) + \sum_{k\ge2} \frac{1}{kU^{k-1}} \times \sum_{\substack{x_1,\ldots,x_k \in \Lambda \\ |x_i - x_{i-1}| = 1 \\ 0 < m(\{x_i\}) < k}} (-1)^{m(\{x_i\})} \binom{k-2}{m(\{x_i\}) - 1} \qquad [1]$$

where $m(x_1, \ldots, x_k)$ is the number of sites $x_i$ with $\omega_{x_i} = 0$. The last sum also includes the condition $|x_k - x_1| = 1$. Simple estimates show that the series is less than $(2d/(U - 4d))N_c(\omega)$. The lowest-order term is a nearest-neighbor interaction,

$$-\frac{1}{U} \sum_{\{x,y\}:|x-y|=1} \delta_{w_x, 1-w_y}$$

that favors pairs with different occupation numbers. Formula [1] is the starting point for most studies of the phase diagram for large $U$. A similar expansion holds for $U < -4d$ and $N_e = |\Lambda| - N_c(\omega)$.

A simple derivation of expansion [1] using Cauchy formula can be found in Gruber and Macris (1996). It can be extended to positive temperatures with the help of Lie–Schwinger series (Datta *et al.* 1999).

Phase diagrams are better discussed in the limit of infinite volumes where boundary effects can be discarded. Let $\Omega^{\text{per}}$ be the set of configurations on $\mathbb{Z}^d$ that are periodic in all $d$ directions, and $\Omega^{\text{per}}(\rho_c) \subset \Omega^{\text{per}}$ be the set of periodic configurations with density $\rho_c$. For $\omega \in \Omega^{\text{per}}$ and $\rho_e \in [0, 1]$, we introduce the energy per site in the infinite volume limit by

$$e(\rho_e, \omega) = \lim_{\Lambda\nearrow\mathbb{Z}^d} \frac{1}{|\Lambda|} E_\Lambda(N_e, \omega) \qquad [2]$$

Here, the limit is taken over any sequence of increasing cubes, and $N_e = \lfloor \rho_e|\Lambda| \rfloor$ is the integer part of $\rho_e|\Lambda|$. Existence of this limit follows from standard arguments.

In the case of the empty configuration $\omega_x \equiv 0$, we get the well-known energy per site of free lattice electrons: for $k \in [-\pi, \pi]^d$, let $\varepsilon(k) = -\sum_{\nu=1}^d \cos k_\nu$; then

$$e(\rho_e, \omega \equiv 0) = \frac{1}{(2\pi)^d} \int_{\varepsilon(k)<\varepsilon_F(\rho_e)} \varepsilon(k)\, dk$$

where $\varepsilon_F(\rho_e)$ is the Fermi energy, defined by

$$\rho_e = \frac{1}{(2\pi)^d} \int_{\varepsilon(k)<\varepsilon_F(\rho_e)} dk$$

The other simple situation is the full configuration $\omega_x \equiv 1$, whose energy is $e(\rho_e, \omega \equiv 1) = e(\rho_e, \omega \equiv 0) - U\rho_e$.

Let $e(\rho_e, \rho_c)$ denote the absolute ground-state energy density, namely,

$$e(\rho_e, \rho_c) = \inf_{\omega \in \Omega^{per}(\rho_c)} e(\rho_e, \omega)$$

Notice that $e(\rho_e, \omega)$ is convex in $\rho_e$, and that $e(\rho_e, \rho_c)$ is the convex envelope of $\{e(\rho_e, \omega) : \omega \in \Omega^{per}(\rho_c)\}$. It may be locally linear around some $(\rho_e, \rho_c)$. This is the case if the infimum is not realized by a periodic configuration. The nonperiodic ground states can be expressed as linear combinations of two or more periodic ground states ("mixtures"). That is, for $1 \leq i \leq n$ there are $\alpha_i \geq 0$ with $\sum_i \alpha_i = 1$, $\omega^{(i)} \in \Omega^{per}$, and $\rho_e^{(i)}$, such that

$$\rho_e = \sum_i \alpha_i \rho_e^{(i)}, \qquad \rho_c = \sum_i \alpha_i \rho_c(\omega^{(i)})$$

and

$$e(\rho_e, \rho_c) = \sum_i \alpha_i e(\rho_e^{(i)}, \omega^{(i)})$$

The simplest mixture is the "segregated state" for densities $\rho_e < \rho_c$: take $\omega^{(1)}$ to be the empty configuration, $\omega^{(2)}$ to be the full configuration, $\rho_e^{(1)} = 0$, $\rho_e^{(2)} = \rho_e/\rho_c$, and $\alpha_2 = 1 - \alpha_1 = \rho_c$.

If $d \geq 2$, a mixture between configurations $\omega^{(i)}$ can be realized as follows. First, partition $\mathbb{Z}^d$ into domains $D_1 \cup \cdots \cup D_n$ such that $|D_i|/|\Lambda| \to \alpha_i$ and $|\partial D_i|/|\Lambda| \to 0$ as $\Lambda \nearrow \mathbb{Z}^d$. Then, define a nonperiodic configuration $\omega$ by setting $\omega_x = \omega_x^{(i)}$ for $x \in D_i$ (see the illustration in Figure 1). The canonical energy can be computed from [2], and it is equal to

$$e(\rho_e, \omega) = \inf_{(\rho_e^{(i)}): \sum_i \alpha_i \rho_e^{(i)} = \rho_e} \sum_{i=1}^{n} \alpha_i e(\rho_e^{(i)}, \omega^{(i)})$$

Furthermore, the infimum is realized by densities $\rho_e^{(i)}$ such that there exists $\mu_e$ with $\rho_e(\mu_e, \omega^{(i)}) = \rho_e^{(i)}$ for all $i$ (see [4] below for the definition of $\rho_e(\mu_e, \omega)$).

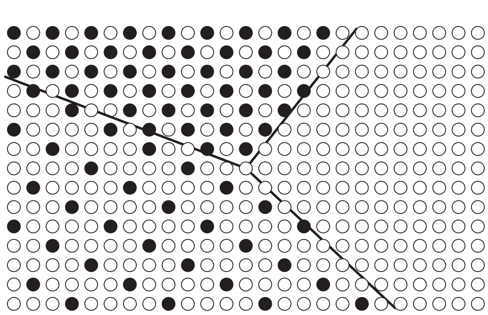

**Figure 1** A two-dimensional mixed configuration formed by periodic configurations of densities $0, 1/5$, and $1/2$.

We define the *canonical ground-state phase diagram* as the set of ground states $\omega$ (either a periodic configuration or a mixture) that minimize the ground-state energy for given densities $\rho_e, \rho_c$:

$$G_{can}(\rho_e, \rho_c) = \{\omega : e(\rho_e, \omega) = e(\rho_e, \rho_c) \text{ and } \rho_c(\omega) = \rho_c\}$$

### Grand-Canonical Ensemble

Properties of the system at finite temperatures are usually investigated within the grand-canonical formalism. The equilibrium state is characterized by an inverse temperature $\beta = 1/k_B T$, and by chemical potentials $\mu_e, \mu_c$, for the electrons and for the classical particles, respectively. In this formalism, the thermodynamic properties are derived from the partition functions

$$\begin{aligned} Z_\Lambda(\beta, \mu_e, \omega) &= \operatorname{tr}_{\mathcal{F}_\Lambda} e^{-\beta[H_\Lambda(\omega) - \mu_e N_\Lambda]} \\ Z_\Lambda(\beta, \mu_e, \mu_c) &= \sum_{\omega \in \Omega_\Lambda} e^{\beta \mu_c N_c(\omega)} Z_\Lambda(\beta, \mu_e, \omega) \end{aligned} \qquad [3]$$

Here, $N_\Lambda = \sum_{x \in \Lambda} a_x^\dagger a_x$ is the operator for the total number of electrons. We then define the free energy by

$$F_\Lambda(\beta, \mu_e, \mu_c) = -\frac{1}{\beta} \log Z_\Lambda(\beta, \mu_e, \mu_c)$$

The first partition function in [3] allows us to introduce an effective interaction for the classical particles, mediated by the electrons, by

$$F_\Lambda(\beta, \mu_e, \mu_c, \omega) = -\mu_c N_c(\omega) - \frac{1}{\beta} \log Z_\Lambda(\beta, \mu_e, \omega)$$

It depends on the inverse temperature $\beta$. Taking the limit of zero temperature gives the corresponding ground-state energy of the electrons in the classical configuration $\omega$:

$$\begin{aligned} E_\Lambda(\mu_e, \mu_c, \omega) &= \lim_{\beta \to \infty} F_\Lambda(\beta, \mu_e, \mu_c, \omega) \\ &= -\mu_c N_c(\omega) + \sum_{j: \lambda_j(\omega) < \mu_e} (\lambda_j(\omega) - \mu_e) \end{aligned}$$

Notice that $F_\Lambda$ and $E_\Lambda$ are strictly decreasing and concave in $\mu_e, \mu_c$ ($E_\Lambda$ is actually linear in $\mu_c$). We also define the energy density in the infinite volume limit by considering a sequence of increasing cubes. For $\omega \in \Omega^{per}$,

$$e(\mu_e, \mu_c, \omega) = \lim_{\Lambda \nearrow \mathbb{Z}^d} \frac{1}{|\Lambda|} E_\Lambda(\mu_e, \mu_c, \omega)$$

The corresponding electronic density is

$$\begin{aligned} \rho_e(\mu_e, \omega) &= \lim_{\Lambda \nearrow \mathbb{Z}^d} \frac{1}{|\Lambda|} \#\{j : \lambda_j(\omega) < \mu_e\} \\ &= -\frac{\partial}{\partial \mu_e} e(\mu_e, \mu_c, \omega) \end{aligned} \qquad [4]$$

and the density of classical particles is $\rho_c(\omega) = \lim_\Lambda N_c(\omega)/|\Lambda|$. One can check that canonical and grand-canonical energies are related by

$$e(\mu_e, \mu_c, \omega) = e(\rho_e(\mu_e, \omega), \omega) - \mu_e\rho_e(\mu_e, \omega) - \mu_c\rho_c(\omega) \qquad [5]$$

Given $(\mu_e, \mu_c)$, the ground-state energy density $e(\mu_e, \mu_c)$ is defined by

$$e(\mu_e, \mu_c) = \inf_{\omega\in\Omega^{\text{per}}} e(\mu_e, \mu_c, \omega)$$

The set of periodic ground-state configurations for given chemical potentials $\mu_e, \mu_c$ is the *grand-canonical ground-state phase diagram*:

$$G_{gc}(\mu_e, \mu_c) = \left\{\omega \in \Omega^{\text{per}} : e(\mu_e, \mu_c, \omega) = e(\mu_e, \mu_c)\right\}$$

It may happen that no periodic configuration minimizes $e(\mu_e, \mu_c, \omega)$ and that $G_{gc}(\mu_e, \mu_c) = \emptyset$. However, results suggest that $G_{gc}(\mu_e, \mu_c)$ is nonempty for almost all $\mu_e, \mu_c$.

The situation simplifies for $U > 4d$ and $\mu_e \in (-U + 2d, -2d)$. Since $\mu_e$ belongs to the gap of $h_\Lambda(\omega)$, we have $\rho_e(\mu_e, \omega) = \rho_c(\omega)$, and

$$e(\mu_e, \mu_c, \omega) = e(\rho_c(\omega), \omega) - (\mu_e + \mu_c)\rho_c(\omega)$$

Thus, $G_{gc}(\mu_e, \mu_c)$ is invariant along the line $\mu_e + \mu_c =$ const. (for $\mu_e$ in the gap).

### Symmetries of the Model

The Hamiltonian $H_\Lambda$ clearly has the symmetries of the lattice (for a box with periodic boundary conditions, there is invariance under translations, rotations by 90°, and reflections through an axis). More important, it also possesses particle–hole symmetries and these are useful since they allow us to restrict investigations to positive $U$ and to certain domains of densities or chemical potentials (see below).

- The classical particle–hole transformation $\omega_x \mapsto \overline{\omega}_x = 1 - \omega_x$ results in

$$H_\Lambda^U(\overline{\omega}) = H_\Lambda^{-U}(\omega) - UN_\Lambda$$

  and $N_c(\overline{\omega}) = |\Lambda| - N_c(\omega)$. It follows that $E_\Lambda^U(N_e, \overline{\omega}) = E_\Lambda^{-U}(N_e, \omega) - UN_e$, and

$$G_{\text{can}}^{-U}(\rho_e, \rho_c) = \left\{\overline{\omega} : \omega \in G_{\text{can}}^U(\rho_e, 1 - \rho_c)\right\}$$

$$G_{gc}^{-U}(\mu_e, \mu_c) = \left\{\overline{\omega} : \omega \in G_{gc}^U(\mu_e - U, -\mu_c)\right\}$$

- An electron–hole transformation can be defined via the unitary transformation $a_x \mapsto \varepsilon_x a_x^\dagger$ and $a_x^\dagger \mapsto \varepsilon_x a_x$, where $\varepsilon_x = 1$ on a sublattice, and $= -1$ on the other sublattice. Then,

$$H_\Lambda^U(\omega) \mapsto H_\Lambda^{-U}(\omega) - UN_c(\omega)$$

  and $N_\Lambda \mapsto |\Lambda| - N_\Lambda$. It follows that $E_\Lambda^U(|\Lambda| - N_e, \omega) = E_\Lambda^{-U}(N_e, \omega) - UN_c(\omega)$, and

$$G_{\text{can}}^{-U}(\rho_e, \rho_c) = G_{\text{can}}^U(1 - \rho_e, \rho_c)$$

$$G_{gc}^{-U}(\mu_e, \mu_c) = G_{gc}^U(-\mu_e, \mu_c - U)$$

- Finally, the particle–hole transformation for both the classical particles and the electrons gives

$$H_\Lambda^U(\overline{\omega}) \mapsto H_\Lambda^U(\omega) + UN_\Lambda + UN_c(\omega) - U|\Lambda|$$

  It follows that

$$E_\Lambda^U(|\Lambda| - N_e, \overline{\omega}) = E_\Lambda^U(N_e, \omega) + U(N_e + N_c(\omega) - |\Lambda|)$$

  and

$$G_{\text{can}}^U(\rho_e, \rho_c) = \left\{\overline{\omega} : \omega \in G_{\text{can}}^U(1 - \rho_e, 1 - \rho_c)\right\}$$

$$G_{gc}^U(\mu_e, \mu_c) = \left\{\overline{\omega} : \omega \in G_{gc}^U(-\mu_e - U, -\mu_c - U)\right\}$$

Any of the first two symmetries allow us to choose the sign of $U$. We assume from now on that $U \geq 0$. The third symmetry indicates that the phase diagrams have a point of central symmetry, given by $\rho_e = \rho_c = 1/2$ in the canonical ensemble and $\mu_e = \mu_c = -U/2$ in the grand-canonical ensemble. Consequently, it is enough to study densities satisfying $\rho_e \leq 1/2$ and chemical potentials satisfying $\mu_e \leq -U/2$.

These symmetries also have useful consequences at positive temperatures. In particular, both species of particles have average density 1/2 at $\mu_e = \mu_c = -U/2$, for all $\beta$.

## The Ground State – Arbitrary Dimensions

### The Segregated State

What follows is best understood in the limit $U \to \infty$ and when $\rho_e < \rho_c$. In this case, the electrons become localized in the domain $\mathcal{D}_\Lambda(\omega) = \{x \in \Lambda : w_x = 1\}$ and their energy per site is that of the full configuration, $e(\rho, \omega \equiv 1)$ (see the section "Canonical ensemble"), where $\rho = \rho_e/\rho_c$ is the effective electronic density. The presence of a boundary for $\mathcal{D}_\Lambda(\omega)$ raises the energy and the correction is roughly proportional to

$$B_\Lambda(\omega) = \#\left\{(x, y) : x \in \mathcal{D}_\Lambda(\omega) \text{ and } y \in \mathbb{Z}^d \setminus \mathcal{D}_\Lambda(\omega)\right\}$$

The following theorem was proposed by Freericks *et al.* (2002).

**Theorem 1**

(i) *Let* $\Lambda \subset \mathbb{Z}^d$ *be a finite box, and* $U > 4d$. *Then for all* $\omega \in \Omega_\Lambda$, *and all* $N_e \le N_c(\omega) = N_c$, *we have the following upper and lower bounds*:

$$\frac{1}{2d}\left| e\left(\frac{N_e}{N_c}, \omega \equiv 0\right)\right| B_\Lambda(\omega) \ge E_\Lambda(N_e, \omega)$$

$$- N_c e\left(\frac{N_e}{N_c}, \omega \equiv 1\right) \ge \left[ a\left(\frac{N_e}{N_c}\right) - \gamma(U)\right] B_\Lambda(\omega)$$

*Here,* $a(\rho) = a(1-\rho)$ *is strictly positive for* $0 < \rho < 1$. $\gamma(U)$ *behaves as* $8d^2/U$ *for large* $U$, *in the sense that* $U\gamma(U) \to 8d^2$ *as* $U \to \infty$.

(ii) *For any* $\rho_e \ne \rho_c$ *that differ from zero, the segregated state is the unique ground state if* $a(\rho_e/\rho_c) > \gamma(U)$, *that is, if* $U$ *is large enough.*

The proof of (i) is rather lengthy and we only show here that it implies (ii). Let $b(\omega) = \lim_\Lambda (B_\Lambda(\omega)/|\Lambda|)$, and notice that $b(\omega) = 0$ for the empty, the full, and the segregated configurations; $0 < b(\omega) < d$ for all other periodic configurations or mixtures. Recall that $\rho_c e(\rho_e/\rho_c, \omega \equiv 1)$ is the energy density of the segregated state. For all densities such that $a(\rho_e/\rho_c) > \gamma(U)$, and all configurations such that $\rho_c(\omega) = \rho_c$, we have

$$e(\rho_e, \omega) \ge \rho_c e\left(\frac{\rho_e}{\rho_c}, \omega \equiv 1\right)$$

and the inequality is strict for any periodic configuration. This shows that the segregated configuration is the unique ground state.

### General Properties of the Grand-Canonical Phase Diagram

We have already seen that the grand-canonical phase diagram is symmetric with respect to $(-U/2, -U/2)$. Other properties follow from concavity of $e(\mu_e, \mu_c)$.

Let $\omega \in G_{gc}(\mu_e, \mu_c) \backslash G_{gc}(\mu'_e, \mu'_c)$ and $\omega' \in G_{gc}(\mu'_e, \mu'_c) \backslash G_{gc}(\mu_e, \mu_c)$. Then,

(a) $\mu_e = \mu'_e$ and $\mu'_c > \mu_c$ imply $\rho_c(\omega') > \rho_c(\omega)$;
(b) $\mu_c = \mu'_c$ and $\mu'_e > \mu_e$ imply $\rho_e(\mu'_e, \omega') > \rho_e(\mu_e, \omega)$, and $\omega$ cannot be obtained by adding some classical particles to the configuration $\omega'$.

It follows from (b) that if $\omega \equiv 1 \in G_{gc}(\mu_e, \mu_c)$, then $\omega \equiv 1 \in G_{gc}(\mu'_e, \mu'_c)$ for all $\mu_e \ge \mu'_e$, $\mu_c \ge \mu'_c$. A similar property holds for the empty configuration. To establish these properties, we can start from

$$e(\mu_e, \mu_c, \omega') - e(\mu_e, \mu_c, \omega) > 0 > e(\mu'_e, \mu'_c, \omega') - e(\mu'_e, \mu'_c, \omega) \quad [6]$$

Since $e(\mu_e, \mu_c, \omega)$ is concave with respect to $\mu_e$ and linear with respect to $\mu_c$, we have

$$e(\mu'_e, \mu'_c, \omega) \le e(\mu_e, \mu_c, \omega) + (\mu_e - \mu'_e)\rho_e(\mu_e, \omega) + (\mu_c - \mu'_c)\rho_c(\omega) \quad [7]$$

Using this inequality for both terms on the right-hand side of [6], we obtain the inequality

$$(\mu'_e - \mu_e)[\rho_e(\mu'_e, \omega') - \rho_e(\mu_e, \omega)] + (\mu'_c - \mu_c)[\rho_c(\omega') - \rho_c(\omega)] \ge 0$$

which proves (a) and the first part of (b). The second part of (b) follows from

$$e(\mu_e, \mu_c, \omega) = -\int_{-\infty}^{\mu_e} d\mu\, \rho_e(\mu, \omega) - \mu_c \rho_c(\omega)$$

Indeed, the minimax principle implies that eigenvalues $\lambda_j(\omega)$ are decreasing with respect to $\omega$ (if $U \ge 0$), so that $\rho_e(\mu_e, \omega)$ is increasing (with respect to $\omega$). Then for any $\omega'' > \omega$ and $\mu'_e > \mu_e$,

$$e(\mu'_e, \mu_c, \omega'') - e(\mu'_e, \mu_c, \omega) > e(\mu_e, \mu_c, \omega'') - e(\mu_e, \mu_c, \omega)$$

and $\omega'' \notin G_{gc}(\mu_e, \mu_c)$ implies $\omega'' \notin G_{gc}(\mu'_e, \mu_c)$.

Next, we discuss domains in the plane of chemical potentials where the empty, full, and chessboard configurations have minimum energy (see, e.g., Gruber and Macris (1996), and references therein). One easily sees that $\omega \equiv 1$ is the unique ground-state configuration if $\mu_c > 0$, or if $\mu_e > 2d$ and $\mu_c > -U$. Similarly, $\omega \equiv 0$ is the unique ground state if $\mu_c < -U$, or if $\mu_e < -U - 2d$ and $\mu_c < 0$. For $U > 4d$, it follows from the expansion [1] that the full configuration is also ground state if $-U + 2d < \mu_e < -2d$ and $\mu_e + \mu_c + U > 4d/(U - 4d)$. These domains can be rigorously extended using energy estimates that involve correlation functions of classical particles. The results are illustrated in Figures 2 ($U < 4d$) and 3 ($U > 4d$).

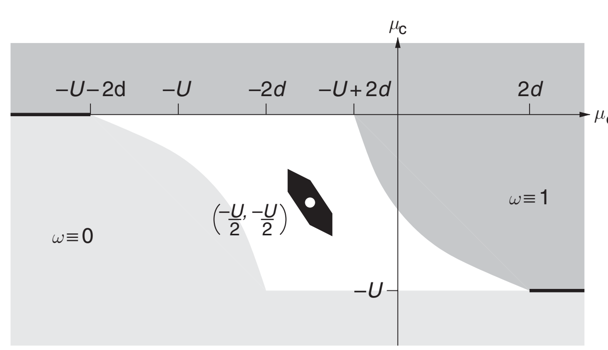

**Figure 2** Grand-canonical ground-state phase diagram for $U < 4d$. Domains for the empty, chessboard, and full configurations, are denoted in light gray, black, and dark gray, respectively.

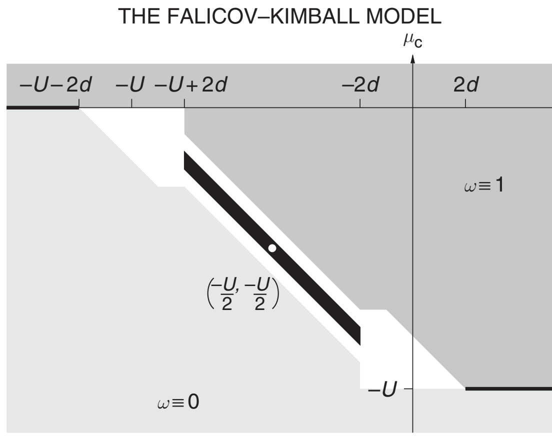

**Figure 3** Grand-canonical ground-state phase diagram for $U > 4d$. Domains for the empty, chessboard, and full configurations are denoted in light gray, black, and dark gray, respectively.

Finally, canonical and grand-canonical phase diagrams are related by the following properties:

(c) If $\omega \in G_{gc}(\mu_e, \mu_c)$, then $\omega \in G_{can}(\rho_e(\mu_e, \omega), \rho_c(\omega))$.
(d) More generally, suppose that $\omega^{(1)}, \ldots, \omega^{(n)} \in G_{gc}(\mu_e, \mu_c)$, and consider a mixture with coefficients $\alpha_1, \ldots, \alpha_n$. The mixture belongs to $G_{can}(\rho_e, \rho_c)$, with $\rho_e = \sum_i \alpha_i \rho_e(\mu_e, \omega^{(i)})$ and $\rho_c = \sum_i \alpha_i \rho_c(\omega^{(i)})$.

To establish (c), observe that any $\omega'$ satisfies $e(\mu_e, \mu_c, \omega') \geq e(\mu_e, \mu_c, \omega)$ if $\omega \in G_{gc}(\mu_e, \mu_c)$. Let $\rho_e = \rho_e(\mu_e, \omega)$ and $\rho_c = \rho_c(\omega)$, and let $\mu'_e$ be such that $\rho_e(\mu'_e, \omega') = \rho_e$. By eqns [5] and [7],

$$e(\rho_e(\mu'_e, \omega'), \omega') - \mu_e \rho_e(\mu'_e, \omega') - \mu_c \rho_c(\omega') \geq e(\rho_e(\mu_e, \omega), \omega) - \mu_e \rho_e(\mu_e, \omega) - \mu_c \rho_c(\omega)$$

Then, $e(\rho_e, \omega') \geq e(\rho_e, \omega)$ for any configuration $\omega'$ such that $\rho_c(\omega') = \rho_c$. Property (d) follows from (c) by a limiting argument, because a mixture can be approximated by a sequence of periodic configurations.

Next we describe further properties of the phase diagrams that are specific to dimensions 1 and 2.

## Ground-State Configurations – Dimension 1

A large number of investigations, either analytical or numerical, have been devoted to the study of the ground-state configurations in one dimension. One-dimensional results also serve as guide to higher dimensions. Recall that symmetries allow us to restrict to $U \geq 0$ and $\rho_e \leq 1/2$.

Most ground-state configurations that appear in the canonical phase diagram seem to be given by an intriguing formula, which we now describe. Let $\rho_e = p/q$ with $p$ relatively prime to $q$. Then corresponding periodic ground-state configurations have period $q$ and density $\rho_c = r/q$ ($r$ is an integer). The occupied sites in the cell $\{0, 1, \ldots, q-1\}$ are given by the solutions $k_0, \ldots, k_{r-1}$ of

$$(pk_j) = j \bmod q, \quad 0 \leq j \leq r-1 \qquad [8]$$

Note that the first classical particle is located at $k_0 = 0$, and $k_0, \ldots, k_{p-1}$ are *not* in increasing order. In order to discuss the solutions of [8], we introduce $\ell = \lfloor q/p \rfloor$ (the integer part of $q/p$), and we write

$$q = (\ell + 1)p - s \qquad [9]$$

where $1 \leq s \leq p-1$, and $s$ is relatively prime to $p$. Next, let $L(x)$ denote the distance between the particle at $x$ and the one immediately preceding it (to the left).

Let us observe that if $\rho_c = \rho_e$, that is, if $r = p$, then

(a) $L(k_j) = \ell$ for $0 \leq j \leq s-1$ and $k_j - \ell = k_{j+p-s}$.
(b) $L(k_j) = \ell + 1$ for $s \leq j \leq p-1$ and $k_j - (\ell+1) = k_{j-s}$.

Indeed, for $pk_j = j + nq$, eqn [9] implies

$$p(k_j - \ell) = j + (n-1)q + (p-s) = j + p - s \bmod q$$

and

$$p(k_j - \ell - 1) = j - s \bmod q$$

Therefore, $k_j - \ell$ is a solution of [8] if $j + p - s \leq p - 1$, while $k_j - (\ell + 1)$ is a solution of [8] if $j - s \geq 0$.

These two properties show that the configuration defined by [8] is such that $L(x) \in \{\ell, \ell+1\}$ for all occupied $x$. A periodic configuration such that all distances between consecutive particles are either $\ell$ or $\ell + 1$ is called *homogeneous*. Let $\omega$ be a homogeneous configuration with period $q$ and density $\rho_c = r/q$, and let $x_0 < \cdots < x_{p-1}$ be the occupied sites in $\{0, 1, \ldots, q-1\}$. We introduce the *derivative* $\omega'$ of $\omega$ as the periodic configuration with period $r$ defined by (see Figure 4)

$$\omega'_i = \begin{cases} 1 & \text{if } L(x_i) = \ell \\ 0 & \text{if } L(x_i) = \ell + 1 \end{cases}$$

A configuration is *most homogeneous* if it can be "differentiated" repeatedly until the empty or the full configuration is obtained.

Let $\omega$ be the homogeneous configuration from [8] and $\omega'$ be its derivative. Using the same arguments as for properties (a) and (b) above, and the fact that $s$ is relatively prime to $p$, we obtain

(c) Let $k'_0, \ldots, k'_{p-1}$ be the solutions of

$$(sk'_j) = j \bmod p$$

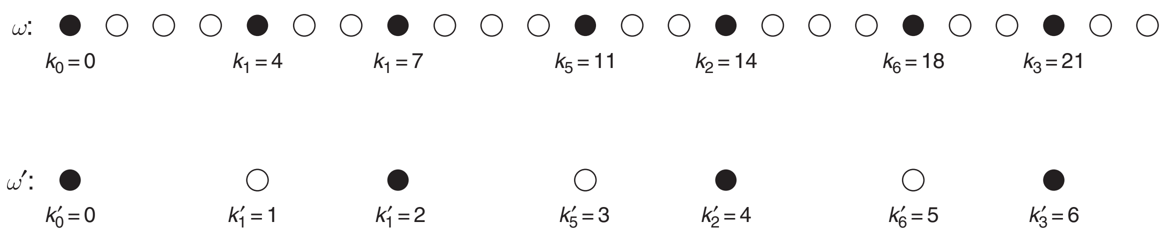

**Figure 4** The configuration $\omega$ given by the formula [8] with $q = 24$ and $p = 7$, and its derivative $\omega'$. Notice that $\ell = 3$ and $s = 4$.

Then $(k'_0, \ldots, k'_{p-1})$ is a permutation of $(0, 1, \ldots, p-1)$. Further, $k'_j - 1 = k'_{j+p-s}$ for $0 \le j \le s-1$, and $k'_j - 1 = k'_{j-s}$ for $s \le j \le p-1$.

Consider the periodic configuration with period $p$ where sites $k'_0, \ldots, k'_{s-1}$ are occupied and sites $k'_s, \ldots, k'_{p-1}$ are empty. Since $k'_0 = 0$, this configuration is precisely the derivative $\omega'$ of $\omega$. Iterating, these properties prove that the solutions of [8] are most homogeneous.

One of the most important results in one dimension is that only most homogeneous configurations are present in the canonical phase diagram, for $U$ large enough and for equal densities $\rho_e = \rho_c$.

**Theorem 2** *Suppose that $\rho_e = \rho_c = p/q$. There exists a constant $c$ such that for $U > c4^q$, the only ground-state configuration is the most homogeneous configuration, given by [8] (together with translations and reflections).*

This theorem was established using the expansion [1] of $E_\Lambda(N_e, \omega)$ in powers of $U^{-1}$. It suggests a devil's staircase structure with infinitely many domains. However, the number of domains for *fixed U* could still be finite. Results from Theorem 2 are illustrated in Figure 5. Notice that $\rho_e = \rho_c$ when $\mu_e$ is in the universal gap. These results have been extended

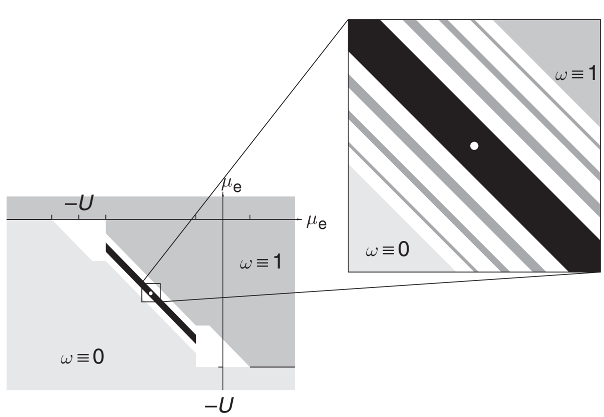

**Figure 5** Grand-canonical ground-state phase diagram in one dimension for $U > 4$ and $\mu_e$ in the universal gap. Chessboard configurations occur in the black domain. Dark gray oblique domains correspond to densities 1/5, 1/4, 1/3, 2/3, 3/4, 4/5. Total width of these domains is of order $U^{-1}$.

to positive temperatures by using "quantum Pirogov–Sinai theory" (Datta *et al.* 1999).

For small $U$, on the other hand, one can use a (nonrigorous) Wigner–Brillouin degenerate perturbation theory (a standard tool in band theory). Let $\rho_e = p/q$ with $p$ relatively prime to $q$, and $\omega$ be a periodic configuration with period $nq, n \in \mathbb{N}$. Then for $U$ small enough ($U \ll 1/q$), we obtain the following expansion for the ground-state energy (Freericks *et al.* 1996):

$$e(\rho_e, \omega) = -\frac{2}{\pi}\sin \pi\rho_e - U\rho_e\rho_c(\omega) - \frac{|\widehat{\omega}(\rho_e)|^2}{4\pi \sin \pi\rho_e} U^2 |\log U| + O(U^2) \qquad [10]$$

where $\widehat{\omega}(\rho_e)$ is the "structure factor" of the periodic configuration $\omega$, namely

$$\widehat{\omega}(\rho_e) = \frac{1}{nq}\sum_{j=0}^{nq-1} e^{-2\pi i \rho_e j} w_j$$

This expansion suggests that the ground-state configuration can be found by maximizing the structure factor. The following theorem holds independently of $U$.

**Theorem 3** *Let $\rho_e = p/q$. There exist $r_1 \ge q/4$ and $r_2 \le 3q/4$ such that the configurations maximizing the structure factor are given as follows:*

(i) *for $\rho_c = r/q$ with $r_1 \le r \le r_2$, use the formula* [8];
(ii) *for $\rho_c \in (r/q, (r+1/q))$ with $r_1 \le r \le r_2 - 1$, the configuration is a mixture of those for $\rho_c = r/q$ and $\rho_c = (r+1)/q$; and*
(iii) *for $\rho_c \in (0, r_1/q)$, the configurations are mixtures of $\omega \equiv 0$ and that for $\rho_c = r_1/q$. For $\rho_c \in (r_2/q, 1)$, the configurations are mixtures of $\omega \equiv 1$ and that for $\rho_c = r_2/q$.*

Some insight for low densities is provided by computing the energy of just one classical particle and one electron on the infinite line, and to compare it with two consecutive classical particles and two electrons. It turns out that the former is more favorable than the latter for $U > 2/\sqrt{3} \approx 1.15$, while "molecules" of two particles are forming

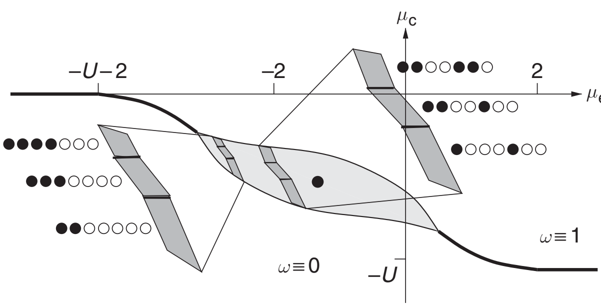

**Figure 6** Grand-canonical ground-state phase diagram for $U \approx 0.4$. Enlarged are domains for $\rho_e = 1/7$ and $2/7$, with the same densities $\rho_c = 2/7, 3/7, 4/7$.

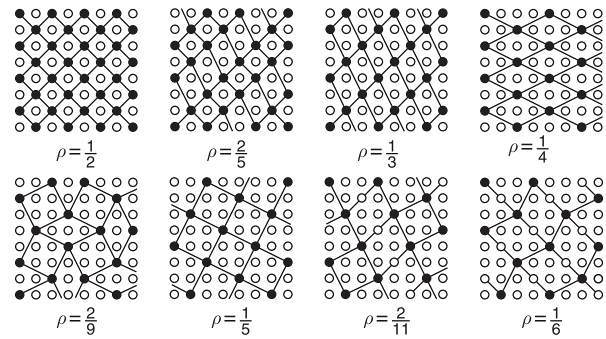

**Figure 7** Ground-state configurations for several densities. Occupied sites are denoted by black circles, empty sites by white circles. Lines are present only to clarify the patterns.

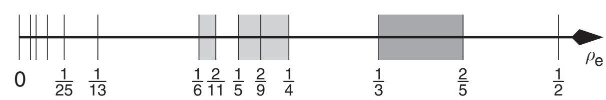

**Figure 8** Canonical ground-state phase diagram in two dimensions for $U > 8$.

when $U < 2/\sqrt{3}$. Smaller $U$ shows even bigger molecules for $\rho_c = n\rho_e$, and $n$-molecules are most homogeneously distributed according to the formula [8]. It should be stressed that the canonical ground state cannot be periodic if $U$ is small and $\rho_c \notin [1/4, 3/4]$, which is different from the case of large $U$.

Only numerical results are available for intermediate $U$. They suggest that configurations occurring in the phase diagram are essentially given by Theorem 3 (together with the segregated configuration). This is sketched in **Figure 6**, where bold coexistence lines for $\mu_e > -U - 2$ and $\mu_e < 2$ represent segregated states.

## Ground-State Configurations – Dimension 2

We discuss the canonical ensemble only, but many results extend to the grand-canonical ensemble. Recall that $G_{\text{can}}(1/2, 1/2)$ consists of the two chessboard configurations for any $U > 0$, and that segregation takes place when $\rho_e \neq \rho_c$, providing $U$ is large enough (Theorem 1). Other results deal with the case of equal densities, and for $U$ large enough (see Haller and Kennedy (2001), and references therein).

**Theorem 4** *Let* $\rho_e = \rho_c \equiv \rho \leq 1/2$.

(i) *If*

$$\rho \in \left\{ \frac{1}{2}, \frac{2}{5}, \frac{1}{3}, \frac{1}{4}, \frac{2}{9}, \frac{1}{5}, \frac{2}{11}, \frac{1}{6} \right\}$$

*then for $U$ large enough, the ground-state configurations are those displayed in* ***Figure*** *7. If $\rho = 1/(n^2 + (n+1)^2)$ with integer $n$, then for $U$ large enough (depending on $\rho$), the ground-state configurations are periodic.*

(ii) *If $\rho$ is a rational number between* 1/3 *and* 2/5, *then for $U$ large enough (depending on the denominator of $\rho$), the ground-state configurations are periodic. Further, the restriction to any horizontal line is a one-dimensional periodic configuration given by* [8], *and the configuration is constant in either the direction $\binom{1}{1}$ or $\binom{1}{-1}$.*

(iii) *Suppose that $U$ is large enough. If $\rho \in (1/6, 2/11)$, the ground-state configurations are mixtures of the configurations $\rho = 1/6$ and $\rho = 2/11$ of* ***Figure*** *7. If $\rho \in (1/5, 2/9)$, the ground-state configurations are mixtures of the configurations $\rho = 1/5$ and $\rho = 2/9$. If $\rho \in (2/9, 1/4)$, the ground-state configurations are mixtures of the configurations $\rho = 2/9$ and $\rho = 1/4$.*

The canonical phase diagram for $\rho_e = \rho_c$ is presented in **Figure 8**.

The situation for densities $\rho \leq 1/2$ that are not mentioned in Theorem 4 is unknown. All these periodic configurations are present in the grand-canonical phase diagram as well. Theorem 4(ii) suggests that the two-dimensional situation is similar to the one-dimensional one where a devil's staircase structure may occur. Let us stress that no periodic configurations occur for large $U$ and densities $\rho_e = \rho_c$ in the intervals (1/6, 2/11), (1/5, 2/9), and (2/9, 1/4). This resembles the one-dimensional situation, but for small $U$.

# Fedosov Quantization

**N Neumaier**, Albert-Ludwigs-University in Freiburg, Freiburg, Germany

## Introduction

On the one hand, quantum mechanics and classical mechanics appear to be formulated within quite different mathematical frameworks, that is, in terms of Hilbert spaces and operators on Hilbert spaces on the quantum side and in terms of phase spaces, that is, symplectic, or more generally, Poisson manifolds, and functions on these phase spaces on the classical side. On the other hand, there is a strong structural similarity between the algebras of observable quantities in both theories which are associative $^*$-algebras over $\mathbb{C}$. In the classical case, the algebra is commutative the product being the pointwise product of functions on the phase space and is endowed with the additional structure of a Poisson bracket by means of which the dynamics of the system can be formulated. In the quantum case, the algebra is the noncommutative composition of operators on a Hilbert space and the dynamics is determined by the corresponding commutator. The difference between functions on a phase space and the operators on a Hilbert space constitutes the main difficulty for the passage from a classical theory to the corresponding quantum theory which would be desirable, since a formulation of the more fundamental but much less intuitive quantum theory is often impossible. Even the consideration of the classical limit leads to the same problem of comparing quite different mathematical objects. One possibility, which is the basic idea of deformation quantization, to avoid these problems is to pass from classical observables to quantum observables not by changing the underlying vector space, but only by deforming the algebraic structures namely the associative product and possibly the $^*$-involution.

This idea motivates the following definition of a star product by Bayen *et al.* (1978), which reassembles the minimal demands made on a suitable quantization:

**Definition 1** A star product on a Poisson manifold $(M,\Pi)$ is an associative $\mathbb{C}[[\nu]]$-bilinear product $\star$ on $\mathcal{C}^\infty(M)[[\nu]]$ such that – writing $f\star g=\sum_{r=0}^{\infty}\nu^r C_r(f,g)$ for $f,g\in\mathcal{C}^\infty(M)$ with $\mathbb{C}$-bilinear maps $C_r$ with values in $\mathcal{C}^\infty(M)$ – the following properties hold:

(i) $C_0(f,g)=fg$,
(ii) $C_1(f,g)-C_1(g,f)=\{f,g\}$, and
(iii) $1\star f=f=f\star 1$.

In case the $\mathbb{C}$-bilinear maps $C_r$ are differential operators, the star product is called differential. If $\overline{f\star g}=\overline{g}\star\overline{f}$, then $\star$ is called Hermitian.

The conditions (i) and (ii) express the correspondence principle in deformation quantization and in case the star product converges the formal parameter is to be identified with $i\hbar$, whence we set $\overline{\nu}=-\nu$ considering the formal parameter as purely imaginary. Since the Fedosov star products we are going to study in the sequel are differential, we shall drop stressing this property explicitly and refer to differential star products as star products, merely.

One main advantage of deformation quantization is that one has the following very general existence result:

**Theorem 1** *On every Poisson manifold* $(M,\Pi)$ *there exist (even differential) star products.*

This theorem was first shown by DeWilde and Lecomte (1983) for the symplectic case and

independently by Fedosov (1985) who gave a beautiful explicit construction using geometrical structures on $(M, \omega)$ to build a star product recursively. Omori *et al.* (1991) gave yet another existence proof of star products on a symplectic manifold $(M, \omega)$ that appears to combine the methods of DeWilde and Lecomte (1983) and Fedosov (1985). The general proof of existence on general Poisson manifolds is due to Kontsevich (2003) and is a consequence of Kontsevich's formality theorem.

If $S = \mathrm{id} + \sum_{r=1}^{\infty} \nu^r S_r$ is a formal series of differential operators on $\mathcal{C}^\infty(M)$ with $S_r 1 = 0$ for $r \geq 1$, then

$$f \star' g := S^{-1}((Sf) \star (Sg)) \qquad [1]$$

again defines a star product. Clearly, $\star'$ is Hermitian in case $\star$ is Hermitian and $\overline{Sf} = S\overline{f}$ for all $f \in \mathcal{C}^\infty(M)[[\nu]]$. The above observation of the shape of certain isomorphisms between star product algebras gives rise to the notion of equivalence of star products:

**Definition 2** Two star products $\star$ and $\star'$ on $(M, \Pi)$ are called equivalent in case there is a formal series $S = \mathrm{id} + \sum_{r=1}^{\infty} \nu^r S_r$ of differential operators on $\mathcal{C}^\infty(M)$ with $S_r 1 = 0$ for $r \geq 1$ such that eqn [1] is satisfied for all $f, g \in \mathcal{C}^\infty(M)[[\nu]]$.

The full classification of star products up to equivalence was first obtained in the symplectic case by Nest and Tsygan (1995) and independently by Deligne (1995) and Bertelson *et al.* (1997). The general Poisson case again follows from Kontsevich's formality theorem. In particular, in the symplectic case, star products are classified in a functorial way by the characteristic class

$$c : \star \mapsto c(\star) \in \frac{[\omega]}{\nu} + H^2_{\mathrm{deRham}}(M)[[\nu]] \qquad [2]$$

defined by Deligne that induces a bijection between the equivalence classes of star products and $[\omega]/\nu + H^2_{\mathrm{deRham}}(M)[[\nu]]$. Moreover, it has been shown (Bertelson *et al.* 1997, Deligne 1995, Nest and Tsygan 1995) that every star product on a symplectic manifold is equivalent to a Fedosov star product. This fact can also be seen as a direct consequence of the explicit computation of the characteristic class of a Fedosov star product (cf. Neumaier (2002)). The importance of Fedosov's construction for the general theory of deformation quantization in the symplectic case is also shown by the fact that in many proofs Fedosov's star products were used to have reference star products to compare with a given star product. Moreover, there is a great variety of modifications and generalizations of Fedosov's method and there are many examples where additional structures on the symplectic manifold suggest to look for star products adapted to them, where modified Fedosov constructions can be applied successfully.

## Fedosov Star Products on $(M, \omega)$

The attempt to construct a star product step by step in fact leads to a cohomological problem, where *a priori* an obstruction in the third Hochschild cohomology of $\mathcal{C}^\infty(M)$ occurs. This problem results from the demand for associativity which is the really most restricting condition on a star product. Therefore, additional arguments are necessary to show that these obstructions can be circumvented, since the concerning cohomology is isomorphic to $\Gamma^\infty(\bigwedge^3 TM)$ and hence, for $\dim(M) \geq 3$, is not trivial at all.

The basic strategy of Fedosov's construction to build in associativity of the resulting product is to begin with a "very large" associative algebra $(\mathcal{W} \otimes \Lambda, \circ)$, where $\circ$ mimicks the well-known Weyl–Moyal star product on a vector space with a constant symplectic Poisson tensor, and to specify a suitable subalgebra which is in bijection to $\mathcal{C}^\infty(M)[[\nu]]$. Pulling back the product to the subalgebra then clearly results in an associative product on $\mathcal{C}^\infty(M)[[\nu]]$, but as we shall see later on, one has to care for the bijection to be sufficiently nontrivial in order to obtain in fact a nontrivial deformation of the usual pointwise product on $\mathcal{C}^\infty(M)[[\nu]]$.

Defining

$$\mathcal{W} \otimes \Lambda := \left( \bigtimes_{s=0}^{\infty} \Gamma^\infty\left( \bigvee^s T^*M \otimes \bigwedge T^*M \right) \right)[[\nu]] \qquad [3]$$

$\mathcal{W} \otimes \Lambda$ becomes in a natural way an associative, supercommutative algebra using the symmetric $\vee$-product in the first factor and the antisymmetric $\wedge$-product in the second factor. This product is denoted by $\mu(a \otimes b) = ab$ for $a, b \in \mathcal{W} \otimes \Lambda$. By $\mathcal{W} \otimes \Lambda^k$ we denote the elements of antisymmetric degree $k$ and set $\mathcal{W} := \mathcal{W} \otimes \Lambda^0$. Besides this pointwise product, the Poisson tensor $\Pi$ corresponding to $\omega$ gives rise to another associative product $\circ$ on $\mathcal{W} \otimes \Lambda$ by

$$a \circ b = \mu\left( \exp\left( \frac{\nu}{2} \Pi^{ij} i_s(\partial_i) \otimes i_s(\partial_j) \right)(a \otimes b) \right) \qquad [4]$$

which is a deformation of $\mu$. Here $i_s(Y)$ denotes the symmetric insertion of a vector field $Y \in \Gamma^\infty(TM)$ and similarly $i_a(Y)$ shall be used to denote the antisymmetric insertion of a vector field. We set $\mathrm{ad}(a)b := [a, b]$, where the latter denotes the

$\deg_a$-graded supercommutator with respect to $\circ$. Denoting the obvious degree maps by $\deg_s, \deg_a$, and $\deg_\nu = \nu\partial_\nu$, one observes that they all are derivations with respect to $\mu$ but $\deg_s$ and $\deg_\nu$ fail to be derivations with respect to $\circ$. Instead, $\mathrm{Deg} := \deg_s + 2\deg_\nu$ is a derivation of $\circ$ and hence $(\mathcal{W} \otimes \Lambda, \circ)$ is formally Deg-graded and the corresponding degree is referred to as the total degree. Sometimes we write $\mathcal{W}_k \otimes \Lambda$ to denote the elements of total degree $\geq k$. The total degree can be used to define an ultrametric $d$ on $\mathcal{W} \otimes \Lambda$ and it is known that $(\mathcal{W} \otimes \Lambda, d)$ is complete, which implies that Banach's fixed-point theorem can be applied in this setting. This observation is important since all the proofs of existence and uniqueness of certain elements in $\mathcal{W} \otimes \Lambda$ we shall construct in the sequel can be reduced to the application of this theorem.

In local coordinates, we define the differential

$$\delta := (1 \otimes \mathrm{d}x^i) i_s(\partial_i) \qquad [5]$$

which satisfies $\delta^2 = 0$ and is a superderivation of $\circ$. Evaluated at a point $m \in M$, the product $a(m)b(m)$ of two elements $a, b \in \mathcal{W} \otimes \Lambda$ can be considered as the $\wedge$-product of two differential forms with polynomial coefficient functions on the vector space $T_m M$. Interpreted this way, the restriction of $\delta$ to the fiber at $m$ is nothing but the exterior derivative of differential forms with polynomial coefficients. Hence, it is clear that there is a homotopy operator $\delta^{-1}$ satisfying

$$\delta\delta^{-1} + \delta^{-1}\delta + \sigma = \mathrm{id} \qquad [6]$$

where $\sigma : \mathcal{W} \otimes \Lambda \to \mathcal{C}^\infty(M)[[\nu]]$ denotes the projection onto the part of symmetric and antisymmetric degree 0. With the above view of $\delta$, this is just the Poincaré Lemma for differential forms with polynomial coefficients, which says that all the cohomology spaces vanish except for the one of degree 0 and the cohomology in degree 0 is just given by the constant functions on the vector space $T_m M$. This means that the $\delta$-cohomology on $\mathcal{W} \otimes \Lambda$ is trivial except for the space of degree 0, which is given by the formal functions on $M$. For computational purposes, it is useful to have a concrete formula of the homotopy operator $\delta^{-1}$ which is given by

$$\delta^{-1} a := \begin{cases} \dfrac{1}{k+l}(\mathrm{d}x^i \otimes 1) i_a(\partial_i) a & \text{for } \deg_s a = ka, \\ \quad \deg_a a = la \text{ with } k + l \neq 0 \\ \quad 0 \quad \text{else} \end{cases} \qquad [7]$$

Now $\ker(\delta) \cap \mathcal{W} = \mathcal{C}^\infty(M)[[\nu]]$ and one might wonder whether this subalgebra of $(\mathcal{W} \otimes \Lambda, \circ)$ is already suitable to induce a deformed product on $\mathcal{C}^\infty(M)[[\nu]]$ by pulling back the product $\circ$ from $\mathcal{W} \otimes \Lambda$. Evidently, the answer to the question is negative since the resulting product just gives back the undeformed pointwise product of formal functions on $M$. Hence one has to find a less trivial superderivation of the product $\circ$ the kernel of which is still in bijection to $\mathcal{C}^\infty(M)[[\nu]]$. The essential new component of Fedosov's construction is a superderivation of $(\mathcal{W} \otimes \Lambda, \circ)$ that is not $\mathcal{C}^\infty(M)[[\nu]]$-linear and hence in a certain sense generates derivatives along the base manifold $M$. Using a torsion-free symplectic connection $\nabla$ on $M$ we define an endomorphism also denoted by $\nabla$ of $\mathcal{W} \otimes \Lambda$ by

$$\nabla := (1 \otimes \mathrm{d}x^i) \nabla_{\partial_i} \qquad [8]$$

which turns out to be a superderivation of $\circ$ due to the fact that $\nabla\omega = \nabla\Pi = 0$. The map $\nabla$ satisfies the identities

$$[\delta, \nabla] = 0, \quad \text{since the connection is torsion-free} \quad [9]$$

$$\nabla^2 = -\frac{1}{\nu}\mathrm{ad}(R),$$
$$\text{where } R := \tfrac{1}{4}\omega_{it} R^t_{jkl}\, \mathrm{d}x^i \vee \mathrm{d}x^j \otimes \mathrm{d}x^k \wedge \mathrm{d}x^l \in \mathcal{W} \otimes \Lambda^2 \quad [10]$$

involves the curvature of the connection. Moreover, we have

$$\delta R = 0 = \nabla R \qquad [11]$$

by the Bianchi identities.

Now one could consider the superderivation $-\delta + \nabla$ of $(\mathcal{W} \otimes \Lambda, \circ)$ and try to define a mapping $\tau$ from $\mathcal{C}^\infty(M)[[\nu]]$ to $\ker(-\delta + \nabla) \cap \mathcal{W}$ such that $\sigma(\tau(f)) = f$ for all $f \in \mathcal{C}^\infty(M)[[\nu]]$. But in case the curvature of the connection does not vanish, the necessary condition for the solvability of the equation $(-\delta + \nabla)\tau(f) = 0$ subject to the additional condition $\sigma(\tau(f)) = f$ is not satisfied. Only in case there is a torsion-free symplectic connection on $M$ with vanishing curvature, this procedure can be carried through and yields again the Weyl–Moyal star product since the fact that $\nabla$ is symplectic in this case implies that the components of the Poisson tensor are constant. However, in general, the kernel of $-\delta + \nabla$ does not have the desired properties to specify a suitable subalgebra of $(\mathcal{W} \otimes \Lambda, \circ)$ and one makes the ansatz

$$\mathfrak{D} = -\delta + \nabla - \frac{1}{\nu}\mathrm{ad}(r) \qquad [12]$$

with an element $r \in \mathcal{W}_3 \otimes \Lambda^1$ for a suitable superderivation. Now a direct computation yields that

$$\mathfrak{D}^2 = \frac{1}{\nu}\mathrm{ad}\left(\delta r - \nabla r + \frac{1}{\nu} r \circ r - R\right) \qquad [13]$$

which vanishes iff $\delta r - \nabla r + (1/\nu) r \circ r - R$ is a central element in $\mathcal{W}_2 \otimes \Lambda^2$. This is the case iff there is a formal series of 2-forms $\Omega \in \nu\Gamma^\infty(\bigwedge^2 T^*M)[[\nu]]$ with

$$\delta r - \nabla r + \frac{1}{\nu} r \circ r - R = 1 \otimes \Omega \qquad [14]$$

After these preparations, one is in the position to prove the following theorem:

**Theorem 2** (Fedosov 1994, theorem 3.2; Fedosov 1996, theorem 5.2.2). *For every formal series $\Omega \in \nu\Gamma^\infty(\bigwedge^2 T^*M)[[\nu]]$ of closed 2-forms there exists a unique element $r \in \mathcal{W}_3 \otimes \Lambda^1$ such that*

$$\delta r = \nabla r - \frac{1}{\nu} r \circ r + R + 1 \otimes \Omega \quad \text{and} \quad \delta^{-1} r = 0 \qquad [15]$$

*Moreover, $r$ satisfies*

$$r = \delta^{-1}\left(R + 1 \otimes \Omega + \nabla r - \frac{1}{\nu} r \circ r\right) \qquad [16]$$

*from which $r$ can be determined recursively. In this case the Fedosov derivation*

$$\mathfrak{D} := -\delta + \nabla - \frac{1}{\nu}\mathrm{ad}(r) \qquad [17]$$

*is a superderivation of antisymmetric degree 1 and has square zero*: $\mathfrak{D}^2 = 0$.

For obvious reasons Fedosov calls $\mathfrak{D}$ a flat or abelian connection for the bundle $\mathcal{W} \otimes \Lambda$ and $\omega + \Omega$ is referred to as the central Weyl curvature of the connection $\mathfrak{D}$. In some sense, the flatness property $\mathfrak{D}^2 = 0$ guarantees that there are sufficiently many flat sections. Before investigating the structure of $\ker(\mathfrak{D}) \cap \mathcal{W}$ we note that the $\mathfrak{D}$-cohomology is trivial on elements $a$ with positive antisymmetric degree since one has the following homotopy formula:

$$\mathfrak{D}\mathfrak{D}^{-1} a + \mathfrak{D}^{-1}\mathfrak{D} a = a$$

where

$$\mathfrak{D}^{-1} a := -\delta^{-1}\left(\frac{1}{\mathrm{id} - [\delta^{-1}, \nabla - (1/\nu)\mathrm{ad}(r)]} a\right) \qquad [18]$$

(cf. Fedosov (1996, theorem 5.2.5)). The reason for this fact, which is also the crucial point for the proof of Theorem 1, is the property of the $\delta$-cohomology to vanish except for the cohomology space of degree 0.

The next step in Fedosov's construction now consists in establishing a bijection between the flat sections $a \in \mathcal{W}$, that is, those elements of $\mathcal{W}$ with $\mathfrak{D} a = 0$, and $\mathcal{C}^\infty(M)[[\nu]]$.

**Theorem 3** (Fedosov 1994, theorem 3.3, Fedosov 1996, theorem 5.2.4). *Let $\mathfrak{D} = -\delta + \nabla - (1/\nu)\mathrm{ad}(r): \mathcal{W} \otimes \Lambda \to \mathcal{W} \otimes \Lambda$ be given as in [17] with $r$ as in [15].*

(i) *Then for any $f \in \mathcal{C}^\infty(M)[[\nu]]$ there exists a unique element $\tau(f) \in \ker(\mathfrak{D}) \cap \mathcal{W}$ such that*

$$\sigma(\tau(f)) = f \qquad [19]$$

*and $\tau : \mathcal{C}^\infty(M)[[\nu]] \to \ker(\mathfrak{D}) \cap \mathcal{W}$ is $\mathbb{C}[[\nu]]$-linear and referred to as the Fedosov–Taylor series corresponding to $\mathfrak{D}$.*

(ii) *In addition, $\tau(f)$ can be obtained recursively for $f \in \mathcal{C}^\infty(M)$ from*

$$\tau(f) = f + \delta^{-1}\left(\nabla \tau(f) - \frac{1}{\nu}\mathrm{ad}(r)\tau(f)\right) \qquad [20]$$

*Using $\mathfrak{D}^{-1}$ according to [18] one can also write*

$$\tau(f) = f - \mathfrak{D}^{-1}(1 \otimes \mathrm{d}f) \quad \text{for all } f \in \mathcal{C}^\infty(M)[[\nu]] \qquad [21]$$

(iii) *Since $\mathfrak{D}$ as constructed above is a $\circ$-superderivation, $\ker(\mathfrak{D}) \cap \mathcal{W}$ is a $\circ$-subalgebra and a new associative product $*$ for $\mathcal{C}^\infty(M)[[\nu]]$, which turns out to be a star product, is defined by pullback of $\circ$ via $\tau$:*

$$f * g := \sigma(\tau(f) \circ \tau(g)) \qquad [22]$$

In the following, we shall refer to the associative product $*$ defined above as the Fedosov star product corresponding to $(\nabla, \Omega)$. The choice of the formal series of closed 2-forms $\Omega$ in fact has a crucial effect on the equivalence class of the resulting star product, whereas the choice of the torsion-free symplectic connection, which in contrast to a Riemannian connection is not unique, does not affect this class. This observation has been the main step in all the proofs of the classification results in deformation quantization of symplectic manifolds. Another way to prove this fact is to compute the characteristic class $c(*)$ introduced by Deligne (1995) using the methods developed in Gutt and Rawnsley (1999) directly which yields:

**Theorem 4** (Neumaier 2002, theorem 2). *Deligne's characteristic class $c(*)$ of a Fedosov star product $*$ as constructed above is given by*

$$c(*) = \frac{1}{\nu}[\omega] + \frac{1}{\nu}[\Omega] \qquad [23]$$

The properties of $\Omega$ with respect to complex conjugation also decide on whether $*$ is Hermitian or not. In case $\Omega$ is real, that is, satisfies $\overline{\Omega} = \Omega$ it is easy to show – observing that $\overline{a \circ b} = (-1)^{kl}\overline{b} \circ \overline{a}$ for $a \in \mathcal{W} \otimes \Lambda^k, b \in \mathcal{W} \otimes \Lambda^l$ – that $\overline{r}$ solves the equations that uniquely determine $r$ and hence $\overline{r} = r$. But then $\mathfrak{D}$ commutes with complex conjugation and

therefore the unique characterization of the Fedosov–Taylor series yields $\overline{\tau(f)} = \tau(\bar{f})$ for all $f \in \mathcal{C}^\infty(M)[[\nu]]$, implying that $*$ is Hermitian.

## Derivations, Automorphisms, and Equivalence Transformations

Having defined the Fedosov star product $*$ corresponding to $(\nabla, \Omega)$, the next logical step is to investigate the structure of its derivations and automorphisms and to find out how they can be described in the framework of Fedosov's construction. In addition, one can ask for an explicit construction of equivalence transformations between two Fedosov star products $*$ and $*'$ obtained from $(\nabla, \Omega)$ and $(\nabla', \Omega')$ that exist according to Theorem 4 iff $[\Omega] = [\Omega']$.

Since the basic philosophy of Fedosov's construction is to consider suitable operations on the algebra $(\mathcal{W} \otimes \Lambda, \circ)$ in order to obtain induced mappings on the level of $(\mathcal{C}^\infty(M)[[\nu]], *)$, one may expect to be able to define derivations of $(\mathcal{C}^\infty(M)[[\nu]], *)$ by considering appropriate fiberwise quasi-inner derivations of $(\mathcal{W} \otimes \Lambda, \circ)$ of the shape

$$\mathcal{D}_h = -\frac{1}{\nu}\mathrm{ad}(h) \qquad [24]$$

where $h \in \mathcal{W}$ and without loss of generality we assume $\sigma(h) = 0$. Our aim is to define $\mathbb{C}[[\nu]]$-linear derivations of $*$ by $\mathcal{C}^\infty(M)[[\nu]] \ni f \mapsto \sigma(\mathcal{D}_h \tau(f))$, but for an arbitrary element $h \in \mathcal{W}$ with $\sigma(h) = 0$ this mapping fails to be a derivation as $\mathcal{D}_h$ does not map elements of $\ker(\mathfrak{D}) \cap \mathcal{W}$ to elements of $\ker(\mathfrak{D}) \cap \mathcal{W}$. In order to achieve this, the supercommutator of $\mathfrak{D}$ and $\mathcal{D}_h$ has to vanish. As $\mathfrak{D}$ is a $\mathbb{C}[[\nu]]$-linear $\circ$-superderivation, we obviously have

$$[\mathfrak{D}, \mathcal{D}_h] = -\frac{1}{\nu}\mathrm{ad}(\mathfrak{D}h) \qquad [25]$$

and hence obviously $\mathfrak{D}h$ must be central, that is, $\mathfrak{D}h$ has to be of the shape $1 \otimes B$ with $B \in \Gamma^\infty(T^*M)[[\nu]]$ to have $[\mathfrak{D}, \mathcal{D}_h] = 0$. From $\mathfrak{D}^2 = 0$, we get that the necessary condition for the solvability of the equation $\mathfrak{D}h = 1 \otimes B$ is the closedness of $B$ since $\mathfrak{D}(1 \otimes B) = 1 \otimes \mathrm{d}B$. But as the $\mathfrak{D}$-cohomology is trivial on elements with positive antisymmetric degree, this condition is also sufficient for the solvability of the equation $\mathfrak{D}h = 1 \otimes B$ and we get the following statement.

**Lemma 1** (Müller-Bahns and Neumaier 2004, lemma 2.1).

(i) *For all formal series $B \in \Gamma^\infty(T^*M)[[\nu]]$ of closed 1-forms on $M$ there is a uniquely determined element $h_B \in \mathcal{W}$ such that $\mathfrak{D}h_B = 1 \otimes B$ and $\sigma(h_B) = 0$. Moreover, $h_B$ is explicitly given by*

$$h_B = \mathfrak{D}^{-1}(1 \otimes B) \qquad [26]$$

(ii) *For all $B \in Z^1_{\mathrm{deRham}}(M)[[\nu]]$ the mapping $D_B : \mathcal{C}^\infty(M)[[\nu]] \to \mathcal{C}^\infty(M)[[\nu]]$, where*

$$D_B f := \sigma(\mathcal{D}_{h_B}\tau(f)) = \sigma\left(-\frac{1}{\nu}\mathrm{ad}(h_B)\tau(f)\right) \qquad [27]$$

*for $f \in \mathcal{C}^\infty(M)[[\nu]]$ defines a $\mathbb{C}[[\nu]]$-linear derivation of $*$ and hence this construction yields a mapping $Z^1_{\mathrm{deRham}}(M)[[\nu]] \ni B \mapsto D_B \in \mathsf{Der}_{\mathbb{C}[[\nu]]}(\mathcal{C}^\infty(M)[[\nu]], \star)$.*

Furthermore, one can show that one even obtains all $\mathbb{C}[[\nu]]$-linear derivations of $*$ by varying $B$ in the derivations $D_B$ constructed above.

**Proposition 1** (Müller-Bahns and Neumaier 2004, proposition 2.2). *The mapping*

$$Z^1_{\mathrm{deRham}}(M)[[\nu]] \ni B \mapsto D_B \in \mathsf{Der}_{\mathbb{C}[[\nu]]}(\mathcal{C}^\infty(M)[[\nu]], *)$$

*defined in Lemma 1 is a bijection. Moreover, $D_{\mathrm{d}f}$ is a quasi-inner derivation for all $f \in \mathcal{C}^\infty(M)[[\nu]]$, that is, $D_{\mathrm{d}f} = (1/\nu)\mathrm{ad}_*(f)$ and the induced mapping $[B] \mapsto [D_B]$ from $H^1_{\mathrm{deRham}}(M)[[\nu]]$ to $\mathsf{Der}_{\mathbb{C}[[\nu]]}(\mathcal{C}^\infty(M)[[\nu]], *)/\mathsf{Der}^{\mathrm{qi}}_{\mathbb{C}[[\nu]]}(\mathcal{C}^\infty(M)[[\nu]], *)$ the space of $\mathbb{C}[[\nu]]$-linear derivations of $*$ modulo the quasi-inner derivations, also is bijective.*

Actually, it is well known that for an arbitrary star product $\star$ on a symplectic manifold the space of $\mathbb{C}[[\nu]]$-linear derivations is in bijection with $Z^1_{\mathrm{deRham}}(M)[[\nu]]$ and that the quotient space of these derivations modulo the quasi-inner derivations is in bijection with $H^1_{\mathrm{deRham}}(M)[[\nu]]$ (cf. Bertelson *et al.* (1997), theorem 4.2), but the remarkable thing about Fedosov star products is that these bijections can be explicitly expressed in terms of $\mathfrak{D}$ resp. $\mathfrak{D}^{-1}$ in a very lucid way.

Now we turn to the consideration of $\mathbb{C}[[\nu]]$-linear automorphisms of $*$. For such automorphisms that start with id, which are also called self-equivalences, it is known (cf. Gutt and Rawnsley (1999), Proposition 3.3) for arbitrary star products $\star$ on $(M, \omega)$ that they are of the form

$$A = \exp(\nu D) \qquad [28]$$

with a $\mathbb{C}[[\nu]]$-linear derivation $D$ of $\star$. Therefore, the above result about the description of all the derivations of $*$ directly yields a complete description of all self-equivalences of $*$.

The description of $\mathbb{C}[[\nu]]$-linear automorphisms that are not self-equivalences of $*$ is slightly more involved and we first need some results about the concrete structure of the equivalence transformations between two Fedosov star products $*$ and $*'$. To compare two Fedosov star products obtained from different torsion-free symplectic connections

$\nabla$ and $\nabla'$ and different but cohomologous formal series of 2-forms $\Omega$ and $\Omega'$, one has to compare the corresponding Fedosov derivations $\mathfrak{D}$ and $\mathfrak{D}'$. First recall some well-known facts about torsion-free symplectic connections on $(M,\omega)$. Given two such connections $\nabla$ and $\nabla'$, it is obvious that $S^{\nabla-\nabla'}(X,Y) := \nabla_X Y - \nabla'_X Y$, where $X, Y \in \Gamma^\infty(TM)$ defines a symmetric tensor field $S^{\nabla-\nabla'} \in \Gamma^\infty(\bigvee^2 T^*M \otimes TM)$ on $M$. Defining $\sigma^{\nabla-\nabla'}(X,Y,Z) := \omega(S^{\nabla-\nabla'}(X,Y),Z)$ it is easy to see that $\sigma^{\nabla-\nabla'} \in \Gamma^\infty(\bigvee^3 T^*M)$ is a totally symmetric tensor field. Conversely, given an arbitrary element $\sigma \in \Gamma^\infty(\bigvee^3 T^*M)$ and a symplectic torsion-free connection $\nabla$ and defining $S^\sigma \in \Gamma^\infty(\bigvee^2 T^*M \otimes TM)$ by $\sigma(X,Y,Z) = \omega(S^\sigma(X,Y),Z)$, then $\nabla^\sigma$ defined by $\nabla^\sigma_X Y := \nabla_X Y - S^\sigma(X,Y)$ again is a torsion-free symplectic connection and all such connections can be obtained this way by varying $\sigma$. Using these relations, one can compare the corresponding mappings $\nabla$ and $\nabla'$ on $\mathcal{W}\otimes\Lambda$. With the notations from above we have

$$\nabla - \nabla' = -(\mathrm{d}x^j \otimes \mathrm{d}x^i) i_s(S^{\nabla-\nabla'}(\partial_i,\partial_j)) = \frac{1}{\nu}\mathrm{ad}(T^{\nabla-\nabla'}) \qquad [29]$$

where $T^{\nabla-\nabla'} \in \Gamma^\infty(\bigvee^2 T^*M \otimes T^*M) \subseteq \mathcal{W}\otimes\Lambda^1$ is defined by $T^{\nabla-\nabla'}(Z,Y;X) := \sigma^{\nabla-\nabla'}(X,Y,Z) = \omega(S^{\nabla-\nabla'}(X,Y),Z)$. Moreover, $T^{\nabla-\nabla'}$ satisfies the equations

$$\delta T^{\nabla-\nabla'} = 0 \qquad [30a]$$

and

$$\nabla T^{\nabla-\nabla'} = R' - R + \frac{1}{\nu} T^{\nabla-\nabla'} \circ T^{\nabla-\nabla'}$$
$$\nabla' T^{\nabla-\nabla'} = R' - R - \frac{1}{\nu} T^{\nabla-\nabla'} \circ T^{\nabla-\nabla'} \qquad [30b]$$

where $R = (1/4)\omega_{it} R^t_{jkl} \mathrm{d}x^i \vee \mathrm{d}x^j \otimes \mathrm{d}x^k \wedge \mathrm{d}x^l$ and $R' = (1/4)\omega_{it} R'^t_{jkl} \mathrm{d}x^i \vee \mathrm{d}x^j \otimes \mathrm{d}x^k \wedge \mathrm{d}x^l$ denote the corresponding elements of $\mathcal{W}\otimes\Lambda^2$ that are built from the curvature tensors of $\nabla$ and $\nabla'$.

Now we are in the position to compare two Fedosov derivations $\mathfrak{D}$ and $\mathfrak{D}'$ resp. the induced star products $*$ and $*'$ obtained from $(\nabla,\Omega)$ and $(\nabla',\Omega)$. The idea for the construction of an equivalence transformation from $*$ to $*'$ is to look for an automorphism $\mathcal{A}_h$ of $(\mathcal{W}\otimes\Lambda, \circ)$ of the form

$$\mathcal{A}_h = \exp\left(\frac{1}{\nu}\mathrm{ad}(h)\right) \quad \text{such that } \mathfrak{D}' = \mathcal{A}_h \mathfrak{D} (\mathcal{A}_h)^{-1} \qquad [31]$$

where $h$ is an element of $\mathcal{W}_3$ guaranteeing that $\mathcal{A}_h$ is well defined and without loss of generality is assumed to satisfy $\sigma(h)=0$. In case one can find such an element $h$ it is clear that $\mathcal{A}_h$ yields a bijection between $\ker(\mathfrak{D})\cap\mathcal{W}$ and $\ker(\mathfrak{D}')\cap\mathcal{W}$ and hence one would obtain an equivalence $S_h$ from $*$ to $*'$ defining

$$S_h f := \sigma(\mathcal{A}_h \tau(f)) = \sigma\left(\exp\left(\frac{1}{\nu}\mathrm{ad}(h)\right)\tau(f)\right) \qquad [32a]$$

with inverse

$$(S_h)^{-1} f = \sigma((\mathcal{A}_h)^{-1}\tau'(f)) = \sigma\left(\exp\left(-\frac{1}{\nu}\mathrm{ad}(h)\right)\tau'(f)\right) \qquad [32b]$$

A direct computation yields

$$\mathcal{A}_h \mathfrak{D}(\mathcal{A}_h)^{-1} = \mathfrak{D} - \frac{1}{\nu}\mathrm{ad}\left(\frac{\exp((1/\nu)\mathrm{ad}(h)) - \mathrm{id}}{(1/\nu)\mathrm{ad}(h)}(\mathfrak{D}h)\right)$$

which is equal to $\mathfrak{D}'$ iff $h$ has been chosen such that

$$T^{\nabla-\nabla'} + r' - r - \frac{\exp(\frac{1}{\nu}\mathrm{ad}(h)) - \mathrm{id}}{\frac{1}{\nu}\mathrm{ad}(h)}(\mathfrak{D}h) \in \mathcal{W}\otimes\Lambda^1 \qquad [33]$$

is a central element. Considering the total degree of the terms in this expression, this is the case iff there is a formal series of 1-forms $C \in \nu\Gamma^\infty(T^*M)[[\nu]]$ such that the expression in eqn [33] equals $1\otimes C$. Applying $\mathfrak{D}$ to this equation and using the equations that $r$ and $r'$ satisfy together with the relations [30] it is cumbersome but not difficult to show that necessarily $\Omega$ and $\Omega'$ have to be cohomologous:

$$\Omega - \Omega' = \mathrm{d}C \qquad [34]$$

with $C$ as above. Now, using [6] one can show that this condition is in fact sufficient and moreover one can even determine the element $h$ in question recursively:

**Theorem 5** (Fedosov 1994, theorem 4.3). *Two Fedosov star products $*$ and $*'$ obtained from $(\nabla,\Omega)$ and $(\nabla',\Omega')$ are equivalent iff $\Omega$ and $\Omega'$ are cohomologous. In case $C \in \nu\Gamma^\infty(T^*M)[[\nu]]$ satisfies $\Omega - \Omega' = \mathrm{d}C$ there is a uniquely determined element $h_C \in \mathcal{W}_3$ with $\sigma(h_C)=0$ such that*

$$T^{\nabla-\nabla'} + r' - r - \frac{\exp((1/\nu)\mathrm{ad}(h_C)) - \mathrm{id}}{(1/\nu)\mathrm{ad}(h_C)}(\mathfrak{D}h_C) = 1\otimes C$$

*Moreover, $h_C$ can be determined recursively from*

$$h_C = C\otimes 1 + \delta^{-1}\left(\nabla h_C - \frac{1}{\nu}\mathrm{ad}(r)h_C - \frac{(1/\nu)\mathrm{ad}(h_C)}{\exp((1/\nu)\mathrm{ad}(h_C)) - \mathrm{id}}(r' - r + T^{\nabla-\nabla'})\right) \qquad [35]$$

*and with the so-constructed $h_C$ one has $\mathfrak{D}' = \mathcal{A}_{h_C}\mathfrak{D}(\mathcal{A}_{h_C})^{-1}$ and thus $S_{h_C}$ according to eqn [32] defines an equivalence transformation from $*$ to $*'$.*

Evidently, in the above construction of the equivalence transformation $S_{h_C}$ there is some choice of the formal series of 1-forms $C$. Different possible choices $C$ and $\widetilde{C}$ differ by a formal series of closed 1-forms but choosing $\widetilde{C}$ instead of $C$ amounts to another equivalence transformation $S_{h_{\widetilde{C}}} = A' S_{h_C} A$ from $*$ to $*'$, where $A$ and $A'$ are certain self-equivalences of $*$ and $*'$, respectively. In case $\Omega$ and $\Omega'$ are real, we have seen that $*$ as well as $*'$ are Hermitian star products and it is easy to verify that choosing a formal series $C$ of 1-forms as above that is moreover real yields an element $h_C$ satisfying $\overline{h_C} = h_C$. But then it is evident that the resulting equivalence transformation is also compatible with complex conjugation, that is, $\overline{S_{h_C} f} = S_{h_C}\overline{f}$ for all $f \in \mathcal{C}^\infty(M)[[\nu]]$.

Now we are prepared to give a construction of all $\mathbb{C}[[\nu]]$-linear automorphisms of a Fedosov star product $*$. It is easy to show that any $\mathbb{C}[[\nu]]$-linear automorphism of a star product $\star$ on a symplectic manifold is the combination of the action of a symplectomorphism $\psi : M \to M$ and an equivalence between $\star$ and the pullback $\star'$ via $\psi^{-1}$ of $\star$, which is defined by $f \star' g = (\psi^{-1})^*((\psi^* f) \star (\psi^* g))$ (cf. Gutt and Rawnsley (1999 Proposition 9.4)). Since the characteristic class of $\star'$ is given by $c(\star') = (\psi^{-1})^* c(\star)$, the necessary and sufficient condition for a symplectomorphism $\psi$ to define a possible zeroth-order term of an automorphism is that $(\psi^{-1})^* c(\star) = c(\star)$ since $\star'$ and $\star$ have to be equivalent.

Within Fedosov's framework, it can be shown that the pullback $*'$ via a symplectomorphism $\psi^{-1}$ of $*$ is identical to the Fedosov star product obtained from $(\nabla' = (\psi^{-1})^* \nabla \psi^*, \Omega' = (\psi^{-1})^* \Omega)$, which just expresses the functoriality of Fedosov's construction. Together with Theorem 4 this particularly shows that $c(*') = (\psi^{-1})^* c(*)$, and therefore $*'$ is equivalent to $*$ iff $\Omega$ and $\Omega'$ differ by a formal series $\mathrm{d}C_\psi$ of exact 2-forms, where $C_\psi \in \nu\Gamma^\infty(T^*M)[[\nu]]$ clearly depends on $\psi$. But in this situation one can apply the construction of equivalence transformations between Fedosov star products given in Theorem 5 with $C$ replaced by $C_\psi$ and $\nabla', \Omega'$ as above yielding an equivalence $S_{h_\psi} := S_{h_{C_\psi}}$ from $*$ to $*'$. Finally, we therefore get that the combination

$$A_\psi := \psi^* S_{h_\psi} \qquad [36]$$

is a $\mathbb{C}[[\nu]]$-linear automorphism of $*$ and it is obvious from the above that every such automorphism can be obtained by considering all symplectomorphisms $\psi$ of $(M, \omega)$ satisfying $[(\psi^{-1})^*\Omega] = [\Omega]$ and composing the resulting $A_\psi$ according to [36] with all self-equivalences $A$ of $*$ according to [28].

## Adaptions, Modifications, and Generalizations

The geometrical construction of Fedosov has gone through many adaptions and modifications that are well suited to the particular geometry of the underlying symplectic manifold. Moreover, there are generalizations that go beyond the case of symplectic manifolds and others that yield more general deformations than star products. We just give a few important examples that stress the power and beauty of Fedosov's construction.

On a Kähler manifold, one can define the notion of star products with separation of variables (cf. Karabegov (1996) that are also called star products of Wick type (cf. Bordemann and Waldmann (1997) and Neumaier (2003). These are star products such that in local holomorphic coordinates the bidifferential operators $C_r$ are of the form

$$C_r(f, g) = \sum_{K, \overline{L}} C_r^{K;\overline{L}} \frac{\partial^{|K|} f}{\partial z^K} \frac{\partial^{|\overline{L}|} g}{\partial \overline{z}^L} \qquad [37]$$

with certain coefficient functions $C_r^{K;\overline{L}}$. These star products can be obtained by a modified Fedosov construction starting from the product $\circ_{\mathrm{Wick}}$ on $\mathcal{W} \otimes \Lambda$ given by

$$a \circ_{\mathrm{Wick}} b = \mu\left(\exp\left(\frac{2\nu}{\mathrm{i}} g^{k\bar{l}} i_s(\partial_{z_k}) \otimes i_s(\partial_{\bar{z}_l})\right)(a \otimes b)\right) \qquad [38]$$

where $g^{k\bar{l}}$ denotes the components of the inverse of the Kähler metric in local holomorphic coordinates. In the case of a Kähler manifold, there is a distinguished torsion-free symplectic connection namely the Kähler connection $\nabla$ that induces a superderivation of $\circ_{\mathrm{Wick}}$ in a way completely analogous to [8]. With these structures the Fedosov construction works for an arbitrary formal series $\Omega$ of closed 2-forms as before, but one can show that the resulting star product is of Wick type iff $\Omega$ is of type (1, 1) and one can even show that one obtains all star products of Wick type by varying $\Omega$ (cf. Neumaier (2003)).

In the case of an almost-Kähler manifold, one can consider a product $\circ'$ on $\mathcal{W} \otimes \Lambda$ similar to $\circ_{\mathrm{Wick}}$ which is adapted to the almost-complex structure (cf. Karabegov and Schlichenmaier (2001)). However, in this situation there is no torsion-free connection that yields a superderivation of this product but only a connection $\nabla'$ with torsion that defines such a superderivation. Nevertheless, one

can consider a generalized Fedosov construction. To this end, one shows that $[\delta, \nabla'] = (1/\nu)\mathrm{ad}'(T')$ with some $T' \in \mathcal{W} \otimes \Lambda^2$ that satisfies $\delta T' = 0$ and encodes the torsion of $\nabla'$ and $\delta R' = \nabla' T'$, where again $\nabla'^2 = -(1/\nu)\mathrm{ad}'(R')$ and $R'$, which depends on the curvature of $\nabla'$, satisfies $\nabla' R' = 0$. But then it is easy to show that there is a unique element $r' \in \mathcal{W}_2 \otimes \Lambda^1$ such that

$$\delta r' = \nabla' r' - \frac{1}{\nu} r' \circ' r' + T' + R' + 1 \otimes \Omega$$

and

$$\delta^{-1} r' = 0 \qquad [39]$$

with $\Omega$ as above, which can also be computed recursively. Clearly, $\mathfrak{D}' = -\delta + \nabla' - (1/\nu)\mathrm{ad}'(r')$ then is a suitable Fedosov derivation with square zero for $\circ'$ and one can proceed as described earlier to obtain a star product $*'$ adapted to the almost-complex structure.

On a cotangent bundle $\pi : T^*Q \to Q$, where $T^*Q$ is equipped with the canonical symplectic form $\omega_0 = -\mathrm{d}\theta_0$, one can consider (cf. Bordemann *et al.* (1998)) the following so-called standard ordered product $\circ_{\mathrm{std}}$ on $\mathcal{W} \otimes \Lambda$ given by

$$a \circ_{\mathrm{std}} b = \mu\Big(\exp\Big(-\nu i_{\mathrm{s}}(\partial_{p_i}) \otimes i_{\mathrm{s}}(\partial_{q^i} + p_l \pi^* \Gamma^l_{ik} \partial_{p_k})\Big) \times (a \otimes b)\Big) \qquad [40]$$

in local Darboux coordinates. Here $\Gamma^l_{ik}$ denotes the Christoffel symbols of a torsion-free connection $\nabla^Q$ on $Q$ in the chart of $Q$ corresponding to the bundle chart $(q, p)$ and it is straightforward to see that $\circ_{\mathrm{std}}$ does not depend on the chosen local coordinates and is associative. In the present situation, one can define a torsion-free symplectic connection $\nabla^{T^*Q}$ on $T^*Q$ solely in terms of $\nabla^Q$ but then the corresponding mapping $\nabla^{T^*Q}$ on $\mathcal{W} \otimes \Lambda$ again fails to be a superderivation of $\circ_{\mathrm{std}}$, whereas the combination $\nabla^{T^*Q} + \mathcal{B}$ with $\mathcal{B} = (\nu/3) p_l \pi^* R^l_{jik} (1 \otimes \mathrm{d}q^i) i_{\mathrm{s}}(\partial_{p_j}) i_{\mathrm{s}}(\partial_{p_k})$, where $R^l_{jik}$ denotes the components of the curvature tensor of $\nabla^Q$, turns out to be a suitable superderivation to start the Fedosov construction with $\circ_{\mathrm{std}}$. In fact, the square of $\nabla^{T^*Q} + \mathcal{B}$ turns out to equal the square of $\nabla^{T^*Q}$ and all the other preconditions of Fedosov's construction are easily verified just replacing $\nabla$ by $\nabla^{T^*Q} + \mathcal{B}$. The particular property of the resulting star product $*_{\mathrm{std}}$ for $\Omega = 0$ on $T^*Q$ is that it is a standard ordered star product, that is, for all $f \in \mathcal{C}^\infty(T^*Q)[[\nu]]$ and all $\chi \in \mathcal{C}^\infty(Q)[[\nu]]$ one has

$$\pi^* \chi *_{\mathrm{std}} f = \pi^* \chi f \qquad [41]$$

and hence $*_{\mathrm{std}}$ in a certain sense is adapted to the vertical polarization.

The methods mentioned so far can even be melted into a more general situation, where one considers a (complex) polarization on $(M, \omega)$ and looks for star products that are adapted to this polarization which are then called polarized deformation quantizations (cf. Donin (2003)). Here again a generalization of Fedosov's construction yields the existence and the classification of such particular star products.

Another recent generalization of Fedosov's construction that goes beyond the framework of smooth symplectic manifolds is that of the construction of star products on symplectic orbispaces (cf. Pflaum (2003)), which are stratified symplectic spaces. The main idea there is to consider Fedosov's construction in local orbicharts and to show that the changes of orbicharts induce isomorphisms between the locally defined deformation quantizations, implying that the locally defined products match together to define a global deformation quantization on the symplectic orbispace. To achieve this property, one has to adjust the local Fedosov constructions appropriately, that is, one has to use locally defined torsion-free symplectic connections and formal series of closed 2-forms that are related by the changes of the orbicharts.

Considering a vector bundle $E \to M$, the sections $\Gamma^\infty(E)$ are naturally a $\mathcal{C}^\infty(M)$-right module and a $\Gamma^\infty(\mathsf{End}(E))$-left module, and it is a natural question whether this bimodule structure can be deformed such that $\Gamma^\infty(E)[[\nu]]$ becomes a $(\mathcal{C}^\infty(M)[[\nu]], \star)$-right module and a $(\Gamma^\infty(\mathsf{End}(E))[[\nu]], \bigstar)$-left module, where $\bigstar$ is a deformation of the usual composition of elements of $\Gamma^\infty(\mathsf{End}(E))$. In order to construct such deformations, one can also adapt Fedosov's construction (cf. Waldmann (2002)) considering $\mathcal{W} \otimes \Lambda \otimes \mathcal{E} = (\mathsf{X}_{s=0}^\infty \Gamma^\infty(\bigvee^s T^*M \otimes \bigwedge T^*M \otimes E))[[\nu]]$ and $\mathcal{W} \otimes \Lambda \otimes \mathcal{E}nd(\mathcal{E}) = (\mathsf{X}_{s=0}^\infty \Gamma^\infty \ (\bigvee^s T^*M \otimes \bigwedge T^*M \otimes \mathsf{End}(E)))[[\nu]]$ and extending the product $\circ$ to these spaces in a natural way making $\mathcal{W} \otimes \Lambda \otimes \mathcal{E}$ a $(\mathcal{W} \otimes \Lambda \otimes \mathsf{End}(\mathcal{E}), \circ) - (\mathcal{W} \otimes \Lambda, \circ)$-bimodule. Furthermore, one has to consider a connection $\nabla^E$ that naturally induces a connection on $\mathsf{End}(E)$, and both have to be added to $\nabla$ to define the corresponding substitute of $\nabla$ on the respective space. Then the Fedosov construction with $\mathcal{W} \otimes \Lambda \otimes \mathcal{E}nd(\mathcal{E})$ can be considered yielding a Fedosov derivation $\mathfrak{D}^{\mathsf{End}(E)}$ with square zero, hence a Fedosov–Taylor series $\tau^{\mathsf{End}(E)}$ and an associative deformation $F \circledast G = \sigma(\tau^{\mathsf{End}(E)}(F) \circ \tau^{\mathsf{End}(E)}(G))$ of the usual composition of sections in the endomorphism bundle. Moreover, there is a map $\mathfrak{D}^E$ on $\mathcal{W} \otimes \Lambda \otimes \mathcal{E}$ that is a superderivation with respect to the bimodule multiplication $\circ$ along $\mathfrak{D}^{\mathsf{End}(E)}$ and $\mathfrak{D}$, respectively. This map also has square zero and the intersection of its kernel with the elements of antisymmetric degree is in bijection to $\Gamma^\infty(E)[[\nu]]$ via a natural generalization $\tau^E$ of the Fedosov–Taylor

series. Defining $F \odot s := \sigma(\tau^{\mathsf{End}(E)}(F) \circ \tau^E(s))$ and $s \cdot f := \sigma(\tau^E(s) \circ \tau(f)), \Gamma^\infty(E)[[\nu]]$ can be given the structure of a $(\Gamma^\infty(\mathsf{End}(E))[[\nu]], \circledast)$-$(\mathcal{C}^\infty(M)[[\nu]], *)$-bimodule which is indeed a deformation of the classical bimodule structure of $\Gamma^\infty(E)$. It is rather evident that the same procedure also works for other products on $\mathcal{W} \otimes \Lambda$ and the above generalizations, in particular for the product $\circ_{\mathrm{Wick}}$ on a Kähler manifold, where one can obtain $(\Gamma^\infty(\mathsf{End}(E))[[\nu]], \circledast_{\mathrm{Wick}})$-$(\mathcal{C}^\infty(M)\ [[\nu]], *_{\mathrm{Wick}})$-bimodules that are adapted to the complex structure in case the curvature endomorphism of the connection $\nabla^E$ is of type $(1,1)$. For example, this holds true for (anti-) holomorphic vector bundles endowed with a Hermitian fiber metric $h$ and the corresponding connection that is compatible with $h$ and the (anti-) holomorphic structure.

Finally, the proof of existence of deformation quantizations on arbitrary Poisson manifolds $(M, \Pi)$, that includes a concrete construction starting from Kontsevich's star product on the flat space $\mathbb{R}^n$ equipped with a Poisson tensor, given by Cattaneo *et al.* (2002) is similar in spirit to Fedosov's construction. There one constructs two bundles $J^\infty$ and $\mathcal{J}^\infty$ of associative algebras, where – as a bundle – $\mathcal{J}^\infty$ is isomorphic to $J^\infty[[\nu]]$ and $J^\infty$ is the bundle of infinite jets of smooth functions on $M$ which is equipped with the canonical flat connection $D_0$. The Poisson tensor gives rise to the structure of a Poisson algebra on each fiber of $J^\infty$ and the canonical map $\mathcal{C}^\infty(M) \to J^\infty$ yields a Poisson algebra isomorphism between $\mathcal{C}^\infty(M)$ and the Poisson algebra of $D_0$-flat sections in $J^\infty$. The second step in the construction consists in a deformation of this correspondence. Using the Kontsevich formula for $\mathbb{R}^n$, each fiber of $\mathcal{J}^\infty$ can be equipped with an associative product which is a deformation of the above product on the fibers of $J^\infty$ in the direction of the Poisson bracket induced by $\Pi$. Then analogously to Fedosov's construction, one constructs a compatible connection $D = D_0 + \nu D_1 + \nu^2 D_2 + \cdots$ which is a deformation of $D_0$. Here compatibility just means that $D$ is a derivation with respect to the above product on sections in $\mathcal{J}^\infty$ implying that the $D$-flat sections form a subalgebra. Moreover, one can achieve that this connection is flat and in this case $\mathcal{C}^\infty(M)[[\nu]]$ turns out to be in bijection to the $D$-flat sections in $\mathcal{J}^\infty$. For the proof of existence of $D$ and for its recursive determination using an adaption of Fedosov's method, again special cases of Kontsevich's formality theorem prove to be the crucial tools. Pulling back the above fiberwise product to $\mathcal{C}^\infty(M)[[\nu]]$ via this isomorphism, one then obtains a star product on $(M, \Pi)$. Since this isomorphism can be determined recursively, the star product can in principle be computed explicitly.

## Quantum Statistics

Quantum particles are described by a complex, square-integrable wave function $\Psi(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N)$ with $|\Psi|^2$ representing the probability density of finding $N$ particles at positions $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N$, which will be assumed to be in a $d$-dimensional square box $V$ with side $L$ and periodic boundary conditions. If the $N$ particles are identical, $|\Psi|^2$ must be totally symmetric in the exchange of any pair of coordinates. Regarding the symmetry properties of $\Psi$ itself, it is an experimental fact (which finds its theoretical explanation in the context of relativistic quantum field theory) that only two possibilities can arise: either $\Psi$ is symmetric or it is antisymmetric, which means that $\Psi(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N) = (-1)^P \Psi(\boldsymbol{x}_{P_1}, \ldots, \boldsymbol{x}_{P_N})$, where $P_1, \ldots, P_N$ is a permutation of $1, \ldots, N$, and $(-1)^P$ is the parity of the permutation. Particles described by a symmetric wave function are called bosons, while particles with an antisymmetric wave function are called fermions, after Bose and Fermi, who introduced these concepts. The fermionic wave function therefore vanishes if two coordinates are equal, a property called Pauli exclusion principle. Particles have an intrinsic quantized angular momentum called spin and particles with semi-integer spin are fermions, while particles with integer spin are bosons. Examples of fermions are electrons, protons, or neutrons, with spin $\sigma = \pm\hbar/2$, where $\hbar$ is the Plank constant; examples of bosons are phonons or mesons with integer spin.

The time evolution of a wave function is driven (through the Schrödinger equation) by the Hamiltonian operator, and the choice of such an operator is determined by the physical system we want to describe. One of the most important physical realizations of a fermionic system is given by the conduction electrons in solids with a crystalline structure (like metals). According to the classical theory of Drude, a crystal can be described as a lattice of atoms in which the valence electrons are lost by the atoms (which become ions) and move freely in the metal; they are responsible for the conduction properties of the crystal. However, if one assumes that the electrons are classical particles (in the sense that they obey the Newtonian mechanics), one obtains wrong predictions about the properties of crystals. One has to take into account that the conduction electrons are quantum particles and this provides us with a natural example of a fermionic system; the Hamiltonian can be taken as

$$H_N = \sum_{i=1}^{N} \left[ -\frac{\hbar^2 \partial^2_{\boldsymbol{x}_i}}{2m} + uc(\boldsymbol{x}_i) \right] + \sum_{i<j} \lambda v(\boldsymbol{x}_i - \boldsymbol{x}_j) \quad [1]$$

The first term represents the nonrelativistic kinetic energy of the electrons ($m$ is the mass), $uc(\boldsymbol{x})$ is a periodic potential due to the ions in the lattice ($c(\boldsymbol{x}) = c(\boldsymbol{x} + \boldsymbol{R})$ with $\boldsymbol{R} = (n_1 a_1, \ldots, n_d a_d), n_i \in Z$) and $\lambda v(\boldsymbol{x} - \boldsymbol{y})$ is a two-body interaction potential, which is modeled by a short-range potential to take into account, phenomenologically, the electrostatic screening. Finally, $\lambda$ and $u$ are couplings which measure the "strength" of the corresponding interaction. Much more complicated and "realistic" Hamiltonians could be considered; for instance, one can add an interaction with a stochastic field to take into account impurities in the lattice, or with a boson field to take into account the dynamics of the ions, and so on. Note also that one can study not only three-dimensional Fermi systems ($d = 3$), but also $d = 2$ or $d = 1$ systems; they can describe the conduction electrons of crystals that are anisotropic and should be considered as bidimensional or one-dimensional systems. We focus on the nonrelativistic

fermionic systems with Hamiltonian [1], which is a problem of great importance from both the conceptual and the applications point of view.

## Second-Quantization Formalism

The Hilbert space of states of a system of $N > 1$ fermions is the space $\mathcal{H}_N$ of all the complex square-integrable antisymmetric functions $\Psi(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N)$. Let $\{\phi_{\boldsymbol{k}}(\boldsymbol{x})\}_{\boldsymbol{k}\in R^d}$ be a basis for $\mathcal{H}_1$ (the one-particle Hilbert space of all the complex square-integrable functions $\Psi(\boldsymbol{x}_1)$), where $\boldsymbol{k}$ is an index called quantum number. Usually, the set of $\phi_{\boldsymbol{k}}(\boldsymbol{x})$ is chosen as the eigenfunctions of the single-particle Hamiltonian

$$-\frac{\hbar^2\partial_{\boldsymbol{x}}^2}{2m} + uc(\boldsymbol{x})$$

for instance, if $u = 0$ then

$$\phi_{\boldsymbol{k}}(\boldsymbol{x}) = \frac{1}{L^{d/2}}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\boldsymbol{x}}$$

with $\hbar\boldsymbol{k}$ representing the momentum; due to periodic boundary conditions, $\boldsymbol{k}$ has the form $\boldsymbol{k} = (2\pi/L)\boldsymbol{n}$, $\boldsymbol{n} = n_1, \ldots, n_d$ with $n_i$ integer and $-[L/2] \le n_i \le [(L-1)/2]$. If we call $|\boldsymbol{k}_1, \ldots, \boldsymbol{k}_N\rangle$ the normalized antisymmetrization of $\phi_{\boldsymbol{k}_1}(\boldsymbol{x}_1)\phi_{\boldsymbol{k}_2}(\boldsymbol{x}_2)\cdots\phi_{\boldsymbol{k}_N}(\boldsymbol{x}_N)$ (Slater determinant), then the set of all possible $|\boldsymbol{k}_1, \ldots, \boldsymbol{k}_N\rangle$ is a basis for $\mathcal{H}_N$; $|\boldsymbol{k}_1, \ldots, \boldsymbol{k}_N\rangle$ describes a state in which the $N$ fermions have quantum numbers $\boldsymbol{k}_1, \ldots, \boldsymbol{k}_N$. One can introduce (Negele and Orland 1988, Berezin 1966) the creation or annihilation operators $a_{\boldsymbol{k}}^+, a_{\boldsymbol{k}}^-$: they are anticommuting operators,

$$\begin{aligned} \{a_{\boldsymbol{k}}^+, a_{\boldsymbol{k}'}^-\} &\equiv a_{\boldsymbol{k}}^+ a_{\boldsymbol{k}'}^- + a_{\boldsymbol{k}'}^- a_{\boldsymbol{k}}^+ = \delta_{\boldsymbol{k},\boldsymbol{k}'} \\ \{a_{\boldsymbol{k}}^+, a_{\boldsymbol{k}'}^+\} &= \{a_{\boldsymbol{k}}^-, a_{\boldsymbol{k}'}^-\} = 0 \end{aligned} \qquad [2]$$

such that $a_{\boldsymbol{k}}^+|\boldsymbol{k}_1, \ldots, \boldsymbol{k}_N\rangle = |\boldsymbol{k}, \boldsymbol{k}_1, \ldots, \boldsymbol{k}_N\rangle$ if $\boldsymbol{k} \neq \boldsymbol{k}_i$, $i = 1, \ldots, N$ and 0 otherwise; $a_{\boldsymbol{k}}^-$ is the adjoint of $a_{\boldsymbol{k}}^+$. The action of $a_{\boldsymbol{k}}^+$ is to create a particle with quantum number $\boldsymbol{k}$ if it is not present in the state, and to yield zero otherwise (according to the Pauli principle). The state $|0\rangle$ such that $a_{\boldsymbol{k}}^-|0\rangle = 0$ for all $\boldsymbol{k}$ is called the vacuum state and it represents a state with no particles. The Fock space is defined as the direct sum of the Hilbert spaces with any number of particles, and all the elements of the Fock space can be generated by linearly superposing products of creation operators acting over the vacuum state. We can extend such definitions by adding a label to such operators to take into account the spin of the particle; for example, $a_{\boldsymbol{k},\sigma}^\pm$ are creation or annihilation operators of a particle with spin $\sigma$ and position $\boldsymbol{k}$. In terms of $a_{\boldsymbol{x},\sigma}^+ = L^{-d/2}\sum_{\boldsymbol{k}}\phi_{\boldsymbol{k}}(\boldsymbol{x})a_{\boldsymbol{k},\sigma}^+$ and of its adjoint $a_{\boldsymbol{x},\sigma}^-$, the Hamiltonian can be written as

$$\begin{aligned} H = &\sum_\sigma\left[\int_V \mathrm{d}\boldsymbol{x}\, a_{\boldsymbol{x},\sigma}^+ \frac{-\hbar^2\partial_{\boldsymbol{x}}^2}{2m} a_{\boldsymbol{x},\sigma}^-\right. \\ &\left. + u\int_V \mathrm{d}\boldsymbol{x}\, c(\boldsymbol{x}) a_{\sigma,\boldsymbol{x}}^+ a_{\boldsymbol{x},\sigma}^-\right] \\ &+ \sum_{\sigma,\sigma'}\lambda\int_V \mathrm{d}\boldsymbol{x}\int_V \mathrm{d}\boldsymbol{y}\, v(\boldsymbol{x}-\boldsymbol{y}) a_{\boldsymbol{x},\sigma}^+ a_{\boldsymbol{x},\sigma}^- a_{\boldsymbol{y},\sigma'}^+ a_{\boldsymbol{y},\sigma'}^- \end{aligned} \qquad [3]$$

According to the postulates of quantum statistical mechanics, the grand canonical partition function is given by $Z = \mathrm{tr}\,\mathrm{e}^{-\beta(H-\mu N)}$, where $\beta = (\kappa T)^{-1}$, $\kappa$ is the Boltzmann constant, $T$ is the temperature, $\mu$ is the chemical potential, $N = \sum_\sigma\int \mathrm{d}\boldsymbol{x}\, a_{\boldsymbol{x},\sigma}^+ a_{\boldsymbol{x},\sigma}^-$, and tr is the trace operation over the Fock space. The thermodynamical average of an observable O is given by $\langle O\rangle = Z^{-1}\mathrm{tr}[\mathrm{e}^{-\beta(H-\mu N)}O]$. Given a fermionic system, one is often interested in its Schwinger functions defined as follows: if $\boldsymbol{x} = (\boldsymbol{x}, t)$ and $t_1 \ge t_2 \ge \cdots \ge t_s$, $s$ even, then

$$S(\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_s) = \frac{\mathrm{tr}\,\mathrm{e}^{-(\beta-t_1)(H-\mu N)}\psi_{\boldsymbol{x}_1}^{\varepsilon_1}\mathrm{e}^{-(t_1-t_2)(H-\mu N)}\psi_{\boldsymbol{x}_2}^{\varepsilon_2}\cdots\mathrm{e}^{-t_s(H-\mu N)}}{\mathrm{tr}\,\mathrm{e}^{-\beta(H-\mu N)}} \qquad [4]$$

with $\varepsilon_i = \pm, -\beta/2 \le t_i \le \beta/2$; periodic and antiperiodic boundary conditions are, respectively, imposed over $x_i$ and $t_i$. From the knowledge of the Schwinger functions, one can compute all the thermodynamical properties of a system at equilibrium or close to equilibrium.

## The Free Fermi Gas

Computation of the physical observables corresponding to the complete Hamiltonian [3] is a very difficult task. The natural starting point consists in taking into account only the kinetic term by putting $\lambda = u = 0$ in [3], obtaining the free Fermi gas model. The resulting model is not trivial at all; its properties are radically different with respect to the ones of a gas of classical particles, and it is sufficient to understand many properties of matter (see, e.g., Mahan (1990)). If

$$\phi_{\boldsymbol{k}}(\boldsymbol{x}) = \frac{1}{L^{d/2}}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\boldsymbol{x}}$$

then $|\boldsymbol{k}_1, \sigma_1, \ldots, \boldsymbol{k}_N, \sigma_N\rangle$ are eigenfunctions of $H$ with eigenvalue $\sum_{\boldsymbol{k},\sigma}\varepsilon(\boldsymbol{k})n_{\boldsymbol{k},\sigma}$, where $\varepsilon(\boldsymbol{k}) = \hbar^2|\boldsymbol{k}|^2/2m$ and $n_{\boldsymbol{k},\sigma} = 0{,}1$, the occupation number, is the eigenvalue $a_{\boldsymbol{k},\sigma}^+ a_{\boldsymbol{k},\sigma}^-$; $n_{\boldsymbol{k},\sigma} = 1$ if in the state there is a fermion with momentum $\boldsymbol{k}$ and spin $\sigma$, and it is zero otherwise. The eigenfunction $|\Omega\rangle$ of $H$ with lowest energy is called the ground state, and it determines the low-temperature properties of the system. In order to find the ground state $|\Omega\rangle$, one has

to minimize $\sum_{k,\sigma} \varepsilon(\boldsymbol{k}) n_{\boldsymbol{k},\sigma}$ with the constraint that $n_{\boldsymbol{k},\sigma}$ can take only the values 0 or 1 and $\sum_{\boldsymbol{k},\sigma} n_{\boldsymbol{k},\sigma} = N$; if there are many solutions to this problem, one says that the ground state is degenerate. An approximate solution is the following: if $d = 3$, one can consider a state such that $n_{\boldsymbol{k},\sigma} = 1$ if $\boldsymbol{k}$ is in a sphere of radius $k_{\mathrm{F}}$ and zero otherwise; since the number of momenta $\boldsymbol{k} = (2\pi/L)\boldsymbol{n}$ in the sphere is approximately given by

$$2\frac{4\pi k_{\mathrm{F}}^2}{3}\frac{L^3}{8\pi^2}$$

we can choose $k_{\mathrm{F}} = (3\pi^2\rho)^{1/3}$, with $\rho = NL^{-3}$. The state $\prod_{|\boldsymbol{k}| \le k_{\mathrm{F}}} a^+_{1/2,\boldsymbol{k}} a^+_{-1/2,\boldsymbol{k}} |0\rangle$ is not the true ground state when $N$,$L$ are finite, but it is a very good approximation of it and converges to it (in a suitable sense) in the limit $N$,$L \to \infty$, $\rho$ fixed. The boundary of the sphere with radius $k_{\mathrm{F}}$ in the space of momenta is called the Fermi surface, and it is a key notion in the theory of Fermi systems; if $d = 2$, it is replaced by a circle and in $d = 1$ by two points.

Coming to the thermodynamical properties, the partition function is given by

$$Z = \prod_{\boldsymbol{k}} \sum_{n_{\boldsymbol{k}}=0,1} \mathrm{e}^{-\beta(\varepsilon(\boldsymbol{k})-\mu)n_{\boldsymbol{k}}} = \prod_{\boldsymbol{k}} (1 + \mathrm{e}^{-\beta(\varepsilon_{\boldsymbol{k}}-\mu)})$$

and the specific heat by

$$C_v = -\frac{\partial}{\partial T}\frac{\partial}{\partial \beta}\log Z$$

One finds, by expressing $\mu$ in terms of $\beta$ through the relation $N = -\partial f/\partial\mu$, that if $d = 3$, in the $L \to \infty$ limit

$$C_v = \frac{\pi^2}{2}\rho\kappa\left(\frac{\kappa T}{\varepsilon_{\mathrm{F}}}\right) + O\left(\frac{\kappa T}{\varepsilon_{\mathrm{F}}}\right)^2$$

where $\varepsilon_{\mathrm{F}} = \hbar^2 k_{\mathrm{F}}^2/2m$. Early models for metals described the electrons as classical particles; however in such a case, a well-known result of classical statistical mechanics states that they should contribute to the specific heat by $\frac{3}{2}\rho\kappa$, while experimentally their contribution is much smaller. The solution of this puzzle was provided by the above formula for $C_v$; the classical value is in fact depressed by a factor

$$\frac{\pi^2}{3}\frac{\kappa T}{\varepsilon_{\mathrm{F}}}$$

which at room temperatures is $O(10^{-2})$, in agreement with experimental data. The average number of electrons with momentum $\hbar\boldsymbol{k}$ is given, in the infinite-volume limit, by

$$\left\langle a^+_{\boldsymbol{k},\sigma} a^-_{\boldsymbol{k},\sigma} \right\rangle = (1 + \mathrm{e}^{\beta(\varepsilon(\boldsymbol{k})-\mu)})^{-1}$$

At zero temperature, it reduces to $\theta(|\boldsymbol{k}| \le k_F)$, that is, it has a discontinuity at the Fermi surface, while at high temperatures it is very close to the Maxwell distribution $\simeq \mathrm{e}^{-\beta(\varepsilon(\boldsymbol{k})-\mu)}$.

Finally, in the free Fermi gas model, all Schwinger functions can be computed. One finds that, if, for instance, $\varepsilon_i = +$ for $i = 1, 2, \ldots, s/2$ and $\varepsilon_i = -$ otherwise, that the Schwinger function with $s \ge 4$ can be expressed as sum of products of the $s = 2$ Schwinger function (also called the propagator)

$$S(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_s) = \sum_{\pi} (-1)^{\pi} \prod_{i,j} S_0\left(\boldsymbol{x}_i - \boldsymbol{x}_{\pi(j)}\right) \qquad [5]$$

where $i = 1, \ldots, s/2$, $j = s/2 + 1, \ldots, s$, $\pi_j$ is a permutation of $j = s/2 + 1, \ldots, s$,$(-1)^{\pi}$ is the parity of this permutation, $\sum_{\pi}$ is the sum over all the possible permutations; such a formula is called the Wick rule. By an explicit computation, $S_0(\boldsymbol{x} - \boldsymbol{y})$ is given by

$$\begin{aligned} &\frac{2\pi}{\beta} \sum_{k_0 = 2\pi(n_0+1/2)\beta^{-1}} \left(\frac{2\pi}{L}\right)^d \sum_{\boldsymbol{k}=(2\pi/L)\boldsymbol{n}} \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{k}(\boldsymbol{x}-\boldsymbol{y})}}{-\mathrm{i}k_0 + |\boldsymbol{k}|^2/2m - \mu} \\ &\quad \equiv \frac{2\pi}{\beta} \sum_{k_0 = 2\pi(n_0+1/2)\beta^{-1}} \left(\frac{2\pi}{L}\right)^d \sum_{\boldsymbol{k}=(2\pi/L)\boldsymbol{n}} \mathrm{e}^{\mathrm{i}\boldsymbol{k}(\boldsymbol{x}-\boldsymbol{y})} \hat{S}_0(\boldsymbol{k}) \end{aligned} \qquad [6]$$

where $\boldsymbol{k} = (k_0, \boldsymbol{k})$. In the limit $L, \beta \to \infty$, for large distances $S(\boldsymbol{x}, \boldsymbol{y})$ decays as a power law, $O(|\boldsymbol{x} - \boldsymbol{y}|^{-1})$ times an oscillating function of period $k_{\mathrm{F}}^{-1}$. Note that $S_0(\boldsymbol{k})$ in the limit $\beta, L \to \infty$ diverges for $k_0 = 0$ and $\varepsilon(\boldsymbol{k}) = \mu$, that is, at the Fermi surface ($\mu = \varepsilon_{\mathrm{F}}$ in the limit $\beta \to \infty$); when $\beta$ is finite, $S_0(\boldsymbol{k})$ is finite even for $L \to \infty$, that is, the finite temperature acts as an infrared cutoff.

## Fermions in an External Potential

The next step consists in adding an external periodic potential to the free Fermi gas model, taking into account the field generated by the ions of the lattice. We consider then [3] with $\lambda = 0$ and $u \ne 0$. As in the previous case, the eigenfunctions of the $N$-particle Hamiltonian can be computed and are expressed in terms of the single-particle eigenfunctions of $-\hbar^2\partial_{\boldsymbol{x}}^2/2m + uc(\boldsymbol{x})$; they are called Bloch waves and have the form

$$\phi_{\boldsymbol{k}}(\boldsymbol{x}) = \frac{1}{\sqrt{L^{d/2}}}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\boldsymbol{x}} u_{\boldsymbol{k}}(\boldsymbol{x}), \quad u_{\boldsymbol{k}}(\boldsymbol{x}) = u_{\boldsymbol{k}}(\boldsymbol{x} + \boldsymbol{R})$$

$\boldsymbol{k}$, called the crystalline momentum, is conserved modulo $\boldsymbol{G}$, the vectors of the reciprocal lattice, defined as

$$G = 2\pi\left(\frac{n_1}{a_1}, \ldots, \frac{n_d}{a_d}\right)$$

The eigenvalue $\varepsilon(\boldsymbol{k})$ of $-\hbar^2\partial_{\boldsymbol{x}}^2/2m + uc(\boldsymbol{x})$ associated with a Bloch wave $\phi_{\boldsymbol{k}}(\boldsymbol{x})$ has some peculiar properties; in the $L \to \infty$ limit, one finds that $\varepsilon(\boldsymbol{k})$ is not a continuous function (unlike the $u = 0$ case) but it has gaps, that is, first-order discontinuities. For $d = 1$, by a convergent power-series expansion in $u$, one finds that $\varepsilon(\boldsymbol{k})$ is a continuous monotonically increasing function except at the points $\pm\pi n/a$, $n$ an integer; at these points $\varepsilon(\boldsymbol{R})$ is discontinuous and $\varepsilon((n\pi/a)^+) - \varepsilon((n\pi/a)^-) \equiv \Delta_n = u\hat{c}_n + O(u^2)$; the gaps divide $\varepsilon(\boldsymbol{k})$ into disconnected pieces called energy bands. Something similar happens in $d = 2, 3$, in which gaps open for $\boldsymbol{R}$ such that $\boldsymbol{G}^2 + 2\boldsymbol{k}\boldsymbol{G} = 0$.

Again, the eigenfunctions of $H$ are given by $|\boldsymbol{k}_1, \sigma_1, \ldots, \boldsymbol{k}_N, \sigma_N\rangle$ with eigenvalue $\sum_{\boldsymbol{k},\sigma} \varepsilon(\boldsymbol{k}) n_{\boldsymbol{k},\sigma}$, and the Fermi surface is still defined by the set $\boldsymbol{k}$ such that $\varepsilon(\boldsymbol{k}) = \varepsilon_{\mathrm{F}}$ with $\varepsilon_{\mathrm{F}}$ determined by the condition $\sum_{\boldsymbol{k}:\varepsilon(\boldsymbol{k})} \leq \varepsilon_F\ 1 = N$. However, in this case the Fermi surface is not anymore a sphere in $d = 3$, but it is in general a polyhedron of a very complex shape. The Schwinger functions are expressed by the Wick rule [5] in terms of the two-point Schwinger functions; they are given by [6] with $e^{i\boldsymbol{k}(x-y)}$ replaced by $\phi_{\boldsymbol{k}}(\boldsymbol{x})\phi_{\boldsymbol{k}}^*(\boldsymbol{y})$ and $|\boldsymbol{k}|^2/2m$ replaced by $\varepsilon(\boldsymbol{k})$. The asymptotic properties of the two-point Schwinger function are quite different with respect to the $u = 0$ case. This is easy to see if $d = 1$; in the limit $L, \beta \to \infty$, $S(\boldsymbol{k})$ is singular if $\mu$ does not belong to the interval $[\varepsilon((n\pi/a)^+), \varepsilon((n\pi/a)^-)]$, whereas it is finite if $\mu$ belongs to such an interval; in the first case, $S(\boldsymbol{x}, \boldsymbol{y})$ decays for large distances as $O(|\boldsymbol{x} - \boldsymbol{y}|^{-1})$, whereas in the second case it is $O(e^{-|\Delta_n||\boldsymbol{x}-\boldsymbol{y}|})$. This means that, depending on the number of particles (which essentially fixes $\mu$), the Schwinger function has a totally different asymptotic behavior. This fact has important consequences in many physical properties; for instance, the conductivity (which can be computed from the $s = 4$ Schwinger function) vanishes if $\mu$ belongs to the interval $[\varepsilon((n\pi/a)^+), \varepsilon((n\pi/a)^-)]$. Similar properties hold for $d = 2, 3$; hence, from the knowledge of the number of particles and the periodic potential generated by the ions, one can predict if the system is an insulator or a metal.

Note also that the conductivity is infinite in the infinite-volume and zero-temperature limit, when $\mu$ does not correspond to a gap; in other words, the electric current in a perfect crystal lattice is not subjected to any dissipation of energy. A finite resistivity is found only if one takes into account deviations from perfect periodicity. To simulate impurities in the lattice, one can add, according to Anderson, to the Hamiltonian an interaction term of the form $\alpha\phi_{\boldsymbol{x}}\psi_{\boldsymbol{x}}^+\psi_{\boldsymbol{x}}^-$, where $\phi_{\boldsymbol{x}}$ is a Gaussian stochastic field. A detailed mathematical investigation has been devoted to the properties of eigenfunctions of $-\hbar^2\partial_{\boldsymbol{x}}^2/2m + \alpha\phi_{\boldsymbol{x}}$, where $\phi_{\boldsymbol{x}}$ is a Gaussian field (see, e.g., Pastur and Figotin (1991)); it is found that if $\alpha$ is large enough in $d = 2, 3$ and for any $\alpha$ in $d = 1$, the single-particle eigenfunctions are exponentially localized, that is, they decay exponentially at large distances; this implies a finite conductivity. One can also add to the Hamiltonian a term $\beta\phi'_{\boldsymbol{x}}\psi_{\boldsymbol{x}}^+\psi_{\boldsymbol{x}}^-$, with $\phi'_{\boldsymbol{x}}$ a quasiperiodic function, in order to describe crystals in which the lattice develops a periodic distortion, with incommensurate period with respect to the lattice periodicity. For $d = 1$ and $\beta$ large, one again finds localized eigenfunctions, whereas for small $\beta$ there are extended states (see, e.g., Pastur and Figotin (1991)); such results are obtained with the Kolgomorov–Arnol'd–Moser (KAM) techniques.

## Interacting Systems

The analysis of noninteracting Fermi systems has been very successful in understanding qualitatively many features of crystals, but there are many properties (e.g., superconductivity or magnetism) which cannot be really explained without taking into account the interaction between fermions; however, the analysis becomes more involved. When there is no interaction, the properties of the many-body system can be understood in terms of the single-body properties; the eigenfunctions of the Hamiltonian are, in fact, obtained in terms of the single-particle eigenfunctions. This is not true when $\lambda \neq 0$ when a description of the system in terms of independent particles is impossible. In order to compute the interacting Schwinger functions, it is convenient to write them in terms of fermionic functional integrals (Berezin 1966). One introduces a set of anticommuting Grassmann variables $\psi_{\boldsymbol{k}}^+, \psi_{\boldsymbol{k}}^-$, $\boldsymbol{k} = (k_0, \boldsymbol{k})$; the Grassmann integration is defined by $\int d\psi_{\boldsymbol{k}}^\sigma \psi_{\boldsymbol{k}}^\sigma = 1$ and $\int d\psi_{\boldsymbol{k}}^\sigma = 0$, $\sigma = \pm$, and the integral of any analytic function of the Grassmann variables can be obtained by expanding it in Taylor series (which is a finite sum if suitable cutoffs are imposed and $L, \beta$ are finite) and using the above rules; finally,

$$\psi_{\boldsymbol{x}}^+ = \frac{1}{L^d\beta} \sum_{\boldsymbol{k}} \phi_{\boldsymbol{k}}(\boldsymbol{x}) e^{ik_0 t} \psi_{\boldsymbol{x}}^+$$

and $\psi_{\boldsymbol{x}}^-$ is defined in an analogous way. The Schwinger function can be written as a Grassmann integral as follows:

$$S(\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N) = \frac{\partial^N}{\partial\phi_{\boldsymbol{x}_1}^{\varepsilon_i} \ldots \partial\phi_{\boldsymbol{x}_N}^{\varepsilon_i}} \log \int P(d\psi) e^{-\nu + \int d\boldsymbol{x} \phi_{\boldsymbol{x}}^\varepsilon \psi_{\boldsymbol{x}}^\varepsilon}\Big|_{\varphi=0} \qquad [7]$$

where $P(\mathrm{d}\psi)$ is the fermionic integration $[\prod_{\boldsymbol{k}} \mathrm{d}\psi^+_{\boldsymbol{k}} d\psi^-_{\boldsymbol{k}}] \exp[\sum_{\boldsymbol{k}} \psi^+_{\boldsymbol{k}}[-\mathrm{i}k_0 + \varepsilon(\boldsymbol{k}) - \mu]\psi^-_{\boldsymbol{k}}]$, while $\boldsymbol{y} = (\boldsymbol{y}, s)$, and

$$\nu = \lambda \sum_{\sigma,\sigma'} \int \mathrm{d}\boldsymbol{x}\, \mathrm{d}\boldsymbol{y}\, v(\boldsymbol{x} - \boldsymbol{y}) \times \delta(t-s)\psi^+_{\boldsymbol{x},\sigma}\psi^-_{\boldsymbol{x},\sigma}\psi^+_{\boldsymbol{y},\sigma'}\psi^-_{\boldsymbol{y},\sigma'} \qquad [8]$$

The Grassmann integral of a monomial of Grassmann variables can be obtained by the Wick rule [5] with propagator the Fourier transform of $(-\mathrm{i}k_0 + \varepsilon(\boldsymbol{k}) - \mu)^{-1}$. As stated earlier, the propagator is finite at nonzero temperature, whereas if $\beta = \infty$, then it is singular when $\boldsymbol{k} = (k_0, \boldsymbol{k})$ is such that $k_0 = 0$ and $\varepsilon(\boldsymbol{k}) = \mu$.

One can write [7] as a series by Taylor-expanding the exponential and using the Wick rule; each order of the expansion can be represented as a sum of Feynman diagrams, very similar to the ones appearing in quantum field theory. We have then an algorithm to compute [7]; nevertheless, to extract information from such a series is quite difficult. One cannot really compute an infinite (in the $L = \infty$ limit) number of coefficients, so one is tempted, for small $\lambda$, to compute only the first few of them, neglecting the others. However, it appears that this approximation is generally not justified, and it leads to wrong results; the reason is that the Schwinger functions for $\lambda = 0$ or $\lambda \neq 0$ are not analytically close, or, in more physical terms, even if $\lambda$ is small, the physical behavior of the free and interacting theories can be quite different, especially at low temperatures. A number of very interesting concepts (e.g., spontaneous symmetry breaking or the mass generation phenomenon), or techniques (e.g., the renormalization group method, or the parquet or random phase approximation) have been introduced in the last 50 years to analyze [7], and indeed many results have been obtained which explain several physical properties of the matter, such as superconductivity or the Kondo effect (see, e.g., Anderson 1985, Abrikosov *et al.* 1965, Mahan 1990, Negele and Orland 1988, Pines 1961). Unfortunately, most of such results are not really mathematically consistent, and in many cases quantitative computations are impossible (in computations one generally neglects terms which, according to a heuristic physical intuition, are irrelevant, but no control of the error introduced by this approximation is attempted). In recent times, attempts towards a mathematical understanding of the functional integral [7] have started (see, e.g., Benfatto and Gallavotti (1995), and references therein); the methods rely on the mathematical implementation of Wilson's renormalization group methods via multiscale analysis (Gallavotti 1985). The necessity of a firmer mathematical basis was felt mainly under the pressure of the recent discovery of high-$T_\mathrm{c}$ superconductors whose behavior is still not understood in terms of the microsopic model [7]; this has forced reconsideration of the validity of the approximations usually made in the analysis of this model.

The behavior of [7] depends crucially on the temperature. At high temperatures, we can simply expand the exponential in [7] in a power series of $\lambda$, and find that each Feynman graph contributing to the $n$th perturbative order is bounded by $C^n_\beta|\lambda|^n$, with $C_\beta \leq C\beta^\gamma$ for some constants $C, \gamma$; this follows immediately by using the Wick rule and by remembering that the propagator is larger than $O(\beta^{-1})$. As the number of Feynman graphs contributing to order $n$ is $O(n!)$, a bound on each Feynman graph is not sufficient to prove the convergence of the series. To prove convergence, one has to take into account cancellations, due to the anticommutativity of fermionic variables. Such cancellations are proved via Gram's inequality for determinants and a bound $C^n_\beta\lambda^n$ can be obtained for the order $n$ (without factorials); hence, convergence follows for temperatures greater than $O(|\lambda|^\alpha)$ for some constant $\alpha > 0$. One finds that $S(\boldsymbol{k}) = S_0(\boldsymbol{k})(1 + A_\lambda(\boldsymbol{k}))$ with $|A_\lambda(\boldsymbol{k})| \leq C|\lambda|$, that is, the interaction has essentially no influence on the physical properties of the system at high temperatures.

## Landau Fermi Liquids

We consider next an intermediate region of temperatures, that is, $\mathrm{e}^{-a/|\lambda|} \leq T \leq |\lambda|^\alpha$ for some constants $a, \alpha$. In this region, the naive expansion in power series of $\lambda$ fails and other techniques, such as renormalization group, are necessary. Such a method allows us to perform a suitable resummation of the naive power series in $\lambda$, and one gets, for $\lambda$ small enough, $T \geq \mathrm{e}^{-a/|\lambda|}$ and $\varepsilon(\boldsymbol{k}) = |\boldsymbol{k}|^2/2m$,

$$\hat{S}(\boldsymbol{k}) = \frac{1}{Z(\lambda)} \frac{1 + A_\lambda(\boldsymbol{k})}{-\mathrm{i}k_0 + v_\mathrm{F}(\lambda)[|\boldsymbol{k}| - k_\mathrm{F}(\lambda)]} \qquad [9]$$

where $Z(\lambda) = 1 + z(\lambda), v_\mathrm{F}(\lambda) = \hbar k_\mathrm{F}/m + v(\lambda)$, and $k_\mathrm{F}(\lambda) = k_\mathrm{F} + \nu(\lambda)$, with $z(\lambda) = O(\lambda^2), \nu(\lambda) = O(\lambda)$, $v(\lambda) = O(\lambda^2)$, and $z(\lambda), \nu(\lambda), v_\mathrm{F}(\lambda)$ essentially temperature independent; moreover, $|A_\lambda(\boldsymbol{k})|$ is $O(\lambda)$. The above formula has been proved rigorously for $d = 2$ (see Rivasseou (1994), and references therein); for $d = 3$, it has been proved at the level of formal perturbation theory (Benfatto and Gallavotti 1995). The case $\varepsilon(\boldsymbol{k}) = |\boldsymbol{k}|^2/2m$ is quite special, as the shape

of the interacting Fermi surface is fixed by the rotation-invariant symmetry; it is necessarily circular ($d = 2$) or spherical ($d = 3$), whereas in general the interaction can also modify its shape. For $d = 2$, if the interacting Fermi surface is symmetric, smooth and convex, a formula like [9] still holds (with a function $k_{\rm F}(\lambda, \boldsymbol{k})$ replacing $k_{\rm F}(\lambda)$) up to exponentially small temperatures (see references in Gentile and Mastropietro (2001)).

It is apparent from [9] that one cannot derive such a formula from a power-series expansion in $\lambda$; by expanding [9] as a series in $\lambda$, one immediately finds that the $n$th term is $O(\lambda^n \beta^n)$, which means that the naive perturbative expansion cannot be convergent up to exponentially small temperatures. It can be derived only by selecting and resumming some special class of terms in the original expansion. A peculiar property of [9] is that the wave function renormalization $Z(\lambda)$ is essentially independent of the temperature. Such temperature independence is a consequence of cancellations in the perturbative series essentially due to the curvature of the Fermi surface. For $d = 1$, a formula similar to [9] is also valid; however, such cancellations are not present and one finds $Z(\lambda) = 1 + O(\lambda^2 \log \beta)$. Comparing $S(\boldsymbol{k})$ given by [9] with the Fourier transform $S_0(\boldsymbol{k})$ of [6], we note that the Schwinger function of the interacting system is still very similar to the Schwinger function of a free Fermi gas, with physical parameters (e.g., the Fermi momentum, the wave function renormalization, or the Fermi velocity) which are changed by the interaction. This property is quite remarkable: the eigenstates cannot be constructed when $\lambda = 0$ starting from the single-particle states but, nevertheless, the physical properties of the interacting system (which can be deduced from the Schwinger functions) are qualitatively very similar to the ones of the free Fermi gas, although with different parameters; this explains why the free Fermi gas model works so well to explain the properties of crystals, although one neglects the interactions between fermions which are, of course, quite relevant. A fermionic system with such a property is called a Landau Fermi liquid (see, e.g., Arbikosov *et al.* 1965, Mahan 1990, Pines 1961), after Landau, who postulated in the 1950s that interacting systems may evolve continuously from the free system in many cases.

It was generally accepted that metals in this range of temperatures were all Landau Fermi liquids (except one-dimensional systems). However, the experimental discovery of the high-$T_{\rm c}$ superconductors (see, e.g., Anderson (1997)) has changed this belief, as such metals in their normal state, that is, above $T_{\rm c}$ are not Landau Fermi liquids; their wave function renormalization behaves like $1 + O(\lambda^2 \log \beta)$ instead of $1 + O(\lambda^2)$ as in Landau Fermi liquid. This behavior has been called marginal-Fermi-liquid behavior and many attempts have been devoted to predict such behavior from [7]. In order to see deviations from Fermi liquid behavior, one could consider Fermi surfaces with flat or almost flat sides or corners (which are quite possible; e.g., in a square lattice with one conduction electron per atom, such as in the "half-filled Hubbard model").

Let us finally consider the last regime, that is, temperatures lower than $O(\mathrm{e}^{-a/|\lambda|})$. Except for very exceptional cases (e.g., asymmetric Fermi surfaces, i.e., such that $\varepsilon(\boldsymbol{k}) \neq \varepsilon(-\boldsymbol{k})$ except for a finite number of points, in which Fermi liquid behavior is found down to $T = 0$ (Feldman *et al.* 2002)), a strong deviation from Fermi liquid behavior is observed; the interacting Schwinger function is not similar to the free one and the physical properties in this regime are totally new.

## One-Dimensional Systems up to $T = 0$

The only case in which the Schwinger functions of the Hamiltonian [3] can be really computed down to $T = 0$ occurs for $d = 1$; in such a case, an expression like [9] is not valid anymore and the system is not a Fermi liquid. On the contrary, when $u = 0$ and for small repulsive $\lambda > 0$, one can prove, for spinning fermions (see Benfatto and Gallavotti (1995), Gentile and Mastropietro (2001) and references therein) that

$$\hat{S}(\boldsymbol{k}) = \frac{\left[k_0^2 + v_{\rm F}^2(\lambda)(|\boldsymbol{k}| - k_{\rm F}(\lambda))^2\right]^{\eta(\lambda)}}{-\mathrm{i}k_0 + v_{\rm F}(\lambda)[|\boldsymbol{k}| - k_{\rm F}(\lambda)]}[1 + A_\lambda(\boldsymbol{k})] \qquad [10]$$

where $k_{\rm F}(\lambda) = k_{\rm F} + O(\lambda)$ and $\eta(\lambda) = a\lambda^2 + O(\lambda^3)$ is a critical index. This means that the interaction changes qualitatively the nature of the singularity at the Fermi surface; $S(\boldsymbol{k})$ is still diverging at the Fermi surface but with an exponent which is no longer 1 but is $1 - 2\eta(\lambda)$, with $\eta(\lambda)$ a nonuniversal (i.e., $\lambda$-dependent) critical index. As a consequence, the physical properties are different with respect to the free Fermi gas; for instance, the occupation number $n_{\boldsymbol{k}}$ is not discontinuous at $k = \pm k_{\rm F}(\lambda)$ when $T = 0$. Nonuniversal critical indices appear in all the other response functions. Fermionic systems behaving in this way are called Luttinger liquids, as they behave like the exactly solvable Luttinger model describing relativistic spinless fermions with linear dispersion relation. The solvability of this model, due to Mattis and Lieb (1966), relies

on the possibility of mapping its Hamiltonian in a system of free bosons. Such a mapping is not possible for the Hamiltonian [3], which is not solvable; however, one can use renormalization group methods and suitable Ward identities to show that its behavior is similar to the Luttinger model (in a sense, one makes perturbation theory not around the free Fermi gas, but around the Luttinger model).

If we take into account the interaction with an external periodic potential with period $a$, that is, consider $u \neq 0$, we find that if $k_F \neq n\pi/a$, then the Schwinger function behaves essentially like [8]. On the contrary, in the filled-band case, $k_F = n\pi/a$, one finds that there is still an energy gap which becomes $O(u^{1+\eta_1})$ with $\eta_1 = O(\lambda)$; this means that the renormalization of the gap is described by a critical index; moreover, $S(\mathbf{x}) \simeq O(e^{-|u|^{1+\eta_1}|\mathbf{x}|})$. A similar behavior is also observed in the presence of quasi-periodic potential. In the attractive case, $\lambda < 0$, $u = 0$, the behavior is much less understood; it is believed that the interaction produces a gap $\Delta_\lambda$ in the spectrum which is nonanalytic in $\lambda$, and $S(\mathbf{x})$ shows an exponential decay rather than a power-law decay, and the interaction converts the system from a metal to an insulator.

Finally, it is remarkable that a large variety of models, like Heisenberg spin chains or bidimensional classical statistical mechanics models, such as the eight-vertex or the Ashkin–Teller model, can be mapped into interacting $d = 1$ fermionic systems, and consequently their critical behavior can be understood by using fermionic techniques (see Gentile and Mastropietro (2001), and references therein).

## Superconductors

The theory up to $T = 0$ for $d = 2, 3$ systems with dispersion relation $|\mathbf{k}|^2/2m$ is based only on approximate computations, predicting the phenomenon of superconductivity. According to the theory of Bardeen, Cooper, and Schrieffer (BCS theory), the interaction between fermions leads to the formation of a gap in the energy spectrum, below the critical temperature. There are many ways to derive the BCS theory. One is based on the fact that one verifies, by perturbative computations, that the effective interaction is stronger when the four momenta of the fermions are such that $\mathbf{k}_1 \simeq -\mathbf{k}_3$ and $\mathbf{k}_2 \simeq -\mathbf{k}_4$. This suggests, heuristically, to replace in [7] $\nu$ with

$$\nu_{BCS} = -\lambda \frac{1}{\beta L^{3d}} \sum_{\mathbf{k},\mathbf{k}'} \psi^+_{\mathbf{k},\sigma} \psi^+_{-\mathbf{k},-\sigma} \psi^-_{\mathbf{k}',-\sigma'} \psi^-_{-\mathbf{k}',\sigma'}$$

which is an interaction between pairs of electrons with opposite spin and momenta, which are called Cooper pairs. Replacing $\nu$ with $\nu_{BCS}$ has the great advantage that it makes the Schwinger functions exactly computable and explains the mechanism of superconductivity in many metals (but not in the recently discovered high-$T_c$ superconductors). On the other hand, proving that [7] with $\nu$ or $\nu_{BCS}$ has a similar behavior is still an important open problem. The two-point Schwinger function in the model with $\nu_{BCS}$ can be written, after the so-called Hubbard–Stratonovitch transformation, as

$$\hat{S}(k_0, \mathbf{k}) = -\beta L^d \frac{\int \frac{-ik_0 - \varepsilon(\mathbf{k}) + \mu}{k_0^2 + \varepsilon^2(\mathbf{k}) + \lambda u^2} e^{-\beta L^d \nu(u)} \, du}{\int e^{-\beta L^d \nu(u)} \, du} \qquad [11]$$

where $\nu(u)$ is a function with a global minimum in $u = 0$ for repulsive interactions $\lambda < 0$, whereas for $\lambda > 0$ and sufficiently small temperatures (for $T \leq T_c$, with $T_c = O(e^{-a/|\lambda|})$), it has the form of a double well with two minima at $u = \pm \Delta_\lambda$ with $\Delta_\lambda = O(e^{-a/|\lambda|})$; for $T$ greater than $T_c$, there is only a global minimum at $u = 0$. By the saddle-point theorem, we find, for $T \leq T_c$ and $\lambda < 0$,

$$\lim_{L \to \infty} S(\mathbf{k}) = \frac{-ik_0 - \varepsilon(\mathbf{k}) + \mu}{k_0^2 + (\varepsilon(\mathbf{k}) - \mu)^2 + \Delta_\lambda^2} \qquad [12]$$

The physical properties predicted by [12] are completely different with respect to the free case: the occupation number is continuous, there is an energy gap in the spectrum, the specific heat is $O(e^{-\Delta_\lambda T})$ and the phenomenon of superconductivity appears. The fact that the interaction generates a gap is called mass generation; a similar mechanism appears in particle theory.

## Conclusions

Many other physical phenomena, observed experimentally, can be essentially understood by studying fermionic systems, but a clear mathematical comprehension is still lacking. We mention: the Kondo effect, that is, the resistance minimum observed in some metals due to magnetic impurities; Mott transition, in which a strong interaction produces an insulating state in a system which should be conductors; antiferromagnetism; fractional quantum Hall effect, and many others. We can say that the situation in this area of study reminds one of the classical mechanics at the end of the nineteenth century; there is agreement on the models to consider, which are believed to be able to take into

account the marvelous properties of the matter experimentally found, but to extract information from them requires deeper and complex analytical and mathematical investigations.

## Introduction

In nonrelativistic quantum mechanics, the state of a $d$-dimensional particle is represented by a unitary vector $\psi$ in the complex separable Hilbert space $L^2(\mathbb{R}^d)$, the so-called "wave function," while its time evolution is described by the Schrödinger equation:

$$
\begin{aligned}
i\hbar \frac{\partial}{\partial t}\psi &= -\frac{\hbar^2}{2m}\Delta\psi + V\psi \\
\psi(0,x) &= \psi_0(x)
\end{aligned}
\qquad [1]
$$

where $\hbar$ is the reduced Planck constant, $m > 0$ is the mass of the particle, and $F = -\nabla V$ is an external force.

In 1942 R P Feynman, following a suggestion by Dirac, proposed an alternative (Lagrangian) formulation of quantum mechanics, and a heuristic but very suggestive representation for the solution of eqn [1]. According to Feynman, the wave function of the system at time $t$ evaluated at the point $x \in \mathbb{R}^d$ is given as an "integral over histories," or as an integral over all possible paths $\gamma$ in the configuration space of the system with finite energy passing at the point $x$ at time $t$:

$$
\psi(t,x) = \left( \int_{\{\gamma|\gamma(t)=x\}} e^{(i/\hbar)S_t^\circ(\gamma)} D\gamma \right)^{-1} \times \int_{\{\gamma|\gamma(t)=x\}} e^{(i/\hbar)S_t(\gamma)} \psi_0(\gamma(0)) D\gamma \qquad [2]
$$

$S_t(\gamma)$ is the classical action of the system evaluated along the path $\gamma$

$$
S_t(\gamma) \equiv S_t^\circ(\gamma) - \int_0^t V(\gamma(s))\,ds \qquad [3]
$$

$$
S_t^\circ(\gamma) \equiv \frac{m}{2}\int_0^t |\dot\gamma(s)|^2\,ds \qquad [4]
$$

$D\gamma$ is a heuristic Lebesgue "flat" measure on the space of paths and $(\int_{\{\gamma|\gamma(t)=x\}} e^{(i/\hbar)} S_t^\circ(\gamma) D\gamma)^{-1}$ is a normalization constant.

Some time later, Feynman himself extended formula [2] to more general quantum systems, including the case of quantum fields.

The Feynman path-integral formulation of quantum mechanics is particularly suggestive, as it provides a spacetime visualization of quantum dynamics, reintroducing in quantum mechanics the concept of trajectory (which was banned in the "orthodox interpretation" of the theory) and creating a connection between the classical description of

the physical world and the quantum one. Indeed, it provides a quantization method, allowing, at least heuristically, to associate a quantum evolution to each classical Lagrangian. Moreover, the application of the stationary-phase method for oscillatory integrals allows the study of the semiclassical limit of the Schrödinger equation, that is, the study of the detailed behavior of the solution when the Planck constant is regarded as a parameter converging to 0. Indeed, when $\hbar$ is small, the integrand in [2] is strongly oscillating and the main contributions to the integral should come from those paths $\gamma$ that make stationary the phase function $S(\gamma)$. These, by Hamilton's least action principle, are exactly the classical orbits of the system.

Feynman path integrals allow also a heuristic calculus in path space, leading to variational calculations of quantities of physical and mathematical interest. An interesting application can be found in topological field theories, as, for instance, Chern–Simons models. In this case, heuristic calculations based on the Feynman path-integral formulation of the theory, where the integration is performed on a space of geometrical objects, lead to the computation of topological invariants.

Even if from a physical point of view, formula [2] is a source of important results, from a mathematical point of view, it lacks rigor: indeed, neither the "infinite-dimensional Lebesgue measure," nor the normalization constant in front of the integral is well defined. In this article, we shall describe the main approaches to the rigorous mathematical realization of Feynman path integrals, as well as their most important applications.

## Possible Mathematical Definitions of Feynman's Measure

In the rigorous mathematical definition of Feynman's complex measure

$$\mu_F := \left( \int_{\{\gamma | \gamma(t)=x\}} \mathrm{e}^{(\mathrm{i}/\hbar)S_t^\circ(\gamma)} D\gamma \right)^{-1} \mathrm{e}^{(\mathrm{i}/\hbar)S_t^\circ(\gamma)} D\gamma \qquad [5]$$

one has to face mainly two problems. First of all, the integral is defined on a space of paths, that is, on an infinite-dimensional space. The implementation of an integration theory is nontrivial: for instance, it is well known that a Lebesgue-type measure cannot be defined on infinite-dimensional Hilbert spaces. Indeed, the assumption of the existence of a $\sigma$-additive measure $\mu$ which is invariant under rotations and translations and assigns a positive finite measure to all bounded open sets leads to a contradiction. In fact, by taking an orthonormal system $\{e_i\}_{i\in\mathbb{N}}$ in an infinite-dimensional Hilbert space $\mathcal{H}$ and by considering the open balls $B_i = \{x \in \mathcal{H}, \|x - e_i\| < 1/2\}$, one has that they are pairwise disjoint and their union is contained in the open ball $B(0,2) = \{x \in \mathcal{H}, \|x\| < 2\}$. By the Euclidean invariance of the Lebesgue-type measure $\mu$, one can deduce that $\mu(B_i) = a, 0 < a < \infty$, for all $i \in \mathbb{N}$. By the $\sigma$-additivity, one has

$$\mu(B(0,2)) \geq \mu(\cup_i B_i) = \sum_i \mu(B_i) = \infty$$

but, on the other hand, $\mu(B(0,2))$ should be finite as $B(0,2)$ is bounded. As a consequence, we can also deduce that the term $D\gamma$ in [2] does not make sense.

The second problem is the fact that the exponent in the density $\mathrm{e}^{(\mathrm{i}/\hbar)S_t^\circ(\gamma)}$ is imaginary, so that the exponential oscillates. Even in finite dimensions, integrals of the form $\int_{\mathbb{R}^N} \mathrm{e}^{\mathrm{i}\Phi(x)} f(x)\,\mathrm{d}x$, with $\Phi, f : \mathbb{R}^N \to \mathbb{R}$ are continuous functions and $f$ is not summable, have to be suitably defined, in order to exploit the cancelations in the integral due to the oscillatory behavior of the exponential.

The study of the rigorous foundation of Feynman path integrals began in the 1960s, when Cameron proved that Feynman's heuristic complex measure [5] cannot be realized as a complex bounded variation $\sigma$-additive measure, even on very nice subsets of the space $(\mathbb{R}^d)^{[0,t]}$ of paths, contrary to the case of complex measures on $\mathbb{R}^n$ of the form $\mathrm{e}^{(i/2)|x|^2}\,\mathrm{d}x$. In other words, it is not possible to implement an integration theory in the traditional (Lebesgue) sense. As a consequence, mathematicians tried to realize [5] as a linear continuous functional on a sufficiently rich Banach algebra of functions, inspired by the fact that a bounded measure can be regarded as a continuous functional on the space of bounded continuous functions. In order to mirror the features of the heuristic Feynman's measure, such a functional should have some properties:

1. it should behave in a simple way under "translations and rotations in path space," as $D\gamma$ denotes a "flat" measure;
2. it should satisfy a Fubini-type theorem, concerning iterated integrations in path space (allowing the construction, in physical applications, of a one-parameter group of unitary operators);
3. it should be approximable by finite-dimensional oscillatory integrals, allowing a sequential approach in the spirit of Feynman's original work; and
4. it should be sufficiently flexible to allow a rigorous mathematical implementation of an infinite-dimensional version of the stationary-phase

method and the corresponding study of the semiclassical limit of quantum mechanics.

Nowadays, several implementations of this program can be found in the literature of physics and mathematics, for instance, by means of analytic continuation of Wiener integrals, or as an infinite-dimensional distribution in the framework of Hida calculus, or via "complex Poisson measures," or via nonstandard analysis, or as an infinite-dimensional oscillatory integral. The last of these methods is particularly interesting as it allows the systematic implementation of an infinite-dimensional version of the stationary-phase method, which can be applied to the study of the semiclassical limit of the solution of the Schrödinger equation [1].

## Analytic Continuation

In one of the first approaches in the definition of Feynman path integrals, formula [2] was realized as the analytic continuation in a suitable complex parameter of a (nonoscillatory) Gaussian integral on the space of paths.

In 1949, inspired by Feynman's work, M Kac observed that by considering the heat equation

$$-\frac{\partial}{\partial t}u = -\frac{1}{2m}\Delta u + V(x)u \qquad u(0,x) = \psi_0(x) \tag{6}$$

instead of the Schrödinger equation [1] and by replacing the oscillatory term $e^{(i/\hbar)S_0(\gamma)}$ in Feynman complex measure with the fast decreasing one $e^{-(1/\hbar)S_0(\gamma)}$, it is possible to give a well-defined mathematical meaning to Feynman's heuristic formula [2] in terms of a well-defined integral on the space of continuous paths $W_{t,x} = \{w \in C(0,t;\mathbb{R}^d) : w(0) = x\}$ with respect to the Wiener Gaussian measure $P_{t,x}$:

$$u(t,x) = \int_{W_{t,x}} e^{-\int_0^t V(\sqrt{1/m}\,w(\tau))\mathrm{d}\tau} \times \psi_0(\sqrt{1/m}\,w(t))\,\mathrm{d}P_{t,x}(w) \tag{7}$$

The path-integral representation [7] for the solution of the heat equation [6] is called Feynman–Kac formula.

The underlying idea of the analytic continuation approach comes from the fact that by introducing in [6] a suitable parameter $\lambda$, proportional, for instance, to the time $t$ as in the case $\lambda = \lambda_1$,

$$-\lambda_1\hbar\frac{\partial}{\partial t}u = -\frac{1}{2m}\hbar^2\Delta u + V(x)u$$

$$u(t,x) = \int_{W_{t,x}} e^{-(1/\lambda_1\hbar)\int_0^t V(\sqrt{\hbar/(m\lambda_1)}\,w(\tau))\,\mathrm{d}\tau} \times \psi_0\left(\sqrt{\hbar/(m\lambda_1)}\,w(t)\right)\mathrm{d}P_{t,x}(w)$$

or to the Planck constant, as in the case $\lambda = \lambda_2$,

$$\lambda_2\frac{\partial}{\partial t}u = \frac{1}{2m}\lambda_2^2\Delta u + V(x)u$$

$$u(t,x) = \int_{W_{t,x}} e^{(1/\lambda_2)\int_0^t V(\sqrt{\lambda_2/m}\,w(\tau))\,\mathrm{d}\tau} \times \psi_0(\sqrt{\lambda_2/m}\,w(t))\,\mathrm{d}P_{t,x}(w)$$

or to the mass, as in the case $\lambda = \lambda_3$,

$$\frac{\partial}{\partial t}u = \frac{1}{2\lambda_3}\Delta u - iV(x)u$$

$$u(t,x) = \int_{W_{t,x}} e^{-i\int_0^t V\left(\sqrt{1/\lambda_3}\,w(\tau)\right)\mathrm{d}\tau} \times \psi_0(\sqrt{1/\lambda_3}\,w(t))\,\mathrm{d}P_{t,x}(w)$$

and by allowing $\lambda$ to assume complex values, then one gets, at least heuristically, Schrödinger equation and its solution by substituting, respectively, $\lambda_1 = -i$, $\lambda_2 = i\hbar$, or $\lambda_3 = -im$. These procedures can be made completely rigorous under suitable conditions on the potential $V$ and initial datum $\psi_0$.

## The Approach via Fourier Transform

This approach has its roots in a couple of papers by K Ito in the 1960s and was extensively developed by S Albeverio and R Høegh-Krohn in the 1970s. The main idea is the definition of oscillatory integrals with quadratic phase function on a real separable Hilbert space $(\mathcal{H}, \langle\cdot,\cdot\rangle)$, the Fresnel integrals,

$$\widetilde{\int_{\mathcal{H}}} e^{(i/2\hbar)\|x\|^2} f(x)\,\mathrm{d}x \tag{8}$$

as the distributional pairing between $e^{(i/2\hbar)\|x\|^2}$ and a complex-valued function $f$ belonging to the space $\mathcal{F}(\mathcal{H})$ of functions that are Fourier transforms of complex bounded variation measures on $\mathcal{H}$, that is,

$$f = \hat{\mu}_f, \qquad f(x) = \int_{\mathcal{H}} e^{i\langle x,y\rangle}\,\mathrm{d}\mu_f(y)$$

$\mathcal{F}(\mathcal{H})$ is a Banach algebra, where the product is the pointwise one and the identity is the function $f(x) = 1\ \forall x \in \mathcal{H}$. The norm of an element $f$ is the total variation of the corresponding measure $\mu_f$, that is, $\|\mu_f\| = \sup\sum_i |\mu_f(E_i)|$, where the supremum is taken over all sequences $\{E_i\}$ of pairwise-disjoint Borel subsets of $\mathcal{H}$, such that $\cup_i E_i = \mathcal{H}$.

Given a function $f \in \mathcal{F}(\mathcal{H})$, $f = \hat{\mu}_f$, its Fresnel integral is defined by the Parseval formula:

$$\widetilde{\int_{\mathcal{H}}} e^{(i/2\hbar)\|x\|^2} f(x)\,\mathrm{d}x := \int_{\mathcal{H}} e^{-(i\hbar/2)\|x\|^2}\,\mathrm{d}\mu_f(x) \tag{9}$$

where the right-hand side is a well-defined absolutely convergent integral with respect to a $\sigma$-additive measure on $\mathcal{H}$.

It is important to recall that this approach provides the implementation of a method of stationary phase for the expansion of the integral in powers of the small parameter $\hbar$ occurring in the integrand. We postpone the discussion of these results, as well as the application to the solution of the Schrödinger equation, to the next section where a generalization of the present approach is described.

### Infinite-Dimensional Oscillatory Integrals

The main idea of this approach is the extension of the definition of oscillatory integrals with quadratic phase function [8] to infinite-dimensional Hilbert spaces by means of a twofold limiting procedure.

The study of integrals of the form

$$I(\hbar) := \int_{\mathbb{R}^N} e^{(i/\hbar)\Phi(x)} f(x)\, dx \qquad [10]$$

where $\Phi(x): \mathbb{R}^N \to \mathbb{R}$ is the phase function and $f: \mathbb{R}^N \to \mathbb{C}$ a complex-valued continuous function, is a classical topic, largely developed in connection with various problems in mathematics (such as the theory of pseudodifferential operators) and physics (such as optics). Particular effort has been devoted to the study of the detailed behavior of the above integral in the limit of "strong oscillations," that is, when $\hbar \to 0$, by means of the method of stationary phase.

Thanks to the cancellations due to the oscillatory term $e^{(i/2\hbar)\Phi(x)}$, the integral can still be defined, even if the function $f$ is not summable, as the limit of a sequence of regularized, hence absolutely convergent, integrals. According to a Hörmander's proposal, the oscillatory integral of a function $f: \mathbb{R}^N \to \mathbb{C}$ is well defined if, for each test function $\phi \in \mathcal{S}(\mathbb{R}^N)$, such that $\phi(0) = 1$, the limit

$$\lim_{\epsilon \to 0} \int_{\mathbb{R}^N} e^{(i/2\hbar)\Phi(x)} \phi(\epsilon x) f(x)\, dx$$

exists and is independent of $\phi$.

This definition has been generalized in the 1980s by D Elworthy and A Truman to the case where the underlying space $\mathbb{R}^N$ is replaced by a real separable infinite-dimensional Hilbert space $(\mathcal{H}, \langle \cdot , \cdot \rangle)$, under the assumption that the phase function is quadratic, that is, $\Phi(x) = \|x\|^2/2$. The "infinite-dimensional oscillatory integral"

$$\widetilde{\int_{\mathcal{H}}^{\circ}} e^{(i/2\hbar)\|x\|^2} f(x)\, dx$$

is defined as the limit of a sequence of finite-dimensional approximations. More precisely, a function $f: \mathcal{H} \to \mathbb{C}$ is "integrable" if, for each increasing sequence $\{P_n\}_{n \in \mathbb{N}}$ of finite-dimensional projector operators in $\mathcal{H}$ converging strongly to the identity operator as $n \to \infty$, the limit

$$\lim_{n \to \infty} \left( \int_{P_n \mathcal{H}} e^{(i/2\hbar)\|P_n x\|^2}\, dP_n x \right)^{-1} \times \int_{P_n \mathcal{H}} e^{(i/2\hbar)\|P_n x\|^2} f(P_n x)\, dP_n x \qquad [11]$$

exists and is independent of the sequence $\{P_n\}_{n \in \mathbb{N}}$. In this case, the limit is denoted by

$$\widetilde{\int_{\mathcal{H}}^{\circ}} e^{(i/2\hbar)\|x\|^2} f(x)\, dx$$

The description of the largest class of integrable functions is still an open problem, even in finite dimension, but it is possible to find some interesting subsets of it. In particular, any function belonging to $\mathcal{F}(\mathcal{H})$, the Banach algebra considered in the approach by Fourier transform, is integrable. Indeed, by assuming that the function $f$ in [11] is of the type

$$f(x) = e^{-(i/\hbar)\langle x, Lx \rangle} g(x)$$

where $L: \mathcal{H} \to \mathcal{H}$ is a linear self-adjoint trace-class operator on $\mathcal{H}$ such that $(I - L)$ is invertible and $g \in \mathcal{F}(\mathcal{H})$, that is, $g(x) = \int_{\mathcal{H}} e^{\langle x, y \rangle} d\mu_g(y)$, then it is possible to prove that $f$ is integrable in the sense of definition [11] and the corresponding infinite-dimensional oscillatory integral can be explicitly computed in terms of a well-defined integral with respect to a bounded variation measure $\mu_f$ by means of the following Parseval's type equality:

$$\widetilde{\int_{\mathcal{H}}^{\circ}} e^{(i/2\hbar)\|x\|^2} e^{-(i/\hbar)\langle x, Lx \rangle} g(x) dx = \det(I - L)^{-1/2} \int_{\mathcal{H}} e^{-(i\hbar/2)\langle x, (I-L)^{-1} x \rangle} d\mu_f(x) \qquad [12]$$

$\det(I - L)$ being the Fredholm determinant of the operator $I - L$, that is, the product of its eigenvalues, counted with their multiplicity. If $L = 0$, then we obtain eqn [9], so that we can look at the infinite-dimensional oscillatory integrals approach as a generalization of the Fourier transform approach, since it allows at least in principle to integrate a class of function larger than $\mathcal{F}(\mathcal{H})$. In fact, recently this feature has been used by S Albeverio and S Mazzucchi in the proof of a Parseval's type equality similar to [12] for infinite-dimensional oscillatory integrals with polynomially growing phase functions.

Feynman's heuristic formula [2] for the representation of the solution of the Schrödinger equation [1] can

be realized as an infinite-dimensional oscillatory integral on the Hilbert space $\mathcal{H}_t$ of absolutely continuous paths $\gamma : [0, t] \in \mathbb{R}^d$ with fixed endpoint $\gamma(t) = 0$ and finite kinetic energy $\int_0^t \dot{\gamma}^2(\tau)\mathrm{d}\tau < \infty$, endowed with the inner product $\langle \gamma_1, \gamma_2 \rangle = \int_0^t \dot{\gamma}_1(\tau)\dot{\gamma}_2(\tau)\mathrm{d}\tau$. One has to take an initial datum $\psi_0 \in L^2(\mathbb{R}^d)$ that is the Fourier transform of a complex bounded variation measure on $\mathbb{R}^d$, that is, $\psi_0(x) = \int_{\mathbb{R}_d} \mathrm{e}^{\mathrm{i}k\cdot x}\mathrm{d}\mu_0(k)$. Moreover, one has to assume that the potential $V$ in [1] is the sum of a harmonic oscillator part plus a bounded perturbation $V_1$ that is the Fourier transform of a complex bounded variation measure $\mu_v$ on $\mathbb{R}^d$:

$$V(x) = \tfrac{1}{2}x\Omega^2 x + V_1(x)$$
$$V_1(x) = \int_{\mathbb{R}_d} \mathrm{e}^{\mathrm{i}k\cdot x}\mathrm{d}\mu_v(k)$$

($\Omega^2$ being a symmetric positive $d \times d$ matrix).

In this case, it is possible to prove that the linear operator $L$ on $\mathcal{H}_t$ defined by

$$(\gamma, L\gamma) \equiv \int_0^t \gamma(\tau)\Omega^2\gamma(\tau)\mathrm{d}\tau$$

is self-adjoint and trace class, and $(I - L)$ is invertible. Moreover, by considering the function $v : \mathcal{H}_t \to \mathbb{C}$

$$v(\gamma) \equiv \int_0^t V_1(\gamma(\tau) + x)\mathrm{d}\tau + 2x\Omega^2 \int_0^t \gamma(\tau)\mathrm{d}\tau, \quad \gamma \in \mathcal{H}_t$$

it is possible to prove that the function $f : \mathcal{H}_t \to \mathbb{C}$ given by

$$f(\gamma) = \mathrm{e}^{-(\mathrm{i}/\hbar)v(\gamma)}\psi_0(\gamma(0) + x)$$

is the Fourier transform of a complex bounded variation measure $\mu_f$ on $\mathcal{H}_t$ and the infinite-dimensional Fresnel integral of the function $g(\gamma) = \mathrm{e}^{-(\mathrm{i}/2\hbar)(\gamma, L\gamma)}f(\gamma)$, that is,:

$$\int_{\gamma(t)=0} \mathrm{e}^{(\mathrm{i}/2\hbar)\int_0^t \dot{\gamma}^2(\tau)\mathrm{d}\tau}\mathrm{e}^{-(\mathrm{i}/\hbar)\int_0^t V(\gamma(\tau)+x)\mathrm{d}\tau}\psi_0(\gamma(0) + x)\mathrm{d}\gamma$$
$$= \widetilde{\int_{\mathcal{H}_t}^0} \mathrm{e}^{(\mathrm{i}/2\hbar)(\gamma,(I-L)\gamma)}\mathrm{e}^{-(\mathrm{i}/\hbar)v(\gamma)}\psi_0(\gamma(0) + x)\mathrm{d}\gamma \qquad [13]$$

is well defined and it is equal to

$$\det(I - L)^{-1/2} \int_{\mathcal{H}_t} \mathrm{e}^{-(\mathrm{i}\hbar/2)(\gamma,(I-L)^{-1}\gamma)}\,\mathrm{d}\mu_f(\gamma)$$

Moreover, it is a representation of the solution of equation [1] evaluated at $x \in \mathbb{R}^d$ at time $t$. Recently, solutions of the Schrödinger equation with quartic anharmonic potential via infinite-dimensional oscillatory integrals have been provided by S Albeverio and S Mazzucchi using a combination of Parseval formula and a new analytic method (the inclusion of such potentials had been a stumbling block for many years).

In this framework, it is possible to implement an infinite-dimensional version of the stationary-phase method and study the asymptotic behavior of the oscillatory integrals in the limit $\hbar \to 0$.

The method of stationary phase was originally proposed by Stokes, who noted that when $\hbar \to 0$ the oscillatory integral [10] is $O(\hbar^n)$ for any $n \in \mathbb{N}$, provided that there are no critical points of the phase function $\Phi$ in the support of the function $f$. As a consequence, one can deduce that the leading contribution to the integral [10] should come from a neighborhood of those points $c \in \mathbb{R}^N$, such that $\nabla\Phi(c) = 0$. More precisely, by assuming that the set $C$ of critical points is finite, that is, $C = \{c_1, \ldots, c_k\}$ and that every critical point is nondegenerate, that is, $\det D^2\Phi(c_i) \neq 0\, \forall c_i \in C$, then one has

$$I(\hbar) \sim \sum_{c_i \in C} \mathrm{e}^{(\mathrm{i}/\hbar)\Phi(c_i)}I_i^*(\hbar) \qquad [14]$$

where $I_i^* : \mathbb{R} \to \mathbb{C}$ are $C^\infty$ functions of $\mathbb{R}$, such that

$$I_i^*(0) = f(c_i)(2\pi\mathrm{i}\hbar)^{N/2}(\det D^2\Phi(c_i))^{-1/2}$$

If some critical point is degenerate, the situation is more complicated: one has to take into account the type of degeneracy and apply the theory of unfoldings of singularities.

These results can be generalized to infinite-dimensional oscillatory integrals of the form

$$I(\hbar) = \widetilde{\int_{\mathcal{H}}} \mathrm{e}^{(\mathrm{i}/2\hbar)\langle x,(I-L)x\rangle}\mathrm{e}^{-(\mathrm{i}/\hbar)v(x)}g(x)\mathrm{d}x \qquad [15]$$

with $v(x) = \int_{\mathcal{H}} \mathrm{e}^{\mathrm{i}\langle x,y\rangle}\mathrm{d}\mu(y)$, $g(x) = \int_{\mathcal{H}} \mathrm{e}^{\mathrm{i}\langle x,y\rangle}\mathrm{d}\nu(y)$, $\mu, \nu$ being complex bounded variation measures on $\mathcal{H}$ satisfying suitable assumptions and $L : \mathcal{H} \to \mathcal{H}$ is a self-adjoint and trace-class linear operator, such that $(I - L)$ is invertible. Under suitable growth condition on the moments of the measures $\mu, \nu$ and by assuming that the phase function $\Phi(x) = \langle x, (I - L)x\rangle - v(x)$ has a finite number of nondegenerate critical points $c_1, \ldots, c_s$, it is possible to prove that the integral $I(\hbar)$ in [15] is equal to

$$I(\hbar) = \sum_{k=1}^{s} \mathrm{e}^{(\mathrm{i}/\hbar)\Phi(c_k)}I_k^*(\hbar) + I_0(\hbar)$$

for some $C^\infty$ functions $I_k^*$ satisfying:

$$I_k^*(0) = [\det(I - L - D^2V(c_k))]^{-1/2}g(c_k)$$
$$k = 1, \ldots, s$$
$$I_0^{(j)}(0) = 0, \quad j = 0, 1, 2, \ldots$$

Moreover, under some additional smallness assumptions on $v$, it has been proved that the phase function $\Phi$ has a unique stationary point $c$ and as $\hbar \to 0$

$$I(\hbar) \sim e^{(i/\hbar)\Phi(c)} I^*(\hbar)$$

for some $C^\infty$ function $I^*$. Each term of the asymptotic expansion in powers of $\hbar$ of the function $I^*$ can be explicitly computed, and it is possible to prove that such an asymptotic expansion is Borel-summable and determines $I^*$ uniquely.

The application of these results to the infinite-dimensional oscillatory integral representation [13] for the solution of the Schrödinger equation allows the study of its semiclassical limit. One has to consider a potential $V$ that is the Fourier transform of a complex bounded variation measure $\mu$ on $(\mathbb{R}^d)$, such that $\int_{\mathbb{R}^d} e^{|\beta|\epsilon} d|\mu|(\beta) < \infty$ for some $\epsilon > 0$, and a particular form for the initial wave function $\psi_0(x) = e^{(i/\hbar)\phi(x)}\chi(x)$, where $\phi$ is real and $\phi, \chi \in C_0^\infty(\mathbb{R}^d)$ are independent of $\hbar$. This initial datum corresponds to an initial particle distribution $\rho_0(x) = |\chi|^2(x)$ and to a limiting value of the probability current $J_{\hbar=0} = \nabla\phi(x)\rho_0(x)/m$, giving an initial particle flux associated to the velocity field $\nabla\phi(x)/m$. One also has to assume that the Lagrange manifold $L_f \equiv (y, -\nabla f)$ intersects transversally the subset $\Lambda_V$ of the phase space made of all points $(y, p)$ such that $p$ is the momentum at $y$ of a classical particle that starts at time zero from $x$, moves under the action of $V$, and ends at $y$ at time $t$. In this case, the Feynman path integral [13] has an asymptotic expansion in powers of $\hbar$ for $\hbar \to 0$, whose leading term is the sum of the values of the function

$$\left| \det\left( \left( \frac{\partial \bar{\gamma}_k^{(j)}}{\partial y_l^{(j)}} (y^{(j)}, t) \right) \right) \right|^{-1/2} e^{-(i/2)\pi m^{(j)}} e^{-(i/\hbar)S} e^{-(i/\hbar)\phi} \chi$$

taken at the points $y^{(j)}$ such that a classical particle starting at $y^{(j)}$ at time zero with momentum $\nabla\phi(y^{(j)})$ is at $x$ at time $t$. $S$ is the classical action along this classical path $\bar{\gamma}^{(j)}$ and $m^{(j)}$ is the Maslov index of the path $\bar{\gamma}^{(j)}$, that is, $m^{(j)}$ is the number of zeros of

$$\det\left( \left( \frac{\partial \bar{\gamma}_k^{(j)}}{\partial y_l^{(j)}} (y^{(j)}, \tau) \right) \right)$$

as $\tau$ varies on the interval $(0, t)$.

### White-Noise Calculus

The leading idea of the present approach, which was originally proposed by C DeWitt-Morette and P Krée and presently realized in the framework of white-noise calculus by T Hida, L Streit, and many other authors, is the realization of the Feynman integrand $e^{(i/\hbar)S_t^\circ(\gamma)}$ as an infinite-dimensional distribution. This idea is similar to the one of the approach via Fourier transform, where the expression $(2\pi i)^{-d/2} \int_{\mathbb{R}^d} e^{(i/2)(x,x)} f(x) dx$ is realized as a distributional pairing between $e^{(i/2)(x,x)}/(2\pi i)^{d/2}$ and the function $f \in \mathcal{F}(\mathbb{R}^d)$ by means of the Parseval-type equality [9] and generalized to infinite-dimensional spaces. In white-noise calculus, the pairing is realized in a different measure space. Indeed, by manipulating the integrand in

$$(2\pi i)^{-d/2} \int_{\mathbb{R}^d} e^{(i/2)(x,x)} f(x) dx$$

one has

$$\int_{\mathbb{R}^d} \frac{e^{(i/2)(x,x)}}{(2\pi i)^{d/2}} f(x) dx = \int_{\mathbb{R}^d} \frac{e^{(i/2)(x,x)+(1/2)(x,x)}}{i^{d/2}} f(x) \frac{e^{-(1/2)(x,x)}}{(2\pi)^{d/2}} dx \qquad [16]$$

where the latter line can be interpreted as the distributional pairing of

$$\frac{e^{(i/2)(x,x)+(1/2)(x,x)}}{i^{d/2}}$$

and $f$ not with respect to Lebesgue measure but rather with respect to the standard Gaussian measure

$$\frac{e^{-(1/2)(x,x)}}{(2\pi)^{d/2}} dx$$

on $\mathbb{R}^d$. The RHS of [16] can be generalized to the case in which $\mathbb{R}^d$ is replaced by a path space, thanks to the fact that on infinite-dimensional spaces, even if Lebesgue measure is meaningless, Gaussian measures are well defined and can be used as reference measures. The detailed realization of this idea as well as its application to the mathematical realization of the Feynman integrand are rather technical and we certainly do not provide details here. We recall that this approach has been successfully applied to the rigorous realization of Feynman path-integral formulation of Chern–Simons models.

### Other Possible Approaches

Another possible mathematical definition of Feynman path integrals is based on Poisson measures. It was originally proposed by A M Chebotarev and V P Maslov and further developed by several authors such as S Albeverio, Ph Blanchard, Ph Combe, R Høegh-Krohn, M Sirugue, and V Kolokol'tsov. It can be applied to "phase-space integrals," to the Dirac equation and in particular algebraic settings, as well as to the Schrödinger

equation, with potentials of the same type "Fourier transform of bounded measure" discussed in the subsection "Infinite-dimensional oscillatory integrals."

Another possible definition of Feynman path integrals is based on a "time-slicing" approximation and a limiting procedure, rather closed to Feynman's original work based on Trotter product formula. The "sequential approach" was proposed originally by A Truman and further extensively developed by D Fujiwara and N Kumano-go. The paths $\gamma$ in formula [2] are approximated by piecewise linear paths and the Feynman path integral is correspondingly approximated by a finite-dimensional integral. In particular, D Fujiwara and N Kumano-go proved that the integrals defined in this way have some important properties, such as invariance under translations and orthogonal transformations. It is also possible to interchange the order of integration with Riemann–Stieltjies integrals and study the semiclassical approximation.

Finally, it is worthwhile to recall a very interesting and intuitive approach to the Feynman integration which is based on nonstandard analysis. It was introduced by S Albeverio, J E Fenstad, R Høegh-Krohn, and T Linstrøm in the 1980s, but it has not been systematically developed yet.

## Abbreviations

| | |
|---|---|
| $D\gamma$ | Heuristic Lebesgue-type measure on the space of paths |
| $P_{t,x}$ | Wiener Gaussian measure on $W_{t,x}$ |
| $S_t$ | Action functional |
| $S_t^\circ$ | Action functional for the free particle |
| $V$ | Potential |
| $W_{t,x}$ | Space of continuous paths with fixed initial point $W_{t,x} = \{w \in C(0,t;\mathbb{R}^d) : w(0) = x\}$ |
| $\hbar$ | Reduced Planck constant |
| $\Phi$ | Phase function |
| $\gamma$ | Path, $\gamma : [0,t] \to \mathbb{R}^d$ |
| $\hat{\mu}$ | Fourier transform of the measure $\mu$ |
| $\psi$ | Wave function, solution of the Schrödinger equation |
| $\mathcal{H}$ | Hilbert space |
| $\widetilde{\int}_{\mathcal{H}}$ | Fresnel integral on the Hilbert space $\mathcal{H}$ |
| $\widetilde{\int^\circ}_{\mathcal{H}}$ | Infinite-dimensional oscillatory integral on the Hilbert space $\mathcal{H}$ |
| $\langle , \rangle$ | inner product |
| $\| \ \|$ | norm |

# Finite-Dimensional Algebras and Quivers

**A Savage**, University of Toronto, Toronto, ON, Canada

## Introduction

Algebras and their representations are ubiquitous in mathematics. It turns out that representations of finite-dimensional algebras are intimately related to quivers, which are simply oriented graphs. Quivers arise naturally in many areas of mathematics, including representation theory, algebraic and differential geometry, Kac–Moody algebras, and quantum groups. In this article, we give a brief overview of some of these topics. We start by giving the basic definitions of associative algebras and their representations. We then introduce quivers and their representation theory, mentioning the connection to the representation theory of associative algebras. We also discuss in some detail the relationship between quivers and the theory of Lie algebras.

## Associative Algebras

An "algebra" is a vector space $A$ over a field $k$ equipped with a multiplication which is distributive and such that

$$a(xy)=(ax)y=x(ay), \quad \forall a\in k,\ x,y\in A$$

When we wish to make the field explicit, we call $A$ a $k$-algebra. An algebra is "associative" if $(xy)z=x(yz)$ for all $x,y,z\in A$. $A$ has a "unit," or "multiplicative identity," if it contains an element $\mathbf{1}_A$ such that $\mathbf{1}_A x = x\mathbf{1}_A = x$ for all $x\in A$. From now on, we will assume all algebras are associative with unit. $A$ is said to be "commutative" if $xy=yx$ for all $x,y\in A$ and finite dimensional if the underlying vector space of $A$ is finite dimensional.

A vector subspace $I$ of $A$ is called a "left (resp. right) ideal" if $xy\in I$ for all $x\in A, y\in I$ (resp. $x\in I, y\in A$). If $I$ is both a right and a left ideal, it is called a two-sided ideal of $A$. If $I$ is a two-sided ideal of $A$, then the factor space $A/I$ is again an algebra.

An algebra homomorphism is a linear map $f: A_1\to A_2$ between two algebras such that

$$f(\mathbf{1}_{A_1})=\mathbf{1}_{A_2}$$
$$f(xy)=f(x)f(y), \quad \forall x,y\in A$$

A representation of an algebra $A$ is an algebra homomorphism $\rho: A\to \mathrm{End}_k(V)$ for a $k$-vector space $V$. Here $\mathrm{End}_k(V)$ is the space of endomorphisms of the vector space $V$ with multiplication given by composition. Given a representation of an algebra $A$ on a vector space $V$, we may view $V$ as an $A$-module with the action of $A$ on $V$ given by

$$a\cdot v=\rho(a)v, \quad a\in A,\ v\in V$$

A morphism $\psi: V\to W$ of two $A$-modules (or equivalently, representations of $A$) is a linear map commuting with the action of $A$. That is, it is a linear map satisfying

$$a\cdot\psi(v)=\psi(a\cdot v), \quad \forall a\in A,\ v\in V$$

Let $G$ be a commutative monoid (a set with an associative multiplication and a unit element). A $G$-graded $k$-algebra is a $k$-algebra which can be expressed as a direct sum $A=\oplus_{g\in G}A_g$ such that $aA_g\subset A_g$ for all $a\in k$ and $A_{g_1}A_{g_2}\subset A_{g_1+g_2}$ for all $g_1,g_2\in G$. A morphism $\psi: A\to B$ of $G$-graded algebras is a $k$-algebra morphism respecting the grading, that is, satisfying $\psi(A_g)\subset B_g$ for all $g\in G$.

## Quivers and Path Algebras

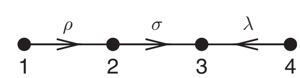
A "quiver" is simply an oriented graph. More precisely, a quiver is a pair $Q=(Q_0,Q_1)$ where $Q_0$ is a finite set of vertices and $Q_1$ is a finite set of arrows (oriented edges) between them. For $a\in Q_1$, we let $h(a)$ denote the "head" of $a$ and $t(a)$ denote the "tail" of $a$. A path in $Q$ is a sequence $x=\rho_1\rho_2\ldots\rho_m$ of arrows such that $h(\rho_{i+1})=t(\rho_i)$ for $1\le i\le m-1$. We let $t(x)=t(\rho_m)$ and $h(x)=h(\rho_1)$ denote the initial and final vertices of the path $x$. For each vertex $i\in Q_0$, we let $e_i$ denote the trivial path which starts and ends at the vertex $i$.

Fix a field $k$. The path algebra $kQ$ associated to a quiver $Q$ is the $k$-algebra whose underlying vector space has basis the set of paths in $Q$, and with the product of paths given by concatenation. Thus, if $x=\rho_1\ldots\rho_m$ and $y=\sigma_1\ldots\sigma_n$ are two paths, then $xy=\rho_1\ldots\rho_m\sigma_1\ldots\sigma_n$ if $h(y)=t(x)$ and $xy=0$ otherwise. We also have

$$e_ie_j=\begin{cases} e_i & \text{if } i=j\\ 0 & \text{if } i\neq j\end{cases}$$
$$e_ix=\begin{cases} x & \text{if } h(x)=i\\ 0 & \text{if } h(x)\neq i\end{cases}$$
$$xe_i=\begin{cases} x & \text{if } t(x)=i\\ 0 & \text{if } t(x)\neq i\end{cases}$$

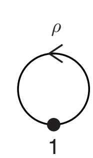
for $x\in kQ$. This multiplication is associative. Note that $e_iA$ and $Ae_i$ have bases given by the set of paths ending and starting at $i$, respectively. The path algebra has a unit given by $\sum_{i\in Q_0}e_i$.

**Example 1** Let $Q$ be the following quiver:



then $kQ$ has a basis given by the set of paths $\{e_1,e_2,e_3,e_4,\rho,\sigma,\lambda,\sigma\rho\}$. Some sample products are $\rho\sigma=0, \lambda\lambda=0, \lambda\sigma=0, e_3\sigma=\sigma e_2=\sigma, e_2\sigma=0$.

**Example 2** Let $Q$ be the following quiver (the so-called "Jordan quiver").



Then $kQ\cong k[t]$, the algebra of polynomials in one variable.

Note that the path algebra $kQ$ is finite dimensional if and only if $Q$ has no oriented cycles (paths with the same head and tail vertex).

**Example 3** Let $Q$ be the following quiver:

Then for every $1 \leq i \leq j \leq n$, there is a unique path from $i$ to $j$. Let $f : kQ \to M_n(k)$ be the linear map from the path algebra to the $n \times n$ matrices with entries in the field $k$ that sends the unique path from $i$ to $j$ to the matrix $E_{ji}$ with $(j, i)$ entry 1 and all other entries zero. Then one can show that $f$ is an isomorphism onto the algebra of lower triangular matrices.

## Representations of Quivers

Fix a field $k$. A representation of a quiver $Q$ is an assignment of a vector space to each vertex and to each arrow a linear map between the vector spaces assigned to its tail and head. More precisely, a representation $V$ of $Q$ is a collection

$$\{V_i | i \in Q_0\}$$

of finite-dimensional $k$-vector spaces together with a collection

$$\{V_\rho : V_{t(\rho)} \to V_{h(\rho)} | \rho \in Q_1\}$$

of $k$-linear maps. Note that a representation $V$ of a quiver $Q$ is equivalent to a representation of the path algebra $kQ$. The dimension of $V$ is the map $d_V : Q_0 \to \mathbb{Z}_{\geq 0}$ given by $d_V(i) = \dim V_i$ for $i \in Q_0$.

If $V$ and $W$ are two representations of a quiver $Q$, then a morphism $\psi : V \to W$ is a collection of $k$-linear maps

$$\{\psi_i : V_i \to W_i | i \in Q_0\}$$

such that

$$W_\rho \psi_{t(\rho)} = \psi_{h(\rho)} V_\rho, \quad \forall \rho \in Q_1$$

**Proposition 1** *Let $A$ be a finite-dimensional $k$-algebra. Then the category of representations of $A$ is equivalent to the category of representations of the algebra $kQ/I$ for some quiver $Q$ and some two-sided ideal $I$ of $kQ$.*

It is for this reason that the study of finite-dimensional associative algebras is intimately related to the study of quivers.

We define the direct sum $V \oplus W$ of two representations $V$ and $W$ of a quiver $Q$ by

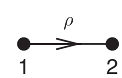
$$(V \oplus W)_i = V_i \oplus W_i, \quad i \in Q_0$$

and $(V \oplus W)_\rho : V_{t(\rho)} \oplus W_{t(\rho)} \to V_{h(\rho)} \oplus W_{h(\rho)}$ by

$$(V \oplus W)_\rho((v, w)) = (V_\rho(v), W_\rho(w))$$

for $v \in V_{t(\rho)}, w \in W_{t(\rho)}, \rho \in Q_1$. A representation $V$ is "trivial" if $V_i = 0$ for all $i \in Q_0$ and "simple" if its only subrepresentations are the zero representation and $V$ itself. We say that $V$ is "decomposable" if it is isomorphic to $W \oplus U$ for some nontrivial representations $W$ and $U$. Otherwise, we call $V$ "indecomposable." Every representation of a quiver has a decomposition into indecomposable representations that is unique up to isomorphism and permutation of the components. Thus, to classify all representations of a quiver, it suffices to classify the indecomposable representations.

**Example 4** Let $Q$ be the following quiver:



Then $Q$ has three indecomposable representations $U$, $V$, and $W$ given by:

$$\begin{aligned} U_1 &= k, \quad & U_2 &= 0, \quad & U_\rho &= 0 \\ V_1 &= 0, \quad & V_2 &= k, \quad & V_\rho &= 0 \\ W_1 &= k, \quad & W_2 &= k, \quad & W_\rho &= 1 \end{aligned}$$

Then any representation $Z$ of $Q$ is isomorphic to

$$Z \cong U^{d_1 - r} \oplus V^{d_2 - r} \oplus W^r$$

where $d_1 = \dim Z_1, d_2 = \dim Z_2, r = \text{rank } Z_\rho$.

**Example 5** Let $Q$ be the Jordan quiver. Then representations $V$ of $Q$ are classified up to isomorphism by the Jordan normal form of $V_\rho$ where $\rho$ is the single arrow of the quiver. Indecomposable representations correspond to single Jordan blocks. These are parametrized by a discrete parameter $n$ (the size of the block) and a continuous parameter $\lambda$ (the eigenvalue of the block).

A quiver is said to be of "finite type" if it has only finitely many indecomposable representations (up to isomorphism). If a quiver has infinitely many isomorphism classes but they can be split into families, each parametrized by a single continuous parameter, then we say the quiver is of "tame" (or "affine") type. If a quiver is of neither finite nor tame type, it is of "wild type." It turns out that there is a rather remarkable relationship between the classification of quivers and their representations and the theory of Kac–Moody algebras.

The "Euler form" or "Ringel form" of a quiver $Q$ is defined to be the asymmetric bilinear form on $\mathbb{Z}^{Q_0}$ given by

$$\langle \alpha, \beta \rangle = \sum_{i \in Q_0} \alpha(i)\beta(i) - \sum_{\rho \in Q_1} \alpha(t(\rho))\beta(h(\rho))$$

In the standard coordinate basis of $\mathbb{Z}^{Q_0}$, the Euler form is represented by the matrix $E = (a_{ij})$ where

$$a_{ij} = \delta_{ij} - \#\{\rho \in Q_1 \mid t(\rho) = i, h(\rho) = j\}$$

Here $\delta_{ij}$ is the Kronecker delta symbol. We define the "Cartan form" of the quiver $Q$ to be the symmetric bilinear form given by

$$(\alpha, \beta) = \langle \alpha, \beta \rangle + \langle \beta, \alpha \rangle$$

Note that the Cartan form is independent of the orientation of the arrows in $Q$. In the standard coordinate basis of $\mathbb{Z}^{Q_0}$, the Cartan form is represented by the Cartan matrix $C = (c_{ij})$ where $c_{ij} = a_{ij} + a_{ji}$.

**Example 6** For the quiver in Example 1, the Euler matrix is

$$E = \begin{pmatrix} 1 & -1 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & -1 & 1 \end{pmatrix}$$

and the Cartan matrix is

$$C = \begin{pmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{pmatrix}$$

The "Tits form" $q$ of a quiver $Q$ is defined by

$$q(\alpha) = \langle \alpha, \alpha \rangle = \tfrac{1}{2}(\alpha, \alpha)$$

It is known that the number of continuous parameters describing representations of dimension $\alpha$ for $\alpha \neq 0$ is greater than or equal to $1 - q(\alpha)$.

Let $\mathfrak{g}$ be the Kac–Moody algebra associated to the Cartan matrix of a quiver $Q$. By forgetting the orientation of the arrows of $Q$, we obtain the underlying (undirected) graph. This is the Dynkin graph of $\mathfrak{g}$. Associated to $\mathfrak{g}$ is a root system and a set of simple roots $\{\alpha_i \mid i \in Q_0\}$ indexed by the vertices of the Dynkin graph.

**Theorem 1** (Gabriel's theorem).

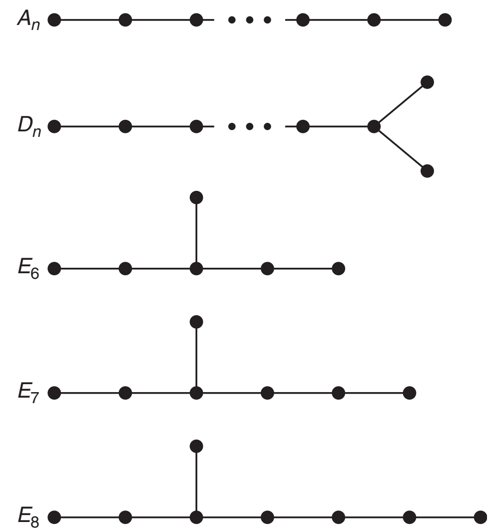
(i) *A quiver is of finite type if and only if the underlying graph is a union of Dynkin graphs of type A, D, or E.*

(ii) *A quiver is of tame type if and only if the underlying graph is a union of Dynkin graphs of type A, D, or E and extended Dynkin graphs of type* $\widehat{A}, \widehat{D}$, *or* $\widehat{E}$ (*with at least one extended Dynkin graph*).

(iii) *The isomorphism classes of indecomposable representations of a quiver Q of finite type are in one-to-one correspondence with the positive roots of the root system associated to the underlying graph of Q. The correspondence is given by*

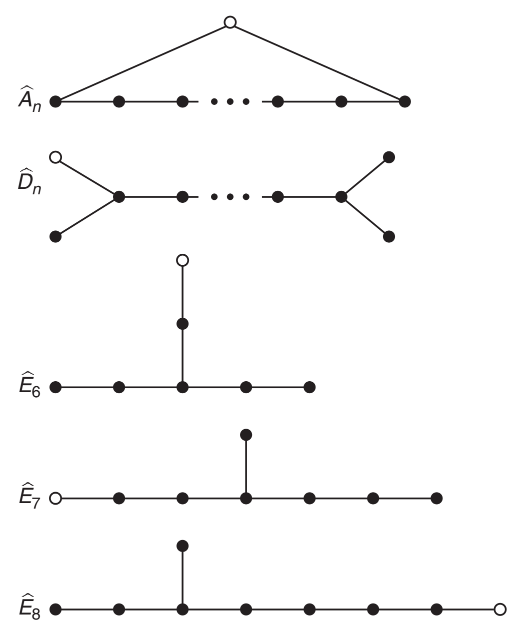
$$V \mapsto \sum_{i \in Q_0} d_V(i)\alpha_i$$

The Dynkin graphs of type $A$, $D$, and $E$ are as follows.



Here the subscript indicates the number of vertices in the graph.

The extended Dynkin graphs of type $\widehat{A}, \widehat{D}$, and $\widehat{E}$ are as follows.



Here we have used an open dot to denote the vertex that was added to the corresponding Dynkin graph of type $A$, $D$, or $E$.

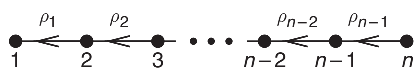
**Theorem 2** (Kac's theorem). *Let Q be an arbitrary quiver. The dimension vectors of indecomposable representations of Q correspond to positive roots*

*of the root system associated to the underlying graph of $Q$ (and are thus independent of the orientation of the arrows of $Q$). The correspondence is given by*

$$d_V \mapsto \sum_{i \in Q_0} d_V(i)\alpha_i$$

Note that in Kac's Theorem, it is not asserted that the isomorphism classes are in one-to-one correspondence with the roots as in the finite case considered in Gabriel's theorem. It turns out that in the general case, dimension vectors for which there is exactly one isomorphism class correspond to real roots while imaginary roots correspond to dimension vectors for which there are families of representations.

**Example 7** Let $Q$ be the quiver of type $A_n$, oriented as follows.



It is known that the set of positive roots of the simple Lie algebra of type $A_n$ is

$$\left\{ \sum_{i=j}^{l} \alpha_i \,\middle|\, 1 \le j \le l \le n \right\} \sqcup \{0\}$$

The zero root corresponds to the trivial representation. The root $\sum_{i=j}^{l} \alpha_i$ for some $1 \le j \le l \le n$ corresponds to the unique (up to isomorphism) representation $V$ with

$$V_i = \begin{cases} k & \textit{if } j \le i \le l \\ 0 & \textit{otherwise} \end{cases}$$

and

$$V_{\rho_i} = \begin{cases} 1 & \textit{if } j \le i \le l-1 \\ 0 & \textit{otherwise} \end{cases}$$

**Example 8** Let $Q$ be the quiver of type $\widehat{A}_n$, with all arrows oriented in the same direction (for instance, counter-clockwise). The positive root $\sum_{i=0}^{n} \alpha_i$ (where $\{0, 1, 2, \ldots, n\}$ are the vertices of the quiver) is imaginary. There is a one-parameter family of isomorphism classes of indecomposable representations where the maps assigned to each arrow are nonzero. The parameter is the composition of the maps around the loop.

If a quiver $Q$ has no oriented cycles, then the only simple $kQ$-modules are the modules $S^i$ for $i \in Q_0$ where

$$S^i_j = \begin{cases} k & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

and $S^i_\rho = 0$ for all $\rho \in Q_1$.

## Ringel–Hall Algebras

Let $k$ be the finite field $\mathbb{F}_q$ with $q$ elements and let $Q$ be a quiver with no oriented cycles. Let $\mathcal{P}$ be the set of all isomorphism classes of $kQ$-modules which are finite as sets (since $k$ is finite dimensional, these are just the quiver representations we considered above). Let $A$ be a commutative integral domain containing $\mathbb{Z}$ and elements $v, v^{-1}$ such that $v^2 = q$. The Ringel–Hall algebra $H = H_{A,v}(kQ)$ is the free $A$-module with basis $\{[V]\}$ indexed by the isomorphism classes of representations of the quiver $Q$, with an $A$-bilinear multiplication defined by

$$[V^1] \cdot [V^2] = v^{\langle \dim V^1, \dim V^2 \rangle} \sum_V g^V_{V^1,V^2}[V]$$

Here $\langle \dim V^1, \dim V^2 \rangle$ is the Euler form and $g^V_{V^1,V^2}$ is the number of submodules $W$ of $V$ such that $V/W \cong V^1$ and $W \cong V^2$. $H$ is an associative $\mathbb{Z}^{Q_0}_{\ge 0}$-graded algebra, with identity element $[0]$, the isomorphism class of the trivial representation. The grading $H = \oplus_\alpha H_\alpha$ is given by letting $H_\alpha$ be the $A$-span of the set of isomorphism classes $[V]$ such that $\dim V = \alpha$.

Let $C = C_{A,v}(kQ)$ be the $A$-subalgebra of $H$ generated by the isomorphism classes $[S^i]$ of the simple $kQ$-modules. $C$ is called the "composition algebra." If the underlying graph of $Q$ is of finite type, then $C = H$.

Now let $\mathcal{K}$ be a set of finite fields $k$ such that the set $\{|k| \,|\, k \in \mathcal{K}\}$ is infinite. Let $A$ be an integral domain containing $\mathbb{Q}$ and, for each $k \in \mathcal{K}$, an element $v_k$ such that $v_k^2 = |k|$. For each $k \in \mathcal{K}$, we have the corresponding composition algebra $C_k$, generated by the elements $[{}^kS^i]$ (here we make the field $k$ explicit). Now let $C$ be the subring of $\prod_{k \in \mathcal{K}} C_k$ generated by $\mathbb{Q}$ and the elements

$$\begin{aligned} t &= (t_k)_{k \in \mathcal{K}}, & t_k &= v_k \\ t^{-1} &= (t_k^{-1})_{k \in \mathcal{K}}, & t_k^{-1} &= (v^k)^{-1} \\ u^i &= (u^i_k)_{k \in \mathcal{K}}, & u^i_k &= [{}^kS^i],\ i \in Q_0 \end{aligned}$$

Now, $t$ lies in the center of $C$ and if $p(t) = 0$ for some polynomial $p$, then $p$ must be the zero polynomial since the set of $v_k$ is infinite. Thus, we may think of $C$ as the $A$-algebra generated by the $u^i, i \in Q_0$, with $A = \mathbb{Q}[t, t^{-1}]$ and $t$ an indeterminate. Let $C^* = \mathbb{Q}(t) \otimes_A C$. We call $C^*$ the "generic composition algebra."

Let $\mathfrak{g}$ be the Kac–Moody algebra associated to the Cartan matrix of the quiver $Q$ and let $U$ be the quantum group associated by Drinfeld and Jimbo to $\mathfrak{g}$. It has a triangular decomposition $U = U^- \otimes U^0 \otimes U^+$.

Specifically, $U^+$ is the $\mathbb{Q}(t)$-algebra with generators $E_i, i \in Q_0$ and relations

$$\sum_{p=0}^{1-c_{ij}} (-1)^p \begin{bmatrix} 1-c_{ij} \\ p \end{bmatrix} E_i^p E_j E_i^{1-c_{ij}-p}, \quad i \neq j$$

where $c_{ij}$ are the entries of the Cartan matrix and

$$\begin{bmatrix} m \\ p \end{bmatrix} = \frac{[m]!}{[p]![m-p]!}$$

$$[n] = \frac{t^n - t^{-n}}{t - t^{-1}}, \quad [n]! = [1][2]\ldots[n]$$

**Theorem 3** *There is a* $\mathbb{Q}(t)$*-algebra isomorphism* $C^* \to U^+$ *sending* $u_i \mapsto E_i$ *for all* $i \in Q_0$.

The proof of Theorem 3 is due to Ringel in the case that the underlying graph of $Q$ is of finite or affine type. The more general case presented here is due to Green.

All of the Kac–Moody algebras considered so far have been simply-laced. That is, their Cartan matrices are symmetric. There is a way to deal with non-simply-laced Kac–Moody algebras using species. We will not treat this subject in this article.

## Quiver Varieties

One can use varieties associated to quivers to yield a geometric realization of the upper half of the universal enveloping algebra of a Kac–Moody algebra $\mathfrak{g}$ and its irreducible highest-weight representations.

### Lusztig's Quiver Varieties

We first introduce the quiver varieties, first defined by Lusztig, which yield a geometric realization of the upper half $\mathcal{U}^+$ of the universal enveloping algebra of a simply laced Kac–Moody algebra $\mathfrak{g}$. Let $Q = (Q_0, Q_1)$ be the quiver whose vertices $Q_0$ are the vertices of the Dynkin diagram of $\mathfrak{g}$ and whose set of arrows $Q_1$ consists of all the edges of the Dynkin diagram with both orientations. By definition, $\mathcal{U}^+$ is the $\mathbb{Q}$-algebra defined by generators $e_i, i \in Q_0$, subject to the Serre relations

$$\sum_{p=0}^{1-c_{ij}} (-1)^p \begin{pmatrix} 1-c_{ij} \\ p \end{pmatrix} e_i^p e_j e^{1-c_{ij}-p} = 0$$

for all $i \neq j$ in $Q_0$, where $c_{ij}$ are the entries of the Cartan matrix associated to $Q$. For any $\nu = \sum_{i \in Q_0} \nu_i i, \nu_i \in \mathbb{N}$, let $\mathcal{U}_\nu^+$ be the subspace of $\mathcal{U}^+$ spanned by the monomials $e_{i_1} e_{i_2} \ldots e_{i_n}$ for various sequences $i_1, i_2, \ldots, i_n$ in which $i$ appears $\nu_i$ times for each $i \in Q_0$. Thus, $\mathcal{U}^+ = \oplus_\nu \mathcal{U}_\nu^+$. Let $\mathcal{U}_\mathbb{Z}^+$ be the subring of $\mathcal{U}^+$ generated by the elements $e_i^p/p!$ for $i \in Q_0, p \in \mathbb{N}$. Then $\mathcal{U}_\mathbb{Z}^+ = \oplus_\nu \mathcal{U}_{\mathbb{Z},\nu}^+$ where $\mathcal{U}_{\mathbb{Z},\nu}^+ = \mathcal{U}_\mathbb{Z}^+ \cap \mathcal{U}_\nu^+$.

We define the involution $\bar{\ }: Q_1 \to Q_1$ to be the function which takes $\rho \in Q_1$ to the element of $Q_1$ consisting of the same edge with opposite orientation. An orientation of our graph/quiver is a choice of a subset $\Omega \subset Q_1$ such that $\Omega \cup \bar{\Omega} = Q_1$ and $\Omega \cap \bar{\Omega} = \emptyset$.

Let $\mathcal{V}$ be the category of finite-dimensional $Q_0$-graded vector spaces $\boldsymbol{V} = \oplus_{i \in Q_0} \boldsymbol{V}_i$ over $\mathbb{C}$ with morphisms being linear maps respecting the grading. Then $\boldsymbol{V} \in \mathcal{V}$ shall denote that $\boldsymbol{V}$ is an object of $\mathcal{V}$. The dimension of $\boldsymbol{V} \in \mathcal{V}$ is given by $\boldsymbol{v} = \dim \boldsymbol{V} = (\dim \boldsymbol{V}_0, \ldots, \dim \boldsymbol{V}_n)$.

Given $\boldsymbol{V} \in \mathcal{V}$, let $E_V$ be the space of representations of $Q$ with underlying vector space $\boldsymbol{V}$. That is,

$$\boldsymbol{E}_V = \bigoplus_{\rho \in Q_1} \mathrm{Hom}(\boldsymbol{V}_{t(\rho)}, \boldsymbol{V}_{h(\rho)})$$

For any subset $Q_1'$ of $Q_1$, let $\boldsymbol{E}_{V,Q_1'}$ be the subspace of $\boldsymbol{E}_V$ consisting of all vectors $x = (x_\rho)$ such that $x_\rho = 0$ whenever $\rho \notin Q_1'$. The algebraic group $G_V = \prod_i \mathrm{Aut}(\boldsymbol{V}_i)$ acts on $\boldsymbol{E}_V$ and $\boldsymbol{E}_{V,Q_1'}$ by

$$(g, x) = ((g_i), (x_\rho)) \mapsto gx$$
$$= (x_\rho') = (g_{h(\rho)} x_\rho g_{t(\rho)}^{-1})$$

Define the function $\varepsilon : Q_1 \to \{-1, 1\}$ by $\varepsilon(\rho) = 1$ for all $\rho \in \Omega$ and $\varepsilon(\rho) = -1$ for all $\rho \in \bar{\Omega}$. Let $\langle \cdot, \cdot \rangle$ be the nondegenerate, $G_V$-invariant, symplectic form on $\boldsymbol{E}_V$ with values in $\mathbb{C}$ defined by

$$\langle x, y \rangle = \sum_{\rho \in Q_1} \varepsilon(\rho) \mathrm{tr}(x_\rho y_{\bar{\rho}})$$

Note that $\boldsymbol{E}_V$ can be considered as the cotangent space of $\boldsymbol{E}_{V,\Omega}$ under this form.

The moment map associated to the $G_V$-action on the symplectic vector space $\boldsymbol{E}_V$ is the map $\psi : \boldsymbol{E}_V \to \boldsymbol{gl}_V = \prod_i \mathrm{End}\boldsymbol{V}_i$, the Lie algebra of $\mathrm{GL}_V$, with $i$-component $\psi_i : \boldsymbol{E}_V \to \mathrm{End}\boldsymbol{V}_i$ given by

$$\psi_i(x) = \sum_{\rho \in Q_1, h(\rho) = i} \varepsilon(\rho) x_\rho x_{\bar{\rho}}$$

**Definition 1** An element $x \in \boldsymbol{E}_V$ is said to be nilpotent if there exists an $N \geq 1$ such that for any sequence $\rho_1, \rho_2, \ldots, \rho_N$ in $H$ satisfying $t(\rho_1) = h(\rho_2)$, $t(\rho_2) = h(\rho_3), \ldots, t(\rho_{N-1}) = h(\rho_N)$, the composition $x_{\rho_1} x_{\rho_2} \ldots x_{\rho_N} : \boldsymbol{V}_{t(\rho_N)} \to \boldsymbol{V}_{h(\rho_1)}$ is zero.

**Definition 2** Let $\Lambda_V$ be the set of all nilpotent elements $x \in \boldsymbol{E}_V$ such that $\psi_i(x) = 0$ for all $i \in I$.

A subset of an algebraic variety is said to be "constructible" if it is obtained from subvarieties from a finite number of the usual set-theoretic operations. A function $f : A \to \mathbb{Q}$ on an algebraic variety $A$ is said to be a constructible function if $f^{-1}(a)$ is a constructible set for all $a \in \mathbb{Q}$ and is empty for all but finitely many $a$. Let $M(\Lambda_V)$ denote the $\mathbb{Q}$-vector space of all constructible functions on $\Lambda_V$. Let $\widetilde{M}(\Lambda_V)$ denote the $\mathbb{Q}$-subspace of $M(\Lambda_V)$ consisting of those functions that are constant on any $G_V$-orbit in $\Lambda_V$.

Let $\boldsymbol{V}, \boldsymbol{V}', \boldsymbol{V}'' \in \mathcal{V}$ such that $\dim \boldsymbol{V} = \dim \boldsymbol{V}' + \dim \boldsymbol{V}''$. Now, suppose that $\boldsymbol{S}$ is an $I$-graded subspace of $\boldsymbol{V}$. For $x \in \Lambda_V$ we say that $\boldsymbol{S}$ is $x$-stable if $x(\boldsymbol{S}) \subset \boldsymbol{S}$. Let $\Lambda_{V;V',V''}$ be the variety consisting of all pairs $(x, \boldsymbol{S})$ where $x \in \Lambda_V$ and $\boldsymbol{S}$ is an $I$-graded $x$-stable subspace of $\boldsymbol{V}$ such that $\dim \boldsymbol{S} = \dim \boldsymbol{V}''$. Now, if we fix some isomorphisms $\boldsymbol{V}/\boldsymbol{S} \cong \boldsymbol{V}', \boldsymbol{S} \cong \boldsymbol{V}''$, then $x$ induces elements $x' \in \Lambda_{V'}$ and $x'' \in \Lambda_{V''}$. We then have the maps

$$\Lambda_{V'} \times \Lambda_{V''} \xleftarrow{p_1} \Lambda_{V;V',V''} \xrightarrow{p_2} \Lambda_V$$

where $p_1(x, \boldsymbol{S}) = (x', x''), p_2(x, \boldsymbol{S}) = x$.

For a holomorphic map $\pi$ between complex varieties $A$ and $B$, let $\pi_!$ denote the map between the spaces of constructible functions on $A$ and $B$ given by

$$(\pi_! f)(y) = \sum_{a \in \mathbb{Q}} a \chi(\pi^{-1}(y) \cap f^{-1}(a))$$

Let $\pi^*$ be the pullback map from functions on $B$ to functions on $A$ acting as $\pi^* f(y) = f(\pi(y))$. We then define a map

$$\widetilde{M}(\Lambda_{V'}) \times \widetilde{M}(\Lambda_{V''}) \to \widetilde{M}(\Lambda_V) \qquad [1]$$

by $(f', f'') \mapsto f' * f''$ where

$$f' * f'' = (p_2)_! p_1^*(f' \times f'')$$

Here $f' \times f'' \in \widetilde{M}(\Lambda_{V'} \times \Lambda_{V''})$ is defined by $(f' \times f'')(x', x'') = f'(x') f''(x'')$. The map [1] is bilinear and defines an associative $\mathbb{Q}$-algebra structure on $\oplus_\nu \widetilde{M}(\Lambda_{V^\nu})$ where $\boldsymbol{V}^\nu$ is the object of $\mathcal{V}$ defined by $\boldsymbol{V}_i^\nu = \mathbb{C}^{\nu_i}$.

There is a unique algebra homomorphism $\kappa : \mathcal{U}^+ \to \oplus_\nu \widetilde{M}(\Lambda_{V^\nu})$ such that $\kappa(e_i)$ is the function on the point $\Lambda_{V^i}$ with value 1. Then $\kappa$ restricts to a map $\kappa_\nu : \mathcal{U}_\nu^+ \to \widetilde{M}(\Lambda_{V^\nu})$. It can be shown that $\kappa_{pi}(e_i^p / p!)$ is the function 1 on the point $\Lambda_{V^{pi}}$ for $i \in Q_0, p \in \mathbb{Z}_{\geq 0}$.

Let $\widetilde{M}_{\mathbb{Z}}(\Lambda_V)$ be the set of all functions in $\widetilde{M}(\Lambda_V)$ that take on only integer values. One can show that if $f' \in \widetilde{M}_{\mathbb{Z}}(\Lambda_{V'})$ and $f'' \in \widetilde{M}_{\mathbb{Z}}(\Lambda_{V''})$, then $f' * f'' \in \widetilde{M}_{\mathbb{Z}}(\Lambda_V)$ in the setup of [1]. Thus $\kappa_\nu(\mathcal{U}_{\mathbb{Z},\nu}^+) \subseteq \widetilde{M}_{\mathbb{Z}}(\Lambda_{V^\nu})$.

Let $\mathrm{Irr}\Lambda_V$ denote the set of irreducible components of $\Lambda_V$. The following proposition was conjectured by Lusztig and proved by him in the affine (and finite) case. The general case was proved by Kashiwara and Saito.

**Proposition 2** *For any* $\nu \in (\mathbb{Z}_{\geq 0})^{Q_0}$, *we have* $\dim \mathcal{U}_\nu^+ = \#\mathrm{Irr}\Lambda_{V^\nu}$.

We then have the following important result due to Lusztig.

**Theorem 4** *Let* $\nu \in (\mathbb{Z}_{\geq 0})^{Q_0}$. *Then,*

(i) *For any* $Z \in \mathrm{Irr}\Lambda_{V^\nu}$, *there exists a unique* $f_Z \in \kappa_\nu(\mathcal{U}_{\mathbb{Z},\nu}^+)$ *such that* $f_Z$ *is equal to 1 on an open dense subset of* $Z$ *and equal to zero on an open dense subset of* $Z' \in \mathrm{Irr}\Lambda_{V^\nu}$ *for all* $Z' \neq Z$.
(ii) $\{f_Z \mid Z \in \mathrm{Irr}\Lambda_{V^\nu}\}$ *is a* $\mathbb{Q}$-*basis of* $\kappa_\nu(\mathcal{U}_\nu^+)$.
(iii) $\kappa_\nu : \mathcal{U}_\nu^+ \to \kappa_\nu(\mathcal{U}_\nu^+)$ *is an isomorphism.*
(iv) *Define* $[Z] \in \mathcal{U}_\nu^+$ *by* $\kappa_\nu([Z]) = f_Z$. *Then* $B_\nu = \{[Z] \times \mid Z \in \mathrm{Irr}\Lambda_{V^\nu}\}$ *is a* $\mathbb{Q}$-*basis of* $\mathcal{U}_\nu^+$.
(v) $\kappa_\nu(\mathcal{U}_{\mathbb{Z},\nu}^+) = \kappa_\nu(\mathcal{U}_\nu^+) \cap \widetilde{M}_{\mathbb{Z}}(\Lambda_{V^\nu})$.
(vi) $B_\nu$ *is a* $\mathbb{Z}$-*basis of* $\mathcal{U}_{\mathbb{Z},\nu}^+$.

From this theorem, we see that $B = \sqcup_\nu B_\nu$ is a $\mathbb{Q}$-basis of $\mathcal{U}^+$, which is called the "semicanonical basis." This basis has many remarkable properties. One of these properties is as follows. Via the algebra involution of the entire universal enveloping algebra $\mathcal{U}$ of $\mathfrak{g}$ given on the Chevalley generators by $e_i \mapsto f_i, f_i \mapsto e_i$ and $h \mapsto -h$ for $h$ in the Cartan subalgebra of $\mathfrak{g}$, one obtains from the results of this section a semicanonical basis of $\mathcal{U}^-$, the lower half of the universal enveloping algebra of $\mathfrak{g}$. For any irreducible highest-weight integrable representation $V$ of $\mathcal{U}$ (or, equivalently, $\mathfrak{g}$), let $v \in V$ be a nonzero highest-weight vector. Then the set

$$\{bv | b \in B, bv \neq 0\}$$

is a $\mathbb{Q}$-basis of $V$, called the semicanonical basis of $V$. Thus, the semicanonical basis of $\mathcal{U}^-$ is simultaneously compatible with all irreducible highest-weight integrable modules. There is also a way to define the semicanonical basis of a representation directly in a geometric way. This is the subject of the next subsection.

One can also obtain a geometric realization of the upper part $U^+$ of the quantum group in a similar manner using perverse sheaves instead of constructible functions. This construction yields the canonical basis of the associated quantum group (a $q$-deformation of the universal enveloping algebra) which also has many remarkable properties and is closely related to the theory of crystal bases.

### Nakajima's Quiver Varieties

We introduce here a description of the quiver varieties first presented by Nakajima. They yield a geometric realization of the irreducible highest-weight representations of simply-laced Kac–Moody algebras. The construction was motivated by the work of Kronheimer and Nakajima on solutions to the anti-self-dual Yang–Mills equations on ALE gravitational instantons (*see* Instantons: Topological Aspects).

**Definition 3** For $v, w \in \mathbb{Z}^I_{\geq 0}$, choose I-graded vector spaces $V$ and $W$ of graded dimensions $v$ and $w$, respectively. Then define

$$\Lambda \equiv \Lambda(v, w) = \Lambda_V \times \bigoplus_{i \in I} \mathrm{Hom}(V_i, W_i)$$

**Definition 4** Let $\Lambda^{st} = \Lambda(v, w)^{st}$ be the set of all $(x, t) \in \Lambda(v, w)$ satisfying the following condition: if $S = (S_i)$ with $S_i \subset V_i$ is $x$-stable and $t_i(S_i) = 0$ for $i \in I$, then $S_i = 0$ for $i \in I$.

The group $G_V$ acts on $\Lambda(v, w)$ via

$$(g, (x, t)) \mapsto ((g_{h(\rho)} x_\rho g^{-1}_{t(\rho)}), (t_i g_i^{-1}))$$

and the stabilizer of any point of $\Lambda(v, w)^{\mathrm{st}}$ in $G_V$ is trivial. We then make the following definition.

**Definition 5** Let $\mathcal{L} \equiv \mathcal{L}(v, w) = \Lambda(v, w)^{st}/G_V$.

We should note that while the above definition and other constructions in this article are algebraic, there are also more geometric ways of looking at quiver varieties. In particular, the space

$$M(v, w) = \left( \bigoplus_{\rho \in Q_1} \mathrm{Hom}(V_{t(\rho)}, V_{h(\rho)}) \right) \oplus \left( \bigoplus_{i \in I} \mathrm{Hom}(W_i, V_i) \oplus \mathrm{Hom}(V_i, W_i) \right)$$

has a natural hyper-Kähler metric and one can consider a hyper-Kähler quotient by the group $\prod U(V_i)$. The variety $\mathcal{L}(v, w)$ is a Lagrangian subvariety of (and is homotopic to) this hyper-Kähler quotient. In the case $\mathfrak{g} = \mathfrak{sl}_n$, the varieties involved are closely related to flag varieties.

Let $w, v, v', v'' \in \mathbb{Z}^I_{\geq 0}$ be such that $v = v' + v''$. Consider the maps

$$\Lambda(v'', 0) \times \Lambda(v', w) \xleftarrow{p_1} \tilde{F}(v, w; v'') \xrightarrow{p_2} F(v, w; v'') \xrightarrow{p_3} \Lambda(v, w) \qquad [2]$$

where the notation is as follows. A point of $F(v, w; v'')$ is a point $(x, t) \in \Lambda(v, w)$ together with an $I$-graded, $x$-stable subspace $S$ of $V$ such that $\dim S = v' = v - v''$. A point of $\tilde{F}(v, w; v'')$ is a point $(x, t, S)$ of $F(v, w; v'')$ together with a collection of isomorphisms $R'_i : V'_i \cong S_i$ and $R''_i : V''_i \cong V_i/S_i$ for each $i \in I$. Then we define $p_2(x, t, S, R', R'') = (x, t, S)$, $p_3(x, t, S) = (x, t)$ and $p_1(x, t, S, R', R'') = (x'', x', t')$ where $x'', x', t'$ are determined by

$$R'_{h(\rho)} x'_\rho = x_\rho R'_{t(\rho)} : V'_{t(\rho)} \to S_{h(\rho)}$$
$$t'_i = t_i R'_i : V'_i \to W_i$$
$$R''_{h(\rho)} x''_\rho = x_\rho R''_{t(\rho)} : V''_{t(\rho)} \to V_{h(\rho)}/S_{h(\rho)}$$

It follows that $x'$ and $x''$ are nilpotent.

**Lemma 1** *One has*

$$(p_3 \circ p_2)^{-1}(\Lambda(v, w)^{st}) \subset p_1^{-1}(\Lambda(v'', 0) \times \Lambda(v', w)^{st})$$

Thus, we can restrict [2] to $\Lambda^{\mathrm{st}}$, forget the $\Lambda(v'', 0)$-factor and consider the quotient by $G_V$ and $G_{V'}$. This yields the diagram

$$\mathcal{L}(v', w) \xleftarrow{\pi_1} \mathcal{F}(v, w; v - v') \xrightarrow{\pi_2} \mathcal{L}(v, w) \qquad [3]$$

where

$$\mathcal{F}(v, w, v - v') \stackrel{\mathrm{def}}{=} \{(x, t, S) \in F(v, w; v - v') | (x, t) \in \Lambda(v, w)^{\mathrm{st}}\}/G_V$$

Let $M(\mathcal{L}(v, w))$ be the vector space of all constructible functions on $\mathcal{L}(v, w)$. Then define maps

$$h_i : M(\mathcal{L}(v, w)) \to M(\mathcal{L}(v, w))$$
$$e_i : M(\mathcal{L}(v, w)) \to M(\mathcal{L}(v - e^i, w))$$
$$f_i : M(\mathcal{L}(v - e^i, w)) \to M(\mathcal{L}(v, w))$$

by

$$h_i f = u_i f$$
$$e_i f = (\pi_1)_!(\pi_2^* f)$$
$$f_i g = (\pi_2)_!(\pi_1^* g)$$

Here

$$u = {}^t(u_0, \ldots, u_n) = w - Cv$$

where $C$ is the Cartan matrix of $\mathfrak{g}$ and we are using diagram 3 with $v' = v - e^i$ where $e^i$ is the vector whose components are given by $e^i_j = \delta_{ij}$.

Now let $\varphi$ be the constant function on $\mathcal{L}(0, w)$ with value 1. Let $L(w)$ be the vector space of functions generated by acting on $\varphi$ with all possible combinations of the operators $f_i$. Then let $L(v, w) = M(\mathcal{L}(v, w)) \cap L(w)$.

**Proposition 3** *The operators $e_i, f_i, h_i$ on $L(w)$ provide it with the structure of the irreducible highest-weight*

*integrable representation of* $\mathfrak{g}$ *with highest weight* $\sum_{i\in Q_0} \boldsymbol{w}_i\omega_i$. *Each summand of the decomposition* $L(\boldsymbol{w}) = \bigoplus_{\boldsymbol{v}} L(\boldsymbol{v},\boldsymbol{w})$ *is a weight space with weight* $\sum_{i\in Q_0} \boldsymbol{w}_i\omega_i - \boldsymbol{v}_i\alpha_i$. *Here the* $\omega_i$ *and* $\alpha_i$ *are the fundamental weights and simple roots of* $\mathfrak{g}$, *respectively.*

Let $Z \in \mathrm{Irr}\mathcal{L}(\boldsymbol{v},\boldsymbol{w})$ and define a linear map $T_Z : L(\boldsymbol{v},\boldsymbol{w}) \to \mathbb{C}$ that associates to a constructible function $f \in L(\boldsymbol{v},\boldsymbol{w})$ the (constant) value of $f$ on a suitable open dense subset of $Z$. The fact that $L(\boldsymbol{v},\boldsymbol{w})$ is finite dimensional allows us to take such an open set on which any $f \in L(\boldsymbol{v},\boldsymbol{w})$ is constant. So we have a linear map

$$\Phi : L(\boldsymbol{v},\boldsymbol{w}) \to \mathbb{C}^{\mathrm{Irr}\mathcal{L}(\boldsymbol{v},\boldsymbol{w})}$$

Then we have the following proposition.

**Proposition 4** *The map* $\Phi$ *is an isomorphism*; *for any* $Z \in \mathrm{Irr}\mathcal{L}(\boldsymbol{v},\boldsymbol{w})$, *there is a unique function* $g_Z \in L(\boldsymbol{v},\boldsymbol{w})$ *such that for some open dense subset* $O$ *of* $Z$ *we have* $g_Z|_O = 1$ *and for some closed* $G_V$*-invariant subset* $K \subset \mathcal{L}(\boldsymbol{v},\boldsymbol{w})$ *of dimension* $< \dim \mathcal{L}(\boldsymbol{v},\boldsymbol{w})$ *we have* $g_Z = 0$ *outside* $Z \cup K$. *The functions* $g_Z$ *for* $Z \in \mathrm{Irr}\Lambda(\boldsymbol{v},\boldsymbol{w})$ *form a basis of* $L(\boldsymbol{v},\boldsymbol{w})$.

## Additional Topics

To conclude, we have given here a brief overview of some topics related to finite-dimensional algebras and quivers. There is much more to be found in the literature. For basics on associative algebras and their representations, the reader may consult introductory texts on abstract algebra such as Lang (2002). For further results (and their proofs) on Ringel–Hall algebras see the papers of Ringel (1990a, b, 1993, 1995, 1996) and of Green (1995) and the references cited therein. The reader interested in species, which extend many of these results to non-simply-laced Lie algebras, should consult Dlab and Ringel (1976).

The book by Lusztig (1993) covers the quiver varieties of Lusztig and canonical bases. Canonical bases are closely related to crystal bases and crystal graphs (see Hong and Kang (2002) for an overview of these topics). In fact, the set of irreducible components of the quiver varieties of Lusztig and Nakajima can be endowed with the structure of a crystal graph in a purely geometric way (see Kashiwara and Saito (1997) and Saito (2002)). Many results on Nakajima's quiver varieties can be found in the original papers (Nakajima 1994, 1998). The overview article (Nakajima 1996) is also useful.

Quiver varieties can also be used to give geometric realizations of tensor products of representations (see Malkin (2002, 2003), Nakajima (2001), and Savage (2003)) and finite-dimensional representations of quantum affine Lie algebras (see Nakajima (2001)). This is just a select few of the many applications of quiver varieties. Much more can be found in the literature.

# Finite Group Symmetry Breaking

**G Gaeta**, Università di Milano, Milan, Italy

## Introduction

It is a commonplace situation that symmetric laws of Nature give rise to physical states which are not symmetric. States related by symmetry operations are equivalent, but still nature selects one of them.

As an example, consider a ferromagnetic system of interacting spins with no external magnetic field. The "up" and "down" states are equivalent, but one of the two is chosen: the interaction makes states with agreeing spin orientation (and therefore macroscopic magnetization) energetically preferred, and fluctuations will decide which state is actually chosen by a given sample.

Finite group symmetry is also commonplace in physics, in particular through crystallographic groups occurring in condensed matter physics – but also through the inversions ($C, P, T$ and their combinations) occurring in high-energy physics and field theory.

The breaking of finite group symmetry has thus been thoroughly studied, and general approaches exist to investigate it in mathematically precise terms with physical counterparts. In particular, a widely applicable approach is provided by the Landau theory of phase transitions – whose mathematical counterpart resides in the realm of equivariant singularity and bifurcation theory. In Landau theory, the state of a system is described by a finite-dimensional variable (the "order parameter"), and physical states correspond to minima of a potential, invariant under a group.

In this article we describe the basics of symmetry breaking analysis for systems described by a symmetric polynomial; in particular, we discuss generic symmetry breakings, that is, those determined by the symmetry properties themselves and independent of the details of the polynomial describing a concrete system. We also discuss how the plethora of invariant polynomials can be to some extent reduced by means of changes of coordinates, that is, how one can reduce to consider certain types of polynomials with no loss of generality. Finally, we will give some indications on extension of this theory, that is, on how one deals with symmetry breakings for more general groups and/or more general physical systems.

## Basic Notions

### Finite Groups

A finite group $(G, \circ)$ is a finite set $G$ of elements $\{g_0, \ldots, g_N\}$ equipped with a composition law $\circ$, and such that the following conditions hold:

1. for all $g, h \in G$ the composition $g \circ h$ belongs to $G$, that is, $g \circ h \in G$;
2. the composition is associative, that is, $(g \circ h) \circ k = g \circ (h \circ k)$ for all $g, h, k \in G$;
3. there is an element in $G$ – which we will denote as $e$ – which is the identity for the action of $\circ$ on $G$, that is, $e \circ g = g = g \circ e$ for all $g \in G$; and
4. for each $g \in G$ there is an element $g^{-1}$ which is the inverse of $g$, that is, $g^{-1} \circ g = e = g \circ g^{-1}$.

In the following, we omit the symbol $\circ$, that is, we write $gh$ to mean $g \circ h$. Similarly, we usually write simply $G$ for the group, rather than $(G, \circ)$.

Given a subset $H \subseteq G$, this is a subgroup of $(G, \circ)$ if $(H, \circ)$ satisfies the group axioms (1)–(4) above. Note that this implies that $e \in H$ whenever $H$ is a subgroup, and $\{e\}$ is a subgroup. Subgroups not coinciding with the whole $G$ and with $\{e\}$ are said to be "proper."

Given two elements $g, h$ we say that $ghg^{-1}$ is the conjugate of $h$ by $g$. The conjugate of a subgroup $H \subseteq G$ by $g \in G$ is the subgroup of elements conjugated to elements of $H, gHg^{-1} = \{(ghg^{-1}), h \in H\}$.

### Group Action

In physics, one is usually interested in a realization of an abstract group as a group of transformations in some set $X$; in physical applications, this is usually a (possibly, function) space or a manifold, and we refer to elements of $X$ as "points." That is, there is a map $\rho: G \mapsto \mathrm{End}(X)$ from $G$ to the group of endomorphisms of $X$, such to preserve the composition law:

$$\rho(g) \cdot \rho(h) = \rho(g \circ h) \quad \forall g, h \in G$$

In this case, we say that we have a "representation" of the abstract group $G$ acting in the "carrier" space or manifold $X$; we also say that $X$ is a $G$-space or $G$-manifold. We often denote by the same letter the abstract element and its representation, that is, write simply $g$ for $\rho(g)$ and $G$ for $\rho(G)$. (In many physically relevant cases, but not necessarily, $X$ has a linear structure and we consider linear endomorphisms. In this case, we sometimes write $T_g$ for the linear operator representing $g$.)

If $x \in X$ is a point in $X$, the $G$-orbit $G(x)$ is the set of points to which $x$ is mapped under $G$, that is,

$$G(x) = \{y \in X: \; y = gx, g \in G\} \subseteq X$$

Belonging to the same orbit is obviously an equivalence relation, and partitions $X$ into equivalence classes. The "orbit space" for the $G$ action on $X$, also denoted as $\Omega = X/G$, is the set of these equivalence classes. It corresponds, in physical terms, to considering $X$ modulo identification of elements related by the group action.

For any point $x \in X$, the "isotropy (sub)group" $G_x$ is the set of elements leaving $x$ fixed,

$$G_x = \{g \in G: \; gx = x\} \subseteq G$$

Points on the same $G$-orbit have conjugated isotropy subgroups: indeed, $y = gx$ implies immediately that $G_y = gG_xg^{-1}$.

When a topology is defined on $X$, the problem arises if the $G$-action preserves it; if this is the case, we say that the $G$-action is "regular." In the case of a compact Lie group (and *a fortiori* for a finite group) we are guaranteed the action is regular. (A physically relevant example of nonregular action is provided by the irrational flow on a torus. In this case $G = R$, realized as the time $t$ irrational flow on the torus $X = \boldsymbol{T}^k$.)

### Spontaneous Symmetry Breaking

Let us now consider the case of physical systems whose state is described by a point $x$ in the $G$-space or $G$-manifold $X$, with $G$ a group acting by smooth mappings $g: X \to X$. In physical problems, $G$ quite often acts by linear and orthogonal transformations. (If this is not the case, the Palais–Mostow theorem guarantees that, for suitable groups (including in particular the finite ones) we can reduce to this case upon embedding $X$ into a suitably larger carrier space $Y$.)

Usually, $G$ represents physical equivalence of states, and $G$-orbits are collections of physically equivalent states. A point which is $G$-invariant, that is, such that $G_x = G$, is called "symmetric" for short.

Let $\Phi$ be a scalar function (potential) defined on $X, \Phi: X \to \boldsymbol{R}$, possibly depending on some parameter $\mu$, such that the physical state corresponds to critical points – usually the (local) minima – of $\Phi$.

A concrete example is provided by the case where $\Phi$ is the Gibbs free energy; more generally, this is the framework met in the Landau theory of phase transitions (Landau 1937, Landau and Lifshitz 1958).

We are interested in the case where $\Phi$ is invariant under the group action, or briefly $G$-invariant, that is, where

$$\Phi(gx) = \Phi(x) \quad \forall x \in X, \; \forall g \in G \qquad [1]$$

A critical point $x$ such that $G_x = G$ is a symmetrical critical point. If $G_x$ is strictly smaller than $G$, then $x$ is a symmetry-breaking critical point.

If a physical system corresponds to a nonsymmetric critical point, we have a spontaneous symmetry breaking: albeit the physical laws (the potential function $\Phi$) are symmetric, the physical state (the critical point for $\Phi$) breaks the symmetry and chooses one of the $G$-equivalent critical points.

It follows from [1] that the gradient of $\Phi$ is covariant under $G$. If $y = g(x)$, then the differential $(Dg)$ of the map $g: X \to X$ is a linear map between the corresponding tangent spaces, $(Dg): T_xX \to T_yX$. The covariance amounts, with $\eta$ the Riemannian metric in $X$, to $(\eta^{ij}\partial_j\Phi)(gx) = [(Dg)^i_k \eta^{km}\partial_m\Phi](x)$; this is also written compactly, with obvious notation, as

$$(\nabla\Phi)(gx) = (Dg)[(\nabla\Phi)(x)] \qquad [2]$$

(in the case of euclidean spaces $(\eta = \delta)$ and linear actions described by matrices $T_g$, the covariance condition reduces to $(\nabla\Phi)^i(T_gx) = (T_g)^i_j \; [(\nabla\Phi)^j(x)]$). As $(Dg)$ is a linear map, $(\nabla\Phi)(x) = 0$ implies the vanishing of $\nabla\Phi$ at all points on the $G$-orbit of $x$.

We conclude that critical points of a $G$-invariant potential come in $G$-orbits: if $x$ is a critical point for

$\Phi$, then each $y \in G(x)$ is also a critical point for $\Phi$. We speak therefore of critical orbits for $\Phi$.

It is thus possible (thanks to the regularity of the $G$-action), and actually convenient, to study spontaneous symmetry breaking in the orbit space $\Omega = X/G$ rather than in the carrier manifold $X$ (Michel 1971).

If $G$ describes physical equivalence, physical states whose symmetries are $G$-conjugated should be seen as physically equivalent. An equivalence class of isotropy types under conjugation will be said to be a symmetry type. We are thus interested, given a $G$-invariant polynomial $\Phi$, to know the symmetry types of its critical points. We denote symmetry types as $[H] = \{gHg^{-1}\}$, and say that $[H] < [K]$ if a group conjugated to $H$ is strictly contained in a group conjugated to $K$.

As we have seen, points on the same $G$-orbit have the same symmetry type. On the other hand, points on different $G$-orbits can have the same isotropy type (e.g., for the standard action of $O(n)$ in $\boldsymbol{R}^n$, all collinear nonzero points will have the same isotropy subgroup but will lie on distinct group orbits).

## G-Invariant Polynomials

Consider a finite group $G$ acting in $X$. (Many of the notions and results mentioned in this section have a much wider range of applicability.) We look at the ring of $G$-invariant scalar polynomials in $x^1, \ldots, x^n$.

By the Hilbert basis theorem, there is a set $\{J_1(x), \ldots, J_k(x)\}$ of $G$-invariant homogeneous polynomials of degrees $\{d_1, \ldots, d_k\}$ such that any $G$-invariant polynomial $\Phi(x)$ can be written as a polynomial in the $\{J_1, \ldots, J_k\}$, that is,

$$\Phi(x) = \Psi[J_1(x), \ldots, J_k(x)] \qquad [3]$$

with $\Psi$ a polynomial. (A similar theorem holds for smooth functions.)

The algebra of $G$-invariant polynomials is finitely generated, that is, we can choose $k$ finite. When the $J_a$ are chosen so that none of them can be written as a polynomial of the others and $r$ has the smallest possible value (this value depends on $G$), we say that they are a minimal integrity basis (MIB). (Note that some of the $J_a$ could be written as nonpolynomial functions of the others, and the $J_\alpha$ could satisfy polynomial relations. For example, consider the group $Z_2$ acting in $\boldsymbol{R}^2$ via $g: (x, y) \to (-x, -y)$; an MIB is made of $J_1(x, y) = x^2, J_2(x, y) = y^2$, and $J_3(x, y) = xy$. None of these can be written as a polynomial function of the others, but $J_1 J_2 = J_3^2$.) In this case, we say that the $\{J_a\}$ are a set of basic invariants for $G$. There is obviously some arbitrarness in the choice of the $J_a$ in an MIB, but the degrees $\{d_1, \ldots, d_k\}$ of $\{J_1, \ldots, J_k\}$ are fixed by $G$. (In mathematical terms, they are determined through the Poincaré series of the graded algebra $P_G$ of $G$-invariant polynomials.)

We will henceforth assume that we have chosen an MIB, with elements $\{J_1, \ldots, J_k\}$ of degrees $\{d_1, \ldots, d_k\}$ in $x$, say with $d_1 \leq d_2 \leq \cdots \leq d_k$.

When the elements of an MIB for $G$ are algebraically independent, we say that the MIB is regular; if $G$ admits a regular MIB we say that $G$ is coregular.

An algebraic relation between elements $J_\alpha$ of the MIB is said to be a relation of the first kind. The algebraic relations among the $J$ are a set of polynomials in $\{J_1, \ldots, J_r\}$, which are identically zero when seen as polynomials in $x$. If there are algebraic relations among these, they are called relations of the second kind, and so on. A theorem by Hilbert guarantees that the chain of relations has finite maximal length. (This is the homological dimension of the graded algebra $P_G$ mentioned above.)

In the following, we will consider a matrix built with the gradients of basic invariants, the $\mathcal{P}$-matrix (Sartori). This is defined as

$$\mathcal{P}_{ih}(x) := \langle \nabla J_i(x), \nabla J_h(x) \rangle \qquad [4]$$

with $\langle .\,, . \rangle$ the scalar product in $T_*X$.

The gradient of an invariant is necessarily a covariant quantity; the scalar product of two covariant quantities is an invariant one, and thus can be expressed again in terms of the basic invariants. Thus, the $\mathcal{P}$-matrix can always be written in terms of the basic invariants themselves.

## Geometry of Group Action

The use of an MIB allows to introduce a map $\boldsymbol{J}: x \to \{J_1(x), \ldots, J_k(x)\}$ from $X$ to a subset $P$ of $\boldsymbol{R}^k$. If the MIB is regular, $P = \boldsymbol{R}^k$, while if the $J_i$ satisfy some relation then $P \subset \boldsymbol{R}^k$ is the submanifold satisfying the corresponding relations. The manifold $P$ is isomorphic to the orbit space $\Omega = X/G$ (the isomorphism being realized by the $\boldsymbol{J}$ map) and provides a more convenient framework to study $\Omega$.

As mentioned above, on physical terms we are mainly interested in the orbit space up to equivalence of symmetry type. The set of points in $X$ (of orbits in $\Omega$) with the same symmetry type will be called a $G$-stratum in $X$ (a $G$-stratum in $\Omega$); the $G$-stratum of the point $x$ will be denoted as $\sigma(x) \subset X$ (the $G$-stratum of the orbit $\omega$ as $\Sigma(\omega) \subset \Omega$). (The notion of stratum was introduced by Whitney in topology; a stratified manifold is a set which can be decomposed as the disjoint union of smooth

manifolds of different dimensions, the topological (or Whitney) strata: $M = \bigcup M^k$, with $M^k \subset \partial M^j$ for all $k < j$.)

It results that the $G$-stratification is compatible with the topological stratification. Indeed, $P$ is a semialgebraic (i.e., it is defined by algebraic equalities and inequalities) stratified manifold in $\boldsymbol{R}^k$; the image of any $G$-stratum in $\Omega$ belongs to a single topological stratum in $P$, and topological strata in $P$ are the union of images of $G$-strata in $\Omega$.

Moreover, the subgroup relations correspond to bordering relations between $G$-strata: if $[G_x] < [G_y]$, then $\sigma(y) \in \partial\sigma(x)$ and (with $\omega_x$ the orbit of $x$) $\Sigma(\omega_y) \in \partial\Sigma(\omega_x)$.

There is a stratum, called the principal stratum $\sigma_0$, which corresponds to minimal isotropy, open and dense in $X$; similarly, the principal stratum $\Sigma_0$ is open and dense in $\Omega$.

## Landau Polynomial

In the Landau (1937) theory of phase transitions, the state of the system under study is described by a $G$-invariant polynomial $\Phi : X \to \boldsymbol{R}$ having a critical point in the origin, with at least some of its coefficients – in particular those controlling the stability of the zero critical point – depending on external control parameters (usually, $X = \boldsymbol{R}^n$ and $G \subseteq \mathrm{O}(n)$; in particular, in solid-state physics $G$ is a crystallographic group). This should be chosen as the most general $G$-invariant polynomial of the lowest degree $\ell$ sufficient to ensure termodynamic stability; in mathematical terms, this amounts to the requirement that there is some open set $\mathcal{B}$ containing the origin and such that – for all values of the control parameters – $\nabla\Phi$ points inwards at all points of $\partial\mathcal{B}$ (i.e., $\mathcal{B}$ is invariant under the gradient flow of $\Phi$). If the polynomials in the MIB are of degree $d_1 \leq d_2 \cdots \leq d_r$, then usually $\ell = 2d_r$.

The $G$-invariance of $\Phi$ and the results recalled above mean that we can always write it in terms of the polynomials in an MIB for $G$ as in [3], $\Phi(x) = \Psi[\boldsymbol{J}(x)]$.

The discussion of previous sections shows that we can study symmetry breakings for $\Phi : X \to \boldsymbol{R}$ by studying critical points of $\Psi : P \to \boldsymbol{R}$; in other words, Landau theory can be worked out in the G-orbit space $\Omega := M/G$. The polynomial $\Psi$ – providing a representation of the Landau polynomial in the orbit space – will also be called Landau–Michel polynomial. (Louis Michel (1923–1999) pioneered the use of orbit space techniques in physics and nonlinear dynamics, originally motivated by the study of hadronic interactions.)

In this way, the evaluation of the map $\Phi : X \to \boldsymbol{R}$ is, in principle, substituted by evaluation of two maps, $\boldsymbol{J} : X \to P$ and $\Psi : P \to \boldsymbol{R}$. However, if, as in Landau theory, we have to consider the most general $G$-invariant polynomial on $X$, we can just consider the most general polynomial on $P$.

## Critical Points of the Landau Polynomial and Geometry of Orbit Space

The $G$-invariance has consequences on the critical points of $\Phi$. We have already seen one such consequence: critical points come in $G$-orbits.

However, this is not all. Indeed, $G$-invariance enforces the presence of a certain set $\chi(G) \in X$ of critical points, and conversely if we look for points which are critical under any $G$-invariant potential, these are precisely the points in $\chi(G)$; the critical points on $\chi(G)$ correspond to critical orbits which we call principal critical orbits.

The set $\chi(G)$ can be determined on the basis of the geometry of the $G$-action. (A trivial example is provided by $X = \boldsymbol{R}$ and $G = Z_2$ acting via $g : x \to -x$; any even function has a critical point in zero, and albeit even functions can, and in general will, have nonzero critical points, this is the only critical point common to all the even functions.) Indeed (Michel 1971): *an orbit $\omega$ is a principal critical orbit if and only if it is isolated in its stratum*.

For the linear orthogonal group actions in $\boldsymbol{R}^n$ often occurring in physics, no nonzero point or orbit can be isolated in its stratum. However, we can quotient out the radial degeneracy and work on $X = S^{n-1} \subset \boldsymbol{R}^n$. In this case, a $G$-orbit $\omega_1$ in $S^{n-1}$ which is isolated in its stratum corresponds to a one-dimensional family $\{\omega_r\}$ of $G$-orbits in $\boldsymbol{R}^n$ (call $X_0$ the corresponding submanifold in $X$); the gradient of $\Phi$ at $x \in X_0$ points along $T_xX_0$. We can thus reduce to consider the restriction $\Phi_0$ of the potential $\Phi$ to $X_0$. (See also the reduction lemma of Golubitsky and Stewart in this context.)

Correspondingly, if $P_0 \subset P$ is the submanifold in $P$ image of $X_0$, that is, $P_0 = \boldsymbol{J}(X_0)$, we can reduce to consider the restriction $\Psi_0$ of $\Psi$ to $P_0$.

As these become one-dimensional problems, general results are available. In particular, one can provide general conditions ensuring the existence of one-dimensional branches of symmetry-breaking solutions bifurcating from zero along any such $X_0$ or $P_0$; this is also known as the equivariant branching lemma of Cicogna and Vanderbauwhede.

## Reduction of the Landau Potential

In realistic problems, $\Phi$ quickly becomes extremely complicated, that is, it includes a high number of terms and therefore of coefficients. A thorough study of different symmetry-breaking patterns, that is, of the symmetry type of minima of $\Phi$ for different values of these coefficients and of the external control parameter, is in this case a prohibitive task. It is possible to reduce the generality of the Landau polynomial with no loss of generality for the corresponding physical problem. Indeed, a change of coordinates in the $X$ space will produce a formally different – but obviously equivalent – Landau polynomial; it is convenient to use coordinates in which the Landau polynomial is simpler.

A systematic and algorithmic reduction procedure – based on perturbative expansion near the origin – is well known in dynamical systems theory (Poincaré–Birkhoff normal forms), and can be adapted to the reduction of Landau polynomials. (An alternative and more general – but also much more demanding – approach is provided by the spectral sequence approach, also originating in normal-form theory.)

We work near the origin, so that we can assume $X = \boldsymbol{R}^n$ (with metric $\eta$), and for simplicity we also take the case where $G$ acts via a linear representation $T_g$. We consider changes of coordinates of the (Poincaré) form

$$x^i = y^i + h^i(y) \qquad [5]$$

generated by a $G$-invariant function $H$: $h^i(y) = \eta^{ij}$ $(\partial H(y)/\partial y^j)$; this guarantees that [5] preserves the $G$-invariance of $\Phi$. The action of [5] on $\Phi$ can be read from its action on the basic invariants $J_a$. It results

$$\begin{aligned} J_a(x) &= J_a(y) + (\delta J_a)(y) \\ \delta J_a &:= \mathcal{P}_{ab}(\partial H/\partial J_b) \end{aligned} \qquad [6]$$

Let us now consider the reduction of an invariant polynomial $\Phi(x) = \Psi(J)$. We write $D_\alpha := \partial/\partial J_\alpha$, and understand that summation over repeated indices is implied. In general,

$$\begin{aligned} \Psi(J) &\to \Psi(J + \delta J) \\ &= \Psi(J) + \sum_{\alpha=1}^{r} \frac{\partial \Psi(J)}{\partial J_\alpha} \delta J_\alpha + \cdots \end{aligned}$$

where the ellipsis means higher-order terms.

Disregarding higher-order terms and using [6] and [4], we get

$$\delta\Psi = \frac{\partial \Psi}{\partial J_\alpha} \mathcal{P}_{\alpha\beta} \frac{\partial H}{\partial J_\beta} \equiv (D_\alpha \Psi)\mathcal{P}_{\alpha\beta}(D_\beta H) \qquad [7]$$

We expand $\Phi$ as a sum of homogeneous polynomials, and write $\Phi(x) = \sum_{k=0}^{\ell} \Phi_k(x)$, where $\Phi_k(ax) = a^{k+1}\Phi_k(x)$. Also, write $\Psi = \sum_k \Psi_k$, where $\Phi_k(x) := \Psi_k[J(x)]$.

It results that under a change of coordinates [5] generated by $H = H_m$ homogeneous of degree $m+1$, the terms $\Psi_k$ with $k \le m$ are not changed, while the terms $\Psi_{m+p}$ change according to

$$\begin{aligned} \Psi_{m+p} &\to \Psi_{m+p} \\ &= \Psi_{m+p} + (D_\alpha \Psi_p)\mathcal{P}_{\alpha\beta}(D_\beta H_m) + \cdots \end{aligned} \qquad [8]$$

We can then operate sequentially with $H_m$ of degree $3, 4, \ldots$; at each stage (generator $H_m$), we are not affecting the terms $\Psi_k$ with $k \le m$. Moreover, we can just consider [8], as higher-order terms are generic and will be taken care of in subsequent steps. (This procedure requires to determine suitable generating functions $H_m$; these are obtained as solutions to homological equations.)

In the above, we disregarded the dependence on the control parameters, such as temperature, pressure, magnetic field, etc; that is, we implicitly considered fixed values for these. However, they have to change for a phase transition to take place. If we consider a full range of values – including in particular the critical ones – for the control parameters, say $\lambda \in \Lambda$, we should take care that the concerned quantities and operators are nonsingular uniformly in $\Lambda$.

This leads to reduction criteria for the Landau and Landau–Michel polynomials (Gufan). Define, for $i = 1, \ldots, k$ the quantities $U_i(J_1, \ldots, J_k) := (\partial F/\partial J_s)\mathcal{P}_{si}$.

### Reduction Criterion

For $\Phi(x) = \Psi(J_1, \ldots, J_k) : \boldsymbol{R}^n \to \boldsymbol{R}$ a $G$-invariant potential depending on physical parameters $\lambda \in \Lambda$, there is a sequence of Poincaré changes of coordinates such that $\Phi$ is expressed in the new coordinates $y$ as $\hat{\Phi}(y) = \hat{\Psi}(J)$, where terms which can be written (up to higher-order terms) uniformly in $\Lambda$ as $\sum_{\alpha=1}^{k} Q_\alpha(J_1, \ldots, J_k)$ $U_\alpha(J_1, \ldots, J_k)$, with $Q_\alpha$ polynomials in $J_1, \ldots, J_k$ satisfying the compatibility condition $(\partial Q_\beta/\partial J_\alpha) = (\partial Q_\alpha/\partial J_\beta)$, are not present in $\hat{\Psi}$.

## Nonstationary and Nonvariational Problems

So far we have considered stationary physical states. In some cases, one is not satisfied with such a description, and wants to study time evolution. A model framework for this is provided by the Ginzburg–Landau equation

$$\dot{x} = f(x) \qquad [9]$$

where $f = \eta(\nabla\Phi) : X \to TX$ (see above for notation). In this case, $G$-invariance of $\Phi$ implies equivariance

of [9]. More generally, we can consider [9] for an equivariant smooth $f$ (not necessarily a gradient), that is, $f^i(gx) = (Dg)^i_j f^j(x)$.

In this case, one shows that

$$f(x) \in T_x\sigma(x) \qquad [10]$$

so that closures of $G$-strata are dynamically invariant, and the dynamics can be reduced to them. This is of special interest for the "most singular" strata, that is, those of lower dimension. The reduction lemma and the equivariant branching lemma mentioned above also hold (and were originally formulated) in this context.

The relation [10] also implies that one can project the dynamics [9] in $X$ to a smooth dynamics $\dot{p} = F(p)$ in the orbit space; this satisfies $F[\boldsymbol{J}(x)] = (D\boldsymbol{J})[f(x)]$. In the gradient case, this (together with initial conditions) embodies the full dynamics in $X$, while in the generic case one loses all information about motions along group orbits (note that these correspond to phonon modes).

An orbit $\omega$ isolated in its stratum is still an orbit of fixed points for any $G$-equivariant dynamics in $X$ in the gradient case, while in the generic case it corresponds to a fixed point for $F$ and to relative equilibria (dynamical orbits which belong to a single group orbit) in $X$. In this case, time averages of physical quantities can be $G$-invariant for nontrivial relative equilibria.

## Extensions and Physical Applications

We have discussed finite group symmetry breaking and focused on polynomial potentials (which can be thought of as Taylor expansions around critical points). For nonfinite groups, and in particular noncompact ones, the situation can be considerably more complicated.

1. An extension of the theory sketched here is provided by Palais' theory, and in particular by his "symmetric criticality principle," which applies in Hilbert or Banach spaces of sections of a fiber bundle satisfying certain conditions. This is especially relevant in connection with field theory and gauge groups.
2. We focused on the situation discussed in classical physics. Finite group symmetry breaking is of course also relevant in quantum mechanics; this is discussed, for example, in the classical books by Weyl (1931) and Wigner (1959), and in the review by Michel *et al.* (2004).
3. One speaks of "explicit symmetry breaking" when a nonsymmetric perturbation is introduced in a symmetric problem. In the Hamiltonian case (or in the Lagrangian one for Noether symmetries), Hamiltonian symmetries correspond to conserved quantities, and nonsymmetric perturbations make these become approximate constants of motion.
4. The symmetry of differential equations – as well as symmetric and symmetry-breaking solutions for symmetric equations – can be studied in general mathematical terms (see, e.g., Olver (1986)).
5. Physical applications of the theory discussed here abound in the literature, in particular through the Landau theory of phase transitions. A number of these, together with a deeper discussion of the underlying theory, is given in the monumental review paper by Michel *et al.* (2004).

# Finite Weyl Systems

**D-M Schlingemann**, Technical University of Braunschweig, Braunschweig, Germany

## Introduction

Finite Weyl systems have their applications in various branches of quantum information theory. They are helpful to tame the growth of complexity for a large class of quantum systems: a key discrepancy between classical and quantum systems is the difference in the growth of complexity as one goes to larger and larger systems. This is encountered by simulating a quantum spin system on a computer, for example, with the aim to determine the ground state of a solid-state model of magnetism. For a model of $N$ classical spins, this involves checking the energy for $2^N$ different configurations, but for a model with quantum spins it requires the solution of an eigenvalue equation in a Hilbert space of dimension $2^N$, which is a vastly more difficult problem for large $N$. For a three-dimensional lattice, three sites each way ($N = 27$), this is a problem in $10^8$ dimensions, and lattice size 4 leads to utterly untractable $10^{19}$ dimensions.

It is therefore highly desirable to find ways of treating at least some aspects of large, complex quantum systems without actually having to write out state vectors component by component. States which are invariant under a suitable discrete abelian symmetry group satisfy this condition. They can be characterized by simple combinatorial data, which do not grow exponentially with the system size $N$. At the same time, the class of these so-called stabilizer states is sufficiently complex to capture some of the key features needed for computation, especially the quantum correlation (entanglement) between subsystems. They have also been shown to be sufficient to generate large quantum error correcting codes.

A further motivation for finite Weyl systems is directly based on constructing quantum error correcting codes from classical coding procedures (*see* Quantum Error Correction and Fault Tolerance). The "quantization" technique which is used there naturally leads to the structure of finite Weyl systems.

Finite Weyl systems precisely represent quantum versions of discrete abelian symmetry groups. It is a standard procedure to build the quantum version of a symmetry group by an appropriate central extension, or equivalently, to study all its projective representations: the composition of two symmetry transformations is only preserved up to a phase on the representation Hilbert space. The unitary operators which represent the symmetry transformations are called Weyl operators.

The simplest and most prominent example for a finite Weyl system is given by the three Pauli matrices and the identity. These four unitary operators build a projective representation of the symmetry group of binary vectors $(0,0)$, $(0,1)$, $(1,0)$, $(1,1)$, where the group law is the addition modulo two. The null-vector $(0,0)$ corresponds to the identity, the vector $(0,1)$ is assigned to $X$, $(1,0)$ corresponds to $Z$, and $(1,1)$ is mapped to $\mathrm{i}Y$. It is not difficult to verify that the product of two Pauli operators preserves the addition of binary vectors up to a phase.

Discrete Weyl systems are deeply related to symplectic geometry for vector spaces over finite fields. The additive structure of the vector space is the underlying abelian symmetry group. The exchange of two Weyl operators within a product produces a phase that is the exponential of an antisymmetric bilinear form, as it is explained in the next section. For irreducible Weyl systems, this antisymmetric form must be symplectic because the Weyl operators generate a full matrix algebra. In particular, this requires that the dimension of the underlying vector space is even. The Pauli matrices are also an example for this more special structure: the binary vectors $(p,q)_{p,q=0,1}$ are a two-dimensional vector space over the field with two elements $\{0,1\}$. The commutation relations for Pauli operators imply that the symplectic form can be evaluated for two binary vectors $(p,q),(p',q')$ according to $pq' - qp' \bmod 2$. It is apparent to interpret the binary vectors $(p,q)$ as points in a discrete phase space, where the first entry corresponds to the momentum and the second to the position. In view of this, discrete Weyl systems serve as a finite-dimensional analog of the canonical commutation relations.

For the generic situation in quantum information theory, an irreducible Weyl system is represented on the Hilbert space describing a system of several single particles. Stabilizer states are left unchanged under the action of a so-called isotropic subgroup which consists of mutually commuting Weyl operators: this kind of invariance is precisely the type of constraint that reduces the complexity for the parametrization of the state. For an efficient description of such states, there are combinatorial techniques available e.g., graph theory.

Operations that preserve the class of stabilizer states (for a particular symmetry group) must be covariant with respect to this symmetry. These operations are called Clifford channels which have far-reaching applications in the theory of quantum error correction. They also allow to take classical coding procedures and turn them into quantum codes: on the classical level, the encoding operation acts on classical phase space as a linear map (additive code). Up to a choice of phases, this induces a quantum channel that preserves the structure of Weyl systems. These codes are called stabilizer codes and have been investigated by many authors (Calderbank *et al.* 1997, Cleve and Gottesman 1996, 1997) (*see* Quantum Error Correction and Fault Tolerance). In particular, the first quantum error correcting codes belong to this class.

This article is organized as follows. In the next section, the basic mathematical notions are provided, like projective representations, Weyl systems, and irreducibility. Moreover, statements on the main structure of Weyl systems are presented. Next, the notion of Weyl covariant channels (Clifford channels) is introduced and their basic properties are stated. In particular, stronger results for the reversible case are given. The relation between symplectic geometry and reversible Clifford operations on finite Weyl systems is explained. Results on the general structure of stabilizer states and stabilizer codes are given in the penultimate section. Finally, the representation of stabilizer codes in terms of graphs is described.

## Finite Weyl Systems

A projective representation of a group $\Xi$ assigns to each group element $\xi$ a unitary operator $\boldsymbol{w}(\xi)$ on a Hilbert space $\mathcal{H}$ such that the group law is preserved up to a phase, that is, the relation

$$\boldsymbol{w}(\xi_1+\xi_2)=f(\xi_1,\xi_2)\boldsymbol{w}(\xi_1)\boldsymbol{w}(\xi_2) \qquad [1]$$

is fulfilled for a phase-valued function $f$ on $\Xi^2$. In the following, we denote a projective representation by a triple $(\boldsymbol{w},f,\mathcal{H})$. A finite Weyl system is a projective representation of a finite abelian group. The operators $\boldsymbol{w}(\xi)$ are called Weyl operators and the function $f$ is called the factor system. We refer to the work by Zmud (1971, 1972) for an analysis of projective representations for general abelian groups.

The Weyl algebra $\mathfrak{A}(\boldsymbol{w},f,\mathcal{H})$ associated with a Weyl system $(\boldsymbol{w},f,\mathcal{H})$ is the smallest norm-closed subalgebra in the space of bounded operators $\mathcal{B}(\mathcal{H})$ which contains all Weyl operators. If the Weyl algebra coincides with the algebra of all bounded operators, then the Weyl system is called irreducible. This is equivalent to the fact that each operator that commutes with all Weyl operators must be a multiple of the identity.

In order to analyze the properties of factor systems systematically, we introduce here a few pieces of the cohomology theory of groups. For each positive integer $k=1,2,3,\ldots$ we introduce the abelian group $C^k(\Xi)$ of $k$-cochains which consists of all phase-valued functions on $\Xi^k$. The product and the inverse of $k$-cochains is defined pointwise. Factor systems are special 2-cochains. Namely, if we consider a Weyl system $(\boldsymbol{w},f,\mathcal{H})$, then associativity implies that the so-called 2-cocycle condition,

$$f(\xi_1+\xi_2,\xi_3)f(\xi_2,\xi_3)^{-1}f(\xi_1,\xi_2+\xi_3)^{-1}f(\xi_1,\xi_2)=1 \qquad [2]$$

holds. This property can also be expressed by a coboundary map $\mathfrak{d}$ which is a group homomorphism from $k$-cochains to $(k+1)$-cochains. We consider here the action of the coboundary map on a 1-cochain $\varphi$ and a 2-cochain $f$:

$$(\mathfrak{d}\varphi)(\xi_1,\xi_2):=\varphi(\xi_1+\xi_2)\varphi(\xi_1)^{-1}\varphi(\xi_2)^{-1} \qquad [3]$$

$$(\mathfrak{d}f)(\xi_1,\xi_2,\xi_3):=f(\xi_1+\xi_2,\xi_3)f(\xi_2,\xi_3)^{-1}\times f(\xi_1,\xi_2+\xi_3)^{-1}f(\xi_1,\xi_2) \qquad [4]$$

The group of 2-cocycles $Z^2(\Xi)$ consists of all 2-cochains $f$ with $\mathfrak{d}f=1$ and the group of all 2-coboundaries $B^2(\Xi)$ contains all 2-cochains of the form $f=\mathfrak{d}\varphi$. The 2-fold concatenation of the coboundary map is the trivial homomorphism $\mathfrak{d}\circ\mathfrak{d}=1$, which implies that each 2-coboundary is a 2-cocycle. The converse is in general not the case and the 2-cohomology group $H^2(\Xi):=Z^2(\Xi)/B^2(\Xi)$ is nontrivial.

The Zmud (1971, 1972) analysis shows that the set of Weyl systems are characterized by elements of the 2-cohomology $H^2(\Xi)$. The multiplication of a Weyl system $(\boldsymbol{w},f,\mathcal{H})$ by a 1-cochain $\varphi$ yields a new family of Weyl operators $(\varphi\boldsymbol{w})(\xi)=\varphi(\xi)\boldsymbol{w}(\xi)$. The 2-cocycle $f$ is altered by the multiplication of the 2-coboundary $\mathfrak{d}\varphi$ and the new Weyl system is given by $(\varphi\boldsymbol{w},\mathfrak{d}\varphi f,\mathcal{H})$. This kind of transformation does not change the cohomology class of the factor system and the corresponding Weyl algebras coincide: $\mathfrak{A}(\boldsymbol{w},f,\mathcal{H})=\mathfrak{A}(\varphi\boldsymbol{w},\mathfrak{d}\varphi f,\mathcal{H})$. Thus, the fundamental properties of a Weyl system only depend on the cohomology class of the factor system. In particular, if the factor system $f=\mathfrak{d}\varphi$ is a 2-coboundary, then we can trivialize the Weyl system $(\boldsymbol{w},\mathfrak{d}\varphi,\mathcal{H})$ by multiplying the inverse 1-cochain $\varphi^{-1}$ and we obtain a true unitary representation $(\varphi^{-1}\boldsymbol{w},1,\mathcal{H})$. The corresponding Weyl algebra $\mathfrak{A}(\boldsymbol{w},\mathfrak{d}\varphi,\mathcal{H})$ is abelian. The relation between cohomology and Weyl systems

can be made even more precise by the following theorem:

**Theorem 1** (Zmud 1971, 1972). *$\theta$ is the group homomorphism on 2-cochains that exchanges the variables*: $(\theta f)(\xi_1, \xi_2) = f(\xi_2, \xi_1)$.

(i) *The antisymmetric part $f^{-1}(\theta f)$ of a factor system (2-cocycle) is an antisymmetric bicharacter, that is, a group homomorphism in both arguments keeping the other variable fixed.*
(ii) *Each symmetric 2-cocycle $f = \theta f$ is a 2-coboundary $f = \eth\varphi$.*
(iii) *The group of antisymmetric bicharacters on $\Xi$ is isomorphic to the 2-cohomology group $H^2(\Xi)$. For each antisymmetric bicharacter $\sigma$ the corresponding 2-cohomology class is uniquely determined by $\sigma = f^{-1}(\theta f)$ for some representative $f \in Z^2(\Xi)$.*

**Example 2** The following Weyl system describes $n$-quantum digits (in short qudits). The system's Hilbert space is spanned by orthonormal vectors $|a\rangle = |a_1, a_2, \ldots, a_n\rangle$ which are labeled by vectors $a$ of the additive group $\mathbb{F}^n$, where $\mathbb{F} = \mathbb{Z}_d$ is the cyclic field of prime order. A projective representation $(\boldsymbol{w}, \chi, \mathbb{C}^{d^n})$ of the additive group $\mathbb{F}^{2n}$ is given by

$$\boldsymbol{w}(p,q)|a\rangle := \mathrm{e}^{(2\pi\mathrm{i}/d)p^{\mathrm{t}}a}|a+q\rangle \quad [5]$$

where $p^{\mathrm{t}}$ is the transposed vector. The factor system $\chi$ assigns to each pair $(p,q),(p',q')$ the phase

$$\chi(p,q|p',q') := \mathrm{e}^{(2\pi\mathrm{i}/d)p^{\mathrm{t}}q'} \quad [6]$$

The finite vector space $\mathbb{F}^{2n}$ is interpreted as finite phase space with a multiplicative symplectic form $\sigma$. It assigns to a pair of vectors $(p,\, q)$, $(a,\, b)$ the phase

$$\sigma(p,q|a,b) := \mathrm{e}^{(2\pi\mathrm{i}/d)(p^{\mathrm{t}}b - a^{\mathrm{t}}q)} \quad [7]$$

The commutation relation for Weyl operators comprise the symplectic form:

$$\boldsymbol{w}(p,q)\boldsymbol{w}(a,b) = \sigma(a,b|p,q)\boldsymbol{w}(a,b)\boldsymbol{w}(p,q) \quad [8]$$

The $d^{2n}$ Weyl operators $\boldsymbol{w}(p,q)$ are a basis of the algebra of all operators acting on the Hilbert space $\mathbb{C}^{d^n}$, hence $(\boldsymbol{w}, \chi, \mathbb{C}^{d^n})$ is irreducible. In particular, this Weyl system is a nice error basis in the sense of (Klappenecker and Roetteler 2002, 2005). Namely, the Weyl operators form a projective representation, on the one hand, and a unitary basis (Werner 2001) on the other.

For $d = 2$ and $n = 4$, we obtain a system of four qubits and the Weyl operators are tensor products of four Pauli matrices including the identity. For instance, the Weyl operator of the binary vector $(p,q) = (0011, 1010)$ can be expressed in terms of Pauli matrices (see Introduction) as follows:

$$\begin{aligned}\boldsymbol{w}(0011,1010) &= \boldsymbol{w}(0,1) \otimes \mathbb{1} \otimes \boldsymbol{w}(1,1) \otimes \boldsymbol{w}(1,0)\\ &= \boldsymbol{i}X \otimes \mathbb{1} \otimes Y \otimes Z\end{aligned} \quad [9]$$

## Clifford Channels

Weyl systems can be seen as quantized symmetries corresponding to finite abelian groups. In the Heisenberg picture the symmetry transformations act on operators $A \in \mathcal{B}(\mathcal{H})$ of the observable algebra by automorphisms (reversible quantum channels):

$$\mathrm{Ad}[\boldsymbol{w}(\xi)](A) := \boldsymbol{w}(\xi)A\boldsymbol{w}(\xi)^* \quad [10]$$

Since a projective representation preserves the group law up to a phase, the corresponding automorphisms preserve the group law:

$$\mathrm{Ad}[\boldsymbol{w}(\xi)] \circ \mathrm{Ad}[\boldsymbol{w}(\eta)] = \mathrm{Ad}[\boldsymbol{w}(\xi+\eta)] \quad [11]$$

A quantum channel $T$ is called a Clifford channel if it is covariant with respect to Weyl systems $(\boldsymbol{w}_1, f_1, \mathcal{H}_1)$ and $(\boldsymbol{w}_2, f_2, \mathcal{H}_2)$, that is, the intertwiner relation

$$T \circ \mathrm{Ad}[\boldsymbol{w}_2(\xi)] = \mathrm{Ad}[\boldsymbol{w}_1(\xi)] \circ T \quad [12]$$

holds. It is required that the antisymmetric part of the factor systems $f_1$ and $f_2$ coincide, that is, $\sigma = f_1^{-1}\theta f_1 = f_2^{-1}\theta f_2$. We call $(\boldsymbol{w}_1, f_1, \mathcal{H}_1)$ the input and $(\boldsymbol{w}_2, f_2, \mathcal{H}_2)$ the output system. We refer to the article by Scutaru (1979), which is concerned with the general properties of covariant channels.

It is a natural question to ask how Clifford channels act on Weyl operators. As shown by Holevo (n.d.), a Clifford channel maps Weyl operators of the output system to multiples of a Weyl operators of the input system, provided the input system is irreducible.

**Theorem 3** (Holevo (n.d.)). *Let $T$ be a Clifford channel such that the input system $(\boldsymbol{w}_1, f_1, \mathcal{H}_1)$ is irreducible. Then there exists a function $\varphi : \Xi \to \mathbb{C}$ such that*

$$T(\boldsymbol{w}_2(\xi)) = \varphi(\xi)\boldsymbol{w}_1(\xi) \quad [13]$$

*holds for all $\xi \in \Xi$. The function $\varphi$ is of positive type, that is, for all complex functions $f$ on $\Xi$ the inequality*

$$0 \le \sum_{\xi,\eta\in\Xi} \varphi(\xi-\eta)\overline{f(\xi)}f(\eta) \quad [14]$$

*holds. Conversely, if the factor systems $f_1 = f_2$ coincide, then a well-defined channel is determined*

*by [13] for any function $\varphi$ of positive type with $\varphi(0)=1$.*

We apply Theorem 3 to a reversible Clifford channel T. Each output Weyl operator $\boldsymbol{w}_2(\xi)$ is mapped to a multiple of an input Weyl operator

$$T(\boldsymbol{w}_2(\xi)) = \varphi(\xi)\boldsymbol{w}_1(\xi) \qquad [15]$$

where $\varphi$ is phase-valued (a 1-cochain) according to the reversibility of $T$. We focus now on the converse problem: construct all reversible Clifford channels for irreducible Weyl systems that have a common antisymmetric part of the factor system. The following theorem gives a useful characterization of reversible Clifford channels.

**Theorem 4** (Schlingemann and Werner 2001). *If $(\boldsymbol{w}_1, f_1, \mathcal{H}_1)$ and $(\boldsymbol{w}_2, f_2, \mathcal{H}_2)$ are irreducible Weyl systems with $f_1^{-1}(\theta f_1) = f_2^{-1}(\theta f_2)$, then there exists a 1-cochain $\varphi$ with coboundary $\eth\varphi = f_1^{-1} f_2$, and a reversible Clifford channel $T_\varphi$ is determined by*

$$T_\varphi(\boldsymbol{w}_2(\xi)) = \varphi(\xi)\boldsymbol{w}_1(\xi) \qquad [16]$$

*If $\tau$ is a 1-cochain that also satisfies $\eth\tau = f_1^{-1} f_2$, then there exists $\eta \in \Xi$ such that*

$$\tau(\xi) = \sigma(\eta|\xi)\varphi(\xi) \qquad [17]$$

$$T_\tau = \mathrm{Ad}[\boldsymbol{w}_1(\eta)] \circ T_\varphi = T_\varphi \circ \mathrm{Ad}[\boldsymbol{w}_2(\eta)] \qquad [18]$$

*holds. In other words, two irreducible Weyl systems determine a reversible Clifford channel up to a "phase space translation $\eta$."*

We consider the Weyl system $(\boldsymbol{w}, f, \mathcal{H})$ over a discrete phase space $\mathbb{F}^{2n}$, where $\mathbb{F}$ is a finite field of prime order. The group of symplectic transformations $\mathrm{Sp}(n, \mathbb{F})$ consists of all $\mathbb{F}$-linear maps s on the phase space $\mathbb{F}^{2n}$ that preserve the symplectic form $\sigma = f^{-1}\theta f$. A further Weyl system $(\boldsymbol{w} \circ \boldsymbol{s}, f \circ \boldsymbol{s}, \mathcal{H})$ is obtained for each symplectic transformation $\boldsymbol{s}$. Here the factor system $f \circ \boldsymbol{s}$ is defined according to $(f \circ \boldsymbol{s})(\xi, \eta) := f(\boldsymbol{s}\xi, \boldsymbol{s}\eta)$ and the corresponding Weyl operators are $(\boldsymbol{w} \circ \boldsymbol{s})(\xi) = \boldsymbol{w}(\boldsymbol{s}\xi)$. Obviously, the antisymmetric part of the factor system $f \circ \boldsymbol{s}$ is the symplectic form $\sigma \circ \boldsymbol{s} = \sigma$. The following statement is a direct consequence of Theorem 4.

**Corollary 5** *For each symplectic transformation $\boldsymbol{s} \in \mathrm{Sp}(n, \mathbb{F})$ there exists a 1-cochain $\varphi$ with coboundary $\eth\varphi = f^{-1}(f \circ \boldsymbol{s})$ and the corresponding reversible Clifford channel $T_{[\varphi, s]}$ is given by*

$$T_{[\varphi, s]}(\boldsymbol{w}(\xi)) = \varphi(\xi)\boldsymbol{w}(\boldsymbol{s}\xi) \qquad [19]$$

*with $\xi, \eta \in \mathbb{F}^{2n}$.*

**Example 6** We consider a finite field $\mathbb{F}$. To a symmetric matrix $\Gamma \in \mathrm{M}_n(\mathbb{F})$ we associate the symplectic transformation on $\mathbb{F}^{2n}$ that maps a phase space vector $(p, q)$ to $(p - \Gamma q, q)$. This shear transformation is viewed as one elementary step of a discrete dynamics. The quantized version of this dynamics is given by the unitary multiplication operator

$$\boldsymbol{u}(\Gamma)|q\rangle = \zeta_d^{q^{\mathrm{t}}\Gamma q}|q\rangle \qquad [20]$$

with the root of unity $\zeta_d = \exp(\mathrm{i}\pi(d+1)/d)$ for $d \neq 2$ and $\zeta_2 = \mathrm{i}$. The unitary operator $\boldsymbol{u}(\Gamma)$ implements a reversible Clifford operation for the symplectic transformation $(p, q) \mapsto (p - \Gamma q, q)$ since the relation

$$\boldsymbol{u}(\Gamma)\boldsymbol{w}(p, q)\boldsymbol{u}(\Gamma)^* = \zeta_d^{q^{\mathrm{t}}\Gamma q}\boldsymbol{w}(p - \Gamma q, q) \qquad [21]$$

holds. The symmetric matrix $\Gamma$ describes a pattern of two-qudit interactions. This can be visualized by a graph $\Gamma$ whose vertices are the positions $x, y = 1, \ldots, n$. Two vertices $x$, $y$ are connected by an edge if the matrix element $\Gamma_y^x \neq 0$ is nonvanishing. The value of the matrix element $\Gamma_y^x$ is interpreted as the strength of the interaction.

**Example 7** The second type of symplectic transformations, which is relevant here, is determined by an invertible matrix $C \in \mathrm{M}_n(\mathbb{F})$. It induces a symplectic transformation which maps the vector $(p, q)$ to $(Cq, -\tilde{C}p)$, where $\tilde{C}$ is the inverse of the transpose of $C$. This is implemented by a unitary transformation $F_{[C]}$. It is called the Fourier transform associated with the invertible matrix $C$:

$$F_{[C]}|p\rangle = \frac{1}{\sqrt{d}^n}\sum_{q \in \mathbb{F}^n} \mathrm{e}^{(2\pi\mathrm{i}/d)p^{\mathrm{t}}Cq}|q\rangle \qquad [22]$$

By construction, the relation

$$F_{[C]}\boldsymbol{w}(p, q)F_{[C]}^* = \mathrm{e}^{(2\pi\mathrm{i}/d)p^{\mathrm{t}}q}\boldsymbol{w}(Cq, -\tilde{C}p) \qquad [23]$$

follows. If $C = \mathrm{diag}(c_1, \ldots, c_n)$ is a diagonal matrix, then $F_{[C]}$ is a local unitary transformation. In fact, the Fourier transform is a tensor product

$$F_{[C]} = F_{[c_1]} \otimes F_{[c_2]} \otimes \cdots \otimes F_{[c_n]} \qquad [24]$$

with $c_x \in \mathbb{F}\backslash 0$, where the tensor product structure is determined by $|q\rangle = |q_1\rangle \otimes \cdots \otimes |q_n\rangle$.

## The Stabilizer Formalism

This section is dedicated to the stabilizer formalism, which has widely been discussed in the literature (Calderbank *et al.* 1997, Gottesman 1996, 1997). We investigated here stabilizer codes from a point of view of symmetries and show how they can be characterized by Clifford channels. We verify that

stabilizer codes are specific Clifford channels in the sense described in the last section. To begin with, we consider an irreducible Weyl system $(\boldsymbol{w}, f, \mathcal{H})$ of an even-dimensional $\mathbb{F}$-vector space $\Xi$ such that the antisymmetric part of the factor system $\sigma := f^{-1}\theta f$ is a symplectic form on $\Xi$. Furthermore, we need to introduce the following notions:

The symplectic complement of a subspace $\mathcal{Q} \subset \Xi$ is the subspace

$$\mathcal{Q}^{\sigma} = \{\xi \in \Xi | \sigma(\xi|q) = 1 \, \forall q \in \mathcal{Q}\} \qquad [25]$$

Furthermore, a subspace $\mathcal{Q}$ of $\Xi$ is isotropic if it is contained in its symplectic complement $\mathcal{Q}^{\sigma} \supset \mathcal{Q}$. In other words, for all pairs of vectors $q, q' \in \mathcal{Q}$ we have $\sigma(q\,|\,q') = 1$.

We consider an isotropic subspace $\mathcal{Q}$ and we denote by $(\boldsymbol{w}|_{\mathcal{Q}}, f|_{\mathcal{Q}}, \mathcal{H})$ the corresponding restriction of the Weyl system $(\boldsymbol{w}, f, \mathcal{H})$. Since $\mathcal{Q}$ is isotropic, it follows that the restriction $f|_{\mathcal{Q}}$ is symmetric. Hence, the Weyl algebra for the restricted system $\mathfrak{A}_{\mathcal{Q}} := \mathfrak{A}(\boldsymbol{w}|_{\mathcal{Q}}, f|_{\mathcal{Q}}, \mathcal{H})$ is an abelian subalgebra of $\mathcal{B}(\mathcal{H})$. As a consequence, all the operators in $\mathfrak{A}_{\mathcal{Q}}$ can be diagonalized simultaneously. To obtain the joint spectral resolution for all operators in $A$, we employ some facts from the theory of finite dimensional abelian C*-algebras:

1. $\mathfrak{A}_{\mathcal{Q}}$ is a finite-dimensional abelian C*-algebra and can be identified with the algebra of complex functions $\mathcal{C}(\mathcal{Q}^{\wedge})$ on a finite set $\mathcal{Q}^{\wedge}$.
2. Each element $\varpi \in \mathcal{Q}^{\wedge}$ is a character (pure state), that is, a linear functional such that $\varpi(AB) = \varpi(A)\varpi(B)$ and $\varpi(A^*) = \overline{\varpi(A)}$.
3. For each operator $A \in \mathfrak{A}_{\mathcal{Q}}$ there exists precisely one function $f_A$ on $\mathcal{Q}^{\wedge}$ which is uniquely determined by $\varpi(A) = f_A(\varpi)$. The isomorphism $A \to f_A$ is called the Gelfand isomorphism.
4. A character $\varpi \in \mathcal{Q}^{\wedge}$ is an irreducible representation of $\mathfrak{A}_{\mathcal{Q}}$ and there is a unique projection $\boldsymbol{e}_{\varpi}$ onto the subspace in $\mathcal{H}$ which carries this irreducible representation.

From these facts we derive a joint spectral resolution for all operators in $\mathfrak{A}_{\mathcal{Q}}$. Namely, each $A \in \mathfrak{A}_{\mathcal{Q}}$ can be written as

$$A = \sum_{\varpi \in \mathcal{Q}^{\wedge}} \boldsymbol{e}_{\varpi}\, \varpi(A) \qquad [26]$$

We are now prepared to introduce the notion of stabilizer codes in accordance with Calderbank *et al.* (1997) and Gottesman (1996, 1997): Let $\mathcal{Q}$ be an isotropic subspace in $\Xi$ and let $\varpi \in \mathcal{Q}^{\wedge}$ be a character of $\mathfrak{A}_{\mathcal{Q}}$. The projection $\boldsymbol{e}_{\varpi}$ is called a stabilizer code. The abelian group that is generated by the Weyl operators $\boldsymbol{w}(q), q \in \mathcal{Q}$, is called stabilizer group. The abelian C*-algebra $\mathfrak{A}_{\mathcal{Q}}$ is called stabilizer algebra. According to the following theorem, each stabilizer code is uniquely associated with a Clifford channel:

**Theorem 8** (Schlingemann 2002, 2004). *Let $\mathcal{Q}$ be an isotropic subspace of $\Xi$ and let $\boldsymbol{e}_{\varpi}$ be the stabilizer code of a character $\varpi$. Then there exists a unique Clifford channel $\boldsymbol{E}_{\varpi}$ with input system $(\boldsymbol{w}_{\varpi}, f_{\varpi}, \mathcal{H}_{\varpi})$ and output system $(\boldsymbol{w}|_{\mathcal{Q}^{\sigma}}, f|_{\mathcal{Q}^{\sigma}}, \mathcal{H})$ such that the following is true:*

(i) *For each $\xi \in \Xi$ the identity*

$$\boldsymbol{E}_{\varpi}(\boldsymbol{w}(\xi)) = \delta_{\mathcal{Q}^{\sigma}}(\xi)\boldsymbol{w}_{\varpi}(\xi) \qquad [27]$$

*is fulfilled.*

(ii) *Let $\boldsymbol{v}_{\varpi} : \mathcal{H}_{\varpi} \to \mathcal{H}$ be the isometry which embeds $\mathcal{H}_{\varpi}$ into $\mathcal{H}$, then*

$$\boldsymbol{E}_{\varpi}(A) = \boldsymbol{v}_{\varpi}^* A \boldsymbol{v}_{\varpi} \qquad [28]$$

*holds for all $A \in \mathcal{B}(\mathcal{H})$.*

(iii) *The channel $\boldsymbol{E}_{\varpi}$ is invariant under translations in the isotropic subspace $\mathcal{Q}$, that is, the identity*

$$\boldsymbol{E}_{\varpi} \circ \mathrm{Ad}[\boldsymbol{w}(q)] = \boldsymbol{E}_{\varpi} \qquad [29]$$

*holds for all $q \in \mathcal{Q}$.*

Stabilizer codes for maximally isotropic subspaces $\mathcal{Q} = \mathcal{Q}^{\sigma}$ are special, since the projection $\boldsymbol{e}_{\varpi}$ onto the eigenspace of the character $\varpi$ is one-dimensional. Thus, $\boldsymbol{e}_{\varpi}$ is the density matrix of a pure state which is called stabilizer state. In view of Theorem 8, the expectation value of a Weyl operators $\boldsymbol{w}(\xi)$ is given by

$$\mathrm{tr}(\boldsymbol{e}_{\varpi}\boldsymbol{w}(\xi)) = \varpi(\boldsymbol{w}(\xi))\delta_{\mathcal{Q}}(\xi) \qquad [30]$$

## Representation by Graphs

As described in the previous section (Theorem 8), each stabilizer codes is a pure Clifford channel which is completely determined by an isotropic subspace and a character of the corresponding stabilizer algebra. A constructive characterization of isotropic subspaces can be given in terms of graphs, as it has been shown in Schlingemann (2002, 2004). The complete description of a stabilizer code requires in addition the choice of a character of the stabilizer algebra. Both data, the isotropic subspace and the character, can be encoded in a single graph $\Lambda$. The set of vertices `N` is partitioned into four different types, the input vertices `I`, the output vertices `J`, the measurement vertices `K` and the syndrome vertices `L` (see **Figure 1**). The edges of the graph are undirected, and a pair of vertices can be connected by at most $d-1$ edges, where self-links are also allowed. The adjacency matrix (also

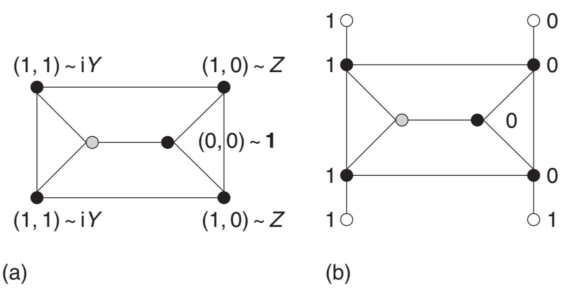

**Figure 1** (a) A graphical representation of a Weyl operator $-Y \otimes Y \otimes Z \otimes Z \otimes \mathbb{1}$ of the stabilizer algebra of a quantum error correcting code, encoding one qubit into five (see 00273). The input vertex is gray, the output vertices are black. Each binary vector represents a Pauli matrix sitting at a tensor position of the output system. (b) The expectation values which are products over all edges, where to each edge with labels $q, q'$ the value $(-1)^{qq'}$ is assigned. The character corresponds to the syndrome configuration (1110) (blanc vertices).

denoted by $\Lambda$) is a symmetric matrix with entries $\Lambda^{\mathtt{x}}_{\mathtt{y}} = 0, 1, \ldots, d-1$ according to the number of edges between $\mathtt{x}$ and $\mathtt{y}$. Thus, the adjacency matrix can be seen as a linear operator on $\mathbb{F}^{\mathtt{N}}$ with cyclic field $\mathbb{F} = \mathbb{Z}_d$. Each subset $\mathtt{A} \subset \mathtt{N}$ corresponds to a linear projection onto the subspace $\mathbb{F}^{\mathtt{A}} \subset \mathbb{F}^{\mathtt{N}}$, which we denote by $\pi_{\mathtt{A}}$. For a convenient description we introduce the following notation: the union of two sets of vertices is written without the symbol $\cup$, that is, instead of $\mathtt{I} \cup \mathtt{J}$ we write $\mathtt{IJ}$.

**Theorem 9** (Schlingemann 2002, 2004). *Let $\mathcal{Q} \subset \mathbb{F}^{\mathtt{J}} \oplus \mathbb{F}^{\mathtt{J}}$ be an isotropic subspace and let $\varpi$ be a character of the stabilizer algebra $\mathfrak{A}_{\mathcal{Q}}$. Then there exists a graph $\Lambda$ with input vertices* $\mathtt{I}$, *output vertices* $\mathtt{J}$, *measurement vertices* $\mathtt{K}$ *and syndrome vertices* $\mathtt{L}$ *such that the following holds*:

(i) *The linear operator $\pi_{\mathtt{JK}} \Lambda \pi_{\mathtt{IKL}}$ is invertible.*
(ii) *The isotropic subspace $\mathcal{Q}$ consists of the vectors $(\pi_{\mathtt{J}} \Lambda \pi_{\mathtt{JK}} q, \pi_{\mathtt{J}} q)$ with $q \in \ker(\pi_{\mathtt{IK}} \Lambda \pi_{\mathtt{JK}})$.*
(iii) *There is a unique vector $a$ in the syndrome subspace $\mathbb{F}^{\mathtt{L}}$ such that the expectation values of the character $\varpi$ are given by*

$$\varpi(\boldsymbol{w}(\pi_{\mathtt{J}} \Lambda \pi_{\mathtt{JK}} q, \pi_{\mathtt{J}} q)) = \zeta_d^{(q+a)^t \Lambda (q+a)} \qquad [31]$$

*with $q \in \ker(\pi_{\mathtt{IK}} \Lambda \pi_{\mathtt{JK}})$.*

Theorems 8 and 9 provide different useful characterizations of stabilizer codes, namely in terms of eigenspaces, Clifford channels, and graphs.

- The original definition of stabilizer codes in terms of eigenspaces goes back to Calderbank, Gottesman, Rains, Shor, and Sloane (see, e.g., Calderbank *et al.* (1997), Gottesman (1996, 1997). They have developed an approach to derive quantum codes from classical binary codes.
- Stabilizer codes can also be characterized by specific Clifford channels (see Theorem 8). The condition for a channel to be a stabilizer code is the covariance with respect to a subgroup of phase space translations. This reflects stabilizer codes in terms of symmetries.
- Theorem 9 yields a characterization of stabilizer codes in terms of graphs providing an explicit expression for the isotropic subspace and the character of the stabilizer code. This graphical representation provides a suggestive encoding of various properties like error-correcting capabilities, multipartite entanglement, the effects of specific local operations. In fact, as it has been shown in Briegel and Raussendorf (2001), Dür *et al.* (2003), and Hein *et al.* (2004) that the entanglement present in a graph state can be derived from its shape.

## Introduction

A typical problem of quantum statistical mechanics is to compute equilibrium states of quantum dynamical systems. However, there is a strange difficulty inherent in this task, which is to describe the solution: if we try to describe the quantum state by specifying all matrix elements of all local density operators, we have a job which grows exponentially with the system size. This approach is obviously out of the question for the large systems statistical mechanics is interested in. Luckily, in practice nobody really wants to see all those numbers anyway, and one is content with determining a few correlation functions, or other easily parametrized characteristics of the state. But for computing a state in the first place, we cannot restrict the state description to a such parameters. So the problem there is again: how can we efficiently parametrize the states of interest?

In this article we collect some results on a particular way of addressing this problem. It originated in the early 1990s (Fannes *et al.* 1992b) in ideas for quantizing the notion of Markov chains (Accardi and Frigerio 1983). Recently, there has been a new surge of interest in such ideas, because they turned out to be very useful for numerical work on quantum spin chains.

Its typical feature is that one does not directly describe expectation values of the state, but instead generates the state from a description of its correlations between neighboring sites. In the language of quantum information theory, it could be said that the method focuses on the entanglement between different parts of the system.

## The Basic Construction

### Notation

We consider a quantum spin chain, that is, a system of infinitely subsystems, labeled by the integers, each of which is a quantum-mechanical $d$-level system. Let us denote the observable algebra at site $x \in \mathbb{Z}$ by $\mathcal{A}_x$. Each $\mathcal{A}_x$ is hence isomorphic to the $d \times d$ matrices. The observables of the whole (infinite) system lie in the infinite tensor product $\mathcal{A}_{\mathbb{Z}} = \bigotimes_{x \in \mathbb{Z}} \mathcal{A}_x$. This is defined as a quasilocal algebra (Bratteli and Robinson 1987, 1997), which is to say that it is the algebra generated by all finite tensor products of elements of the $\mathcal{A}_x$, say $\bigotimes_{x \in \Lambda} A_x$ with $A_x \in \mathcal{A}_x$ and $\Lambda$ finite. Such an element is said to be localized in $\Lambda$, and we denote by $\mathcal{A}_\Lambda$ the corresponding algebra. For $\Lambda_1 \subset \Lambda_2$, we identify $\mathcal{A}_{\Lambda_1}$ with a subalgebra of $\mathcal{A}_{\Lambda_2}$, by tensoring with the identity operator on all sites in $\Lambda_2 \backslash \Lambda_1$. $\mathcal{A}_{\mathbb{Z}}$ is the completion of the union of all $\mathcal{A}_\Lambda$, with $\Lambda$ finite, under the C$^*$-norm.

A state $\omega$ on $\mathcal{A}_{\mathbb{Z}}$ is uniquely specified by its expectations on the subalgebras $\mathcal{A}_\Lambda$. Since these are finite-dimensional matrix algebras, we can write $\omega(A) = \mathrm{tr}(\rho_\Lambda A)$ for $A \in \mathcal{A}_\Lambda$, with a "local density operator" $\rho_\Lambda$. The system of local density operators must be consistent with respect to restrictions (partial traces).

So far we have not used the structure of the underlying lattice $\mathbb{Z}$ in any way. This enters via the translation automorphisms $\tau_n$ of $\mathcal{A}_{\mathbb{Z}}$, which identify $\mathcal{A}_x$ with $\mathcal{A}_{x+n}$. A state is called translationally invariant, if $\omega \circ \tau_n = \omega$. The translationally invariant states form a weakly compact convex subset of the state space of $\mathcal{A}_{\mathbb{Z}}$, whose extreme points are called ergodic states.

### How to Generate Correlations

Correlations between parts of a systems typically have their origin in an interaction in the past. Even if the subsystems are dynamically separated later on, the correlation persists, and one can take this as a motivation to model correlations from two ingredients: a simplified prototype of a correlated system, and some evolution taking the parts of the simplified system to the parts of the given system. Let us consider a composite system, whose parts have observable algebras $\mathcal{A}_1$ and $\mathcal{A}_2$, respectively, so that the whole system has algebra $\mathcal{A}_1 \otimes \mathcal{A}_2$. We can build a state $\omega$ on this system from a simpler one,

say a state $\eta$ on some $\mathcal{B}_1 \otimes \mathcal{B}_2$, and two completely positive unit preserving maps $T_i : \mathcal{A}_i \to \mathcal{B}_i$ such that

$$\omega(A_1 \otimes A_2) = \eta(T_1(A_1) \otimes T_2(B_2))$$

Some features of $\eta$ are inherited by $\omega$. For example, when $\eta$ is separable (a convex combination of products), which is always the case if either $\mathcal{B}_1$ or $\mathcal{B}_2$ is classical (i.e., an abelian algebra), then the same holds for $\omega$. Hence, if we want to describe quantum correlated "entangled" states, we have to build the correlations on an entangled state $\eta$. Similarly, the "size" of the model system $\mathcal{B}_1 \otimes \mathcal{B}_2$ limits the strength of correlations in $\omega$. As for every correlated state, we can look at the linear functionals on $\mathcal{A}_2$, which are of the form $A \mapsto \omega(A_1 \otimes A)$ with fixed $A_1 \in \mathcal{A}_2$. The dimension of the space of such functionals might be called the correlation dimension of $\omega$. This dimension is 1 for product states, and can clearly not increase by passing from $\eta$ to $\omega$. Hence, it is bounded by the dimensions of $\mathcal{B}_1$ and $\mathcal{B}_2$, even if $\mathcal{A}_1$ and $\mathcal{A}_2$ are infinite dimensional. "Finite correlation" in the sense of the title of this article refers to the finiteness of the correlation dimension between the two halves of a spin chain.

## The VBS Construction, and Matrix Product States

The so-called valence bond solid (VBS) states on a chain are constructed by applying these ideas to the correlations across every link of a spin chain. Let us introduce a correlated model state $\eta_x$ on some algebra $\mathcal{B}_x^- \otimes \mathcal{B}_x^+$ for every bond $(x, x+1)$. Then the state at site $x$ is a function of contributions from both bonds connecting it, and we express this by a completely positive map $T_x : \mathcal{A}_x \to \mathcal{B}_{x-1}^+ \otimes \mathcal{B}_x^-$. Then an observable $A_1 \otimes \cdots \otimes A_L$ on a chain piece of length $L$ is first mapped by $\bigotimes_{x=1}^L T_x$ to an element of $\mathcal{B}_0^+ \otimes \mathcal{B}_1^- \otimes \cdots \otimes \mathcal{B}_{L-1}^+ \otimes \mathcal{B}_L^-$. Evaluating with the states $\eta_1 \otimes \cdots \otimes \eta_{L-1}$, we are left with an element of $\mathcal{B}_0^+ \otimes \mathcal{B}_L^-$, which we can evaluate with yet another state $\eta_{0L}$ describing the boundary conditions for the construction (see Figure 1).

Clearly, if we take the algebras $\mathcal{B}_x^\pm$ large enough, and the model states $\eta_x$ sufficiently highly entangled, we can generate every state on the finite chain. However, we can get an interesting class of states, even for fixed finite dimensions of the $\mathcal{B}_x^\pm$. By restricting this correlation dimension, we can set a level of complexity for the state description. We can then try to handle a given physical problem first with simple states of low correlation dimension, and increase this parameter only as needed. A typical problem here is to determine the ground state of a finite-range Hamiltonian. We can then optimize each $T_x$ and $\eta_x$ separately, minimizing the ground

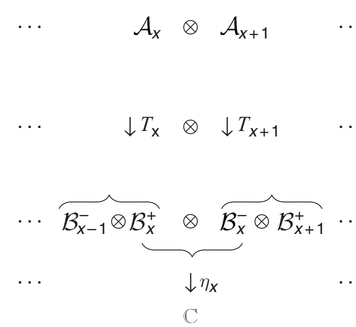

**Figure 1**

state energy with all other elements fixed. This is a semidefinite programming problem, for which very efficient methods are known. The global minimization is then done by letting the optimization site $x$ sweep over the whole chain as often as needed.

In a ground-state problem one is looking for a pure state, and it is therefore sufficient to choose both the model states $\eta_x$ and the operations $T_x$ to pure, that is, without decomposition into sums of similar objects. The scheme is thus run at the vector level rather than the operator level: we take the algebras $\mathcal{B}_x^+ = \mathcal{B}_x^-$ as the operators on a Hilbert space $\mathcal{K}_x$, and $\eta_x = (\dim \mathcal{K}_x)^{-1} |\Omega_x\rangle\langle\Omega_x|$ with the (unnormalized) maximally entangled vector

$$\Omega_x = \sum_j |j\rangle \otimes |j\rangle \in \mathcal{K}_x \otimes \mathcal{K}_x \qquad [1]$$

The maps $T_x$ will be implemented by a single operator $V_x : \mathcal{K}_{x-1} \otimes \mathcal{K}_x \to \mathcal{H}$ as $T_x(A) = V_x^* A V_x$. Then the vectors $\Psi \in \mathcal{H}^{\otimes L}$ contributing to the state on the chain of length $L$ are of the form

$$\begin{aligned}\Psi &= V_1 \otimes \cdots V_L \left(|j_0\rangle \otimes \Omega^{\otimes L} \otimes |i_L\rangle\right) \\ &= \sum_{j_0, j_1, \ldots, j_L} (V_1 \otimes \cdots V_L) |j_0, j_1, j_1, \ldots, j_{L-1}, j_L\rangle\end{aligned}$$

where $j_0, j_L$ are labels for bases in $\mathcal{K}_0$ and $\mathcal{K}_L$, describing the possible choices at the boundary, and we have used the special form of $\Omega$. We write out the operators $V_x$ in components, so that

$$V_x |jj'\rangle = \sum_\mu |\mu\rangle V_{x;jj'}^\mu$$

with suitable $\dim \mathcal{K}_{x-1} \times \dim \mathcal{K}_x$ dimensional matrices $V_x^\mu$, in terms of which the above expression can be interpreted as a matrix product. The components of $\Psi$ in a product basis $\{|\mu\rangle\}$ become

$$\langle \mu_1, \ldots, \mu_L | \Psi \rangle = \langle j_0 | V_1^{\mu_1} V_2^{\mu_2} \cdots V_L^{\mu_L} | j_L \rangle \qquad [2]$$

Due to this form the states generated in this way have also been called "matrix product states" (Klümper 1991). If one wants to consider periodic

boundary conditions, the indices $j_0$ and $j_L$ can also be contracted, and the expression becomes a trace. For some simulations it is also convenient to choose $\sim\mathcal{K}_0 = \dim \mathcal{K}_L = 1$, so there is only one matrix element to be considered.

The scheme for getting ground-state vectors described here is essentially the same as the density matrix renormalization group method (Verstraete *et al.* 2004). However, the version given here appears to be more transparent, more flexible, and in some cases (e.g., periodic boundary conditions) vastly more efficient. However, it may be too early for such judgment, since this is very much work in progress (Verstraete *et al.* 2005).

In the sequel, we will focus not so much on the numerical aspects, but on the possibility this construction offers to explicitly construct nontrivial translationally invariant states on the infinite chain. Numerically, even in a translation invariant situation the matrices $V_x^\mu$ obtained by optimization may turn out to depend on $x$ (Wolf, Private Communication), that is, one has to admit the possibility of a spontaneous symmetry breaking. However, for the construction of states on the infinite chain we will simply fix all $V_x$ to be equal. In some sense this turns the matrix product into a matrix power, which could be analyzed by methods familiar from the transfer matrix formalism of statistical mechanics. In eqn [2] this does not work, because of the $\mu$-dependence of the matrices involved. Nevertheless, a slight reorganization of the construction will lead to a transfer-matrix-like formalism.

### The Evolution Operator Construction

Fixing all $T_x$ to be the same in Figure 1 still does not fix the state uniquely, since both in the mixed state version and in the pure state version of the construction some boundary information enters, as well. This boundary information then has to be chosen in such a way that a consistent family of local density operators is generated. It turns out that by rearranging the construction a little bit one can trivially solve one boundary condition, and reduce the other to finding a fixed point of a linear operator. This rearrangement was first carried out in Fannes *et al.* (1992b), where the term "finitely correlated state" was also coined.

The basic element of the VBS construction was the operators $T : \mathcal{A} \to \mathcal{B}^+ \otimes \mathcal{B}^-$ (here already taken independent of $x$). This is specified by $\dim \mathcal{A} \cdot \dim \mathcal{B}^+ \cdot \dim \mathcal{B}^-$ matrix elements. However, assuming we can identify the algebras $\mathcal{B}^\pm$, we can also consider these matrix elements as those of an "evolution operator" $\mathbb{E} : \mathcal{A} \otimes \mathcal{B} \to \mathcal{B}$. This operator is once again taken to be completely positive and unit preserving. We introduce its $n$th iterate $\mathbb{E}^{(n)} : \mathcal{A}^{\otimes n} \otimes \mathcal{B} \to \mathcal{B}$ by the recursion

$$\mathbb{E}^{(1)} = \mathbb{E}, \qquad \mathbb{E}^{(n+1)} = \mathbb{E}(\mathrm{id}_{\mathcal{A}} \otimes \mathbb{E}^{(n)}) \qquad [3]$$

Clearly, these operators are again completely positive and unit preserving. Another way to express this iteration is to look at $\mathbb{E}$ as a family of maps on $\mathcal{B}$, parametrized by $A \in \mathcal{A}$: We set $\mathbb{E}_A(B) = \mathbb{E}(A \otimes B)$, and find

$$\mathbb{E}^{(n)}(A_1 \otimes \cdots \otimes A_n \otimes B) = \mathbb{E}_{A_1} \cdots \mathbb{E}_{A_1}(B) \qquad [4]$$

An important special role is played by the operator $\widehat{\mathbb{E}} = \mathbb{E}_{\mathbb{1}}$, which is again completely positive and unit preserving.

Now given any state $\eta$ on $\mathcal{B}$, we get a state $\omega_n$ on $\mathcal{A}^{\otimes n}$, by setting

$$\omega_n(A_1 \otimes \cdots A_n) = \eta\Big(\mathbb{E}^{(n)}(A_1 \otimes \cdots \otimes A_n \otimes \mathbb{1})\Big) \qquad [5]$$

Since $\widehat{\mathbb{E}}(\mathbb{1}) = \mathbb{1}$, this family of states is consistent with respect to increasing $n$, by adding sites on the right, that is, $\omega_{n+1}(A \otimes \mathbb{1}) = \omega_n(A)$. In other words, the family $\omega_n$ defines a state on the infinite right half-chain. This state can be extended to the full chain, as a translationally invariant state if and only if consistency also holds for adding sites on the left, that is, if $\omega_{n+1}(\mathbb{1} \otimes A) = \omega_n(A)$ for all $A \in \mathcal{A}^{\otimes n}$. For this we need a condition on the state $\eta$: it must be invariant under the map $\widehat{\mathbb{E}}$ (i.e., $\eta(\widehat{\mathbb{E}}(B)) = \eta(B)$ for all $B \in \mathcal{B}$). This is the only requirement, and we call $\omega$ the state $\mathcal{A}_{\mathbb{Z}}$ generated by $\mathbb{E}$ and $\eta$. Note that since $\widehat{\mathbb{E}}$ has the invariant vector $\mathbb{1}$, its transpose also has an invariant vector, which can also be chosen as a state. We will often look at unique invariant state, in which case we can call $\omega$ the state generated by $\mathbb{E}$, without having to mention $\eta$.

The valence bond picture was very much suggested by trying to describe correlations in a spatially distributed quantum system (the chain). The construction given here is perhaps more readily suggested by a process in time, rather than space. In fact, the paper by Fannes *et al.* (1992b) was partly motivated by an attempt to define a quantum analog of Markov processes (Accardi and Frigerio 1983). In fact, we can think of the construction as a general form for a repeated measurement in quantum theory. The object on which the measurements are performed has observable algebra $\mathcal{B}$, whereas $\mathcal{A}$ describes the successive outputs. Choosing $\mathcal{A}$ to be classical (abelian) we would find in $\omega$ the joint probability distribution of the sequence of measured values, when the initial state of the object is $\eta$ (not necessarily invariant). Allowing nonabelian $\mathcal{A}$ would

then correspond to a family of delayed choice experiments: while $\mathbb{E}$ describes the interaction of the system with the measurement apparatus (including the overall state change $\widehat{\mathbb{E}}$), we are still free to make correlated and even entangled measurements on the successive output systems. This interpretation suggests many extensions, in particular, to continuous time (where the case of abelian outputs is discussed extensively in the classic book by Davies 1976), or to cases allowing an external quantum input in each step, in which case we are looking at a quantum channel with memory $\mathcal{B}$ (Kretschmann and Werner 2005).

In spite of the different natural interpretations, however, the constructions in this and previous paragraphs give exactly the same class of translationally invariant states on the chain, as was shown in (Fannes *et al.* 1992b).

## Ergodic Decomposition

A state on $\mathcal{A}_{\mathbb{Z}}$ is called ergodic if it is an extreme point of the compact convex subset of translationally invariant states. Often in statistical mechanics, one finds states which may be ergodic, but nevertheless contain a breaking of translation symmetry. Such states can be decomposed into periodic states, that is, states which are invariant with respect to some power of the shift. In general, new decompositions may become possible for any period. If no decomposition into periodic states is possible, the state is called completely ergodic.

In this section we consider the question of how to decompose a finitely correlated state into ergodic components, using a well-established connection between ergodicity and clustering properties (Bratteli and Robinson 1987, 1997), that is, the decay of correlation functions.

Correlation functions are very easily evaluated for finitely correlated states: let $A_\pm$ be two observables localized on $n_\pm$ sites, and suppose that these sites are separated by $L$ sites. Then eqn [5] gives

$$\omega\left(A_- \otimes \mathbb{1}^{\otimes L} \otimes A_+\right) = \eta\left(\mathbb{E}_{A_-}^{(n_-)}\, \widehat{\mathbb{E}}^L\, \mathbb{E}_{A_-}^{(n_+)}(\mathbb{1})\right) \qquad [6]$$

The $L$-dependence of this operator is clearly governed by the matrix powers of $\widehat{\mathbb{E}}$. By assumption this operator always has the eigenvalue 1, because $\widehat{\mathbb{E}}(\mathbb{1}) = \mathbb{1}$, and has norm $\leq 1$, because it is also completely positive. The spectrum is hence contained in the unit circle. Each eigenvalue with modulus $<1$ thus contributes exponentially decaying terms to the correlation function [6]. From eigenvalues of modulus 1, which make up the so-called peripheral spectrum, we may get constant or periodic contributions. This distinction is directly reflected in the ergodic properties (Fannes *et al.* 1992b):

- When the eigenvalue 1 is simple, there is a unique invariant state $\eta$, and $\lim_n n^{-1}\sum_{k=0}^{n-1}\widehat{\mathbb{E}}^k(B) = \eta(B)\mathbb{1}$. This implies, by [6] and (Bratteli and Robinson 1987, 1997, theorem 4.3.22), that $\omega$ is ergodic.
- When the eigenvalue 1 is simple, the peripheral spectrum consists precisely of the $p$th roots of unity for some $p \geq 1$. The state $\omega$ is then the equal-weight convex combination of $p$ periodic states with period $p$, which are translates of each other.
- In particular (i.e., for $p = 1$), a peripheral spectrum consisting only of the simple eigenvalue 1 implies that $\omega$ is exponentially clustering in the sense that

$$\begin{aligned}&\left|\omega\left(A_- \otimes \mathbb{1}^{\otimes L} \otimes A_+\right) - \omega(A_-)\omega(A_+)\right| \\ &\quad \leq \mathrm{poly}(L)\, r^L \|A_-\|\|A_+\|\end{aligned} \qquad [7]$$

  where $r$ is the largest modulus of eigenvalues other than 1, and poly is polynomial obtained from the Jordan normal form of $\widehat{\mathbb{E}}$. By the previous item, the state $\omega$ is then completely ergodic.
- Conversely, if a state is finitely correlated, and is ergodic (resp. completely ergodic), it has a representation such that 1 is a simple eigenvalue (resp. the peripheral spectrum is trivial).

## Purity

### Pure States

As in the case of the VBS construction, there is a version of the evolution operator construction, which is especially suited to produce pure states. Pure states are those which cannot be decomposed into a weighted sum of other states. For a translationally invariant state, this is a much stronger property than ergodicity and even complete ergodicity: not only the decomposition into periodic states is impossible, but any decomposition whatsoever. Nevertheless, this is what one expects from a ground state of translationally invariant interaction.

From the formula [5] it is clear that if we decompose the $\mathbb{E}$-operator entering for a site $x$ into a sum two completely positive terms, we will have decomposed $\omega$ into two positive terms. These might still be equal, but it is certainly suggestive to look at states generated with an $\mathbb{E}$, which cannot be decomposed nontrivially into a sum of other

completely positive maps. Such maps are called pure, and are characterized by the form

$$\mathbb{E}(A \otimes B) = V^*(A \otimes B)V \\ V : \mathbb{C}^k \to \mathbb{C}^d \otimes \mathbb{C}^k \text{ is isometric} \qquad [8]$$

and $\mathcal{A}$ and $\mathcal{B}$ are the algebras of $d \times d$ and $k \times k$ matrices, respectively. Finitely correlated states generated from such a pure evolution operator are called purely generated. These are the candidates for pure finitely generated states.

The form of a pure map is reminiscent of the Stinespring dilation of a general completely positive map: for a general $\mathbb{E}$, we can set

$$\mathbb{E}(A \otimes B) = V^*(\mathbb{1}_{\widetilde{\mathcal{A}}} \otimes A \otimes B)V \qquad [9]$$

where $\widetilde{\mathcal{A}}$ is some auxiliary matrix algebra. Since the invariance condition for $\eta$ does not involve the $\mathcal{A}$ algebras, we get a purely generated state $\widetilde{\omega}$ with one-site algebra $(\widetilde{\mathcal{A}} \otimes \mathcal{A})$, whose restriction to the original chain is $\omega$. Hence, purely generated states are the prototypes from which all other finitely correlated are obtained by sitewise restriction.

But are such states pure? Since $\widehat{\mathbb{E}}$ need not have a trivial peripheral spectrum, the previous section tells us that a purely generated state may have a nontrivial decomposition into other, perhaps periodic states. But this is the only restriction we have to make. Indeed, the following statements about a finitely correlated state $\omega$ are equivalent (Fannes *et al.* 1994, theorem 1.5):

- $\omega$ is pure;
- $\omega$ is purely generated, and the operator $\widehat{\mathbb{E}}$ has trivial peripheral spectrum;
- the mean entropy of $\omega$ vanishes, and $\omega$ is clustering, that is, [7] holds; and
- $\mathbb{E}$ has the form [8], and no subalgebra of $\mathcal{B}$, which contains $\mathbb{1}$, is invariant under all operators $\mathbb{E}_A$.

### The Asymptotic Form of the Local Support

Let us now fix an isometry $V$, such that $\widehat{\mathbb{E}}$ has trivial peripheral spectrum, and let $\rho$ denote the unique invariant state of $\widehat{\mathbb{E}}$. Then the vectors $\Psi \in \mathcal{H}^{\otimes n}$ in the support of $\omega$ are of the form [2] and depend, apart from the fixed choice of the $V_x^\mu \equiv V^\mu$, on the boundary indices $j_0, j_n = 1, \ldots, k$. We can consider this as a map $\Gamma_n$ from $k \times k$ matrices to $\mathcal{H}^{\otimes n}$:

$$\langle \mu_1, \ldots, \mu_n \,|\, \Gamma_n(B) \rangle = \mathrm{tr}(B V^{\mu_1} V^{\mu_2} \cdots V^{\mu_n}) \qquad [10]$$

and denote the range of $\Gamma_n$ by $\mathcal{G}_n$. Then $\mathcal{G}_n$ is at most $k^2$-dimensional. Moreover, this family of subspaces is nested, that is, $\mathcal{G}_{n+m} \subseteq \mathcal{G}_n \otimes \mathcal{H}^{\otimes n}$ and $\mathcal{G}_{n+m} \subset \mathcal{H}^{\otimes m} \otimes \mathcal{G}_m$. Using that $\widehat{\mathbb{E}}(B)^n \to \rho(B)\mathbb{1}$ converges exponentially fast, we also find that $\Gamma_n$ is asymptotically an isometry between $\mathcal{G}_n$, and the Hilbert space of $k \times k$ matrices with scalar product $\langle B, C \rangle_\rho = \mathrm{tr}(\rho B^* C)$. Hence, all the spaces $\mathcal{G}_n$ are asymptotically identified, even though they are contained in each other. This "self-similarity" is the source of many further properties. For example, for any density matrix $\widetilde{\rho}$ on $\ell + m + r$ sites supported by $\mathcal{G}_{\ell+m+r}$, and any observable $A$, localized on $m$ sites in the middle of this interval (with $\ell$ to the left and $r$ to the right), we get the expectation $\mathrm{tr}(\widetilde{\rho}A) \approx \omega(A)$, up to exponentially small terms depending only on $\ell$ and $r$.

### Ground States and Gaps

Suppose we fix some interval length $\ell$, and let $h$ be the projection onto the complement of $\mathcal{G}_\ell$ in $\mathcal{H}^{\otimes \ell}$. We now consider $h$ as the interaction term of a lattice interaction, that is, we consider the formal Hamiltonian

$$H = \sum_x \tau_x(h) \qquad [11]$$

Then in the finitely correlated state $\omega$, each term in this sum has expectation zero, which is the absolute minimum for such expectations, because $h \geq 0$. In this sense $\omega$ is the ground state for this Hamiltonian. Usually, ground states are not characterized in this way: one can only require that the average energy is minimized with respect to all translationally invariant states (Bratteli and Robinson 1987, 1997, theorem 6.2.58). Hence, one can usually perturb a ground state locally such that some terms in [11] have less than average expectation, at the expense of others. For $\omega$ this is clearly impossible. Moreover, any state $\omega'$ with $\omega'(\tau_x(h)) = 0$ for all $x$ must coincide with $\omega$, even if we do not impose translation invariance. This follows from the previous section: the local density operators of $\omega'$ must all be supported in $\mathcal{G}_n$ by the nesting property; hence, if we compare density operators on intervals of length $\ell + m + r$ on observables localized on the middle $m$ sites, we get $\omega'(A) \approx \omega(A)$, up to errors exponentially small in $\ell$ and $r$.

The Hamiltonian [11] involves an infinite sum, which can be mathematically understood as a quadratic form in the GNS-representation associated with $\omega$ (Bratteli and Robinson 1987, 1997). This is the Hilbert space spanned by vectors written as $A\Omega$, with the scalar products $\langle A\Omega, B\omega \rangle = \omega(A^*B)$, for local operators $A, B$. The ground-state property then implies $H\Omega = 0$, and $H \geq 0$, because $h \geq 0$. It can be seen that $H$ generates a well-defined dynamics, and is essentially self-adjoint on the domain of such vectors. Thus also the spectrum of $H$ is a well-defined concept. This suggests a strengthening of the

ground-state property: not only is $\Omega$ the unique eigenvector of $H$ for eigenvalue 0, but there is a gap $\gamma > 0$ between zero and the next eigenvalue. This property is of considerable interest for models in solid-state physics and statistical mechanics. It was shown for all ergodic pure finitely correlated states in (Fannes *et al.* 1992b).

## Density

### Density of Finitely Correlated Pure States

The natural topology in which to consider the approximation between states on the chain is the weak topology. A sequence $\omega_n$ converges weakly to $\omega$ if for all local $A$ the expectations converge, that is, $\omega_n(A) \to \omega(A)$.

Let us start from an arbitrary translationally invariant state $\omega$, and see how we can approximate it. First, we can split the chains into intervals of length $L$, and replace $\omega$ by the tensor product of the restrictions of $\omega$ to each of these intervals. This state is not translationally invariant, so we average it over the $L$ translations, and call the resulting state $\omega_L$. Consider a local observable $A$, whose localization region has length $R$. Then for $L - R$ out of the $L$ translates contributing to $\omega_L$ the expectation will be the same as for $\omega$, and we get

$$\omega_L(A) = \left(1 - \frac{R}{L}\right)\omega(A) + \frac{R}{L}\widetilde{\omega}(A),$$

where the error term $\widetilde{\omega}$ is again a state. Hence, $\omega_L$ converges weakly to $\omega$ as $L \to \infty$. One can show easily that $\omega_L$ is finitely correlated, with an algebra $\mathcal{B}$ essentially equal to $\mathcal{A}^{\otimes L}$. Hence, the finitely correlated states are weakly dense in the set of translationally invariant states.

We can make the approximating states purer by a very simple trick. In the previous construction we always take two intervals together, and replace the tensor product of the two restrictions by a purification, that is, by a pure state on an interval of length $2L$, whose restrictions to the two length-$L$ subintervals coincide with $\omega$. We average this over $2L$ translates, and call the result $\eta_L$. The estimates showing that $\eta_L \to \omega$ weakly are exactly the same as before. Moreover, one can show (Fannes *et al.* 1992a) that $\eta_L$ is purely generated.

Being defined as a convex combination of other states, $\eta_L$ is not pure, and the peripheral spectrum of $\widehat{\mathbb{E}}$ will contain all the $2L$th roots of unity. However, we can use that such a rich peripheral spectrum is not generic for $\widehat{\mathbb{E}}$ constructed from an isometry $V$. Therefore, if we choose an isometry $V_\varepsilon$ close to the isometry $V$ generating $\eta_L$, we obtain a purely generated state $\eta_L^\varepsilon$ with trivial peripheral spectrum. Since the expression for expectations of such states depends continuously on the generating isometry, we have that $\eta_L^\varepsilon \to \eta_L$ as $\varepsilon \to 0$. But we know from the previous section that such states are pure. Hence, the pure finitely correlated states are weakly dense in the set of all translationally invariant states (Fannes *et al.* 1992a).

This has implications for the geometry of the compact convex set of translationally invariant states, which are rather counter-intuitive for the intuitions trained on finite-dimensional convex bodies. To begin with, the extreme points (the ergodic states) are dense in the whole body. This is not such a rare occurrence in infinite-dimensional convex sets, and is shared, for example, by the set of operators $F$ with $0 \le F \le \mathbb{1}$ on an infinite-dimensional Hilbert space (Davies 1976). Together with the property that the translationally invariant states form a simplex, it actually fixes the structure of this compact convex set to be the so-called Poulsen simplex. This was known also without looking at finitely correlated states. The rather surprising result of the above density argument is that even the small subclass of states which are extremal, not only in the translationally invariant subset but even in the whole state space, is still dense.

### Finitely Correlated Pure States with Bounded Memory Dimension

It is clear in the above construction that the dimension of the algebra $\mathcal{B}$ goes to infinity for an approximating sequence. How many states can we get with a fixed memory algebra $\mathcal{B}$? The dimension of this manifold can be estimated easily from the number of parameters needed to describe the map $\mathbb{E}$, and this dimension is certainly small compared to the dimension of the state space of the length $L$ piece of the chain as $L \to \infty$. However, since this is an infinite set, and not a linear subspace, we do not get an immediate bound on the dimension of the linear span of these states. What we want to show in this section is that the space of finitely correlated states with fixed $\mathcal{B}$ nevertheless generates a low-dimensional subspace of states on any large interval of the chain. To this end we will have to exhibit many observables $A$, localized on $L$ sites, whose expectation is the same for all finitely correlated states with given $\mathcal{B}$.

Let us look first at the case of purely generated states, or rather at the vectors $\Psi \in \mathcal{H}^{\otimes L}$, which can be written in the form [2], which in the translation invariant case becomes

$$\langle \mu_1, \ldots, \mu_L \mid \Psi \rangle = \langle j_0 | V^{\mu_1} V^{\mu_2} \cdots V^{\mu_L} | j_L \rangle \qquad [12]$$

for some collection $V^1, \ldots, V^d$ of $k \times k$ matrices, and some basis labels $j_0, j_L \in \{1, \ldots, k\}$. The span of all such vectors will be denoted by $\mathcal{V}_L(k, d)$, and we would like to analyze the growth of dim $\mathcal{V}_L(k, d)$, as $L \to \infty$. Now a vector with components $a(\mu_1, \ldots, \mu_L)$ lies in the orthogonal complement of $\mathcal{V}_L(k, d)$ if and only if

$$\sum_{\mu_1,\ldots,\mu_L} a(\mu_1, \ldots, \mu_L) V^{\mu_1} V^{\mu_2} \cdots V^{\mu_L} = 0$$

for any collection of matrices $V^\mu$. In other words, this expression, considered as a noncommutative polynomial in $d$ variables, is a polynomial identity for $k \times k$ matrices. The simplest such identity, for $k = 2$, $d = 3, L = 5$, is $[A, [B, C]^2] = 0$. (For the proof observe that $[B, C]$ is traceless, so its square is a multiple of the identity by the Cayley–Hamilton theorem.) This identity alone implies the existence of many more identities. For example, we can substitute higher-order polynomials for $A, B, C$, and multiply the identity with arbitrary polynomial from the right or form the left. There is a well-developed theory for such identities, called the theory of polynomial identity (PI) rings. In that context, the precise growth we are looking for has been worked out (Drensky 1998):

$$\lim_{L\to\infty} \frac{\log \dim \mathcal{V}_L(k, d)}{\log L} = (d-1)k^2 + 1 \qquad [13]$$

Thus, the dim $\mathcal{V}_L(k, d)$ only grows like a polynomial in $L$, of known degree, and the joint support of all purely generated finitely correlated state is exponentially small compared to $\mathcal{H}^{\otimes L}$.

We can apply the same idea to the set of all finitely correlated states with $\mathcal{B}$ equal to the $k \times k$ matrices. The joint support in this case is the full space, since the trace state on the chain, which is a product state generated with $k = 1$, already has full support. However, it is still true all but a polynomial number of expectation values of $\omega$ are already fixed by specifying $k$. Indeed, formula [5] for a general state is precisely of the form [12], with the difference that the arguments $A$ replace $\mu$, and the matrices $\mathbb{E}_A$ are now operators on the $k^2$-dimensional space $\mathcal{B}$. If we only want an upper bound, we can ignore subtlatties coming from Hermiticity and normalization constraints on $\mathbb{E}$, and we get that the dimension of all finitely correlated states generated from the $k \times k$ matrices, restricted to a subchain of length $L$, grows at most like $L^\alpha$, with $\alpha \leq (d^2 - 1)k^2 + 1$.

# Finite-Type Invariants

**D Bar-Natan**, University of Toronto, Toronto, ON, Canada

## Introduction

Knots belong to sailors and climbers and upon further reflection, perhaps also to geometers, topologists, or combinatorialists. Surprisingly, throughout the 1980s, it became apparent that knots are also closely related to several other branches of mathematics in general and mathematical physics in particular. Many of these connections (though not all!) factor through the notion of "finite-type invariants" (aka "Vassiliev" or "Goussarov–Vassiliev" invariants) (Goussarov 1991, 1993, Vassiliev 1990, 1992, Birman-Lin 1993, Kontsevich 1993, Bar-Natan 1995).

Let $V$ be an arbitrary invariant of oriented knots in oriented space with values in some abelian group $A$. Extend $V$ to be an invariant of 1-singular knots, knots that may have a single singularity that locally looks like a double point $\times$, using the formula

$$V(\times) = V(\overcrossing) - V(\undercrossing) \qquad [1]$$

Further extend $V$ to the set $\mathcal{K}^m$ of $m$-singular knots (knots with $m$ double points) by repeatedly using [1].

**Definition 1** We say that $V$ is of type $m$ if its extension $V|_{\mathcal{K}^{m+1}}$ to $(m+1)$-singular knots vanishes identically. We also say that $V$ is of finite type if it is of type $m$ for some $m$.

Repeated differences are similar to repeated derivatives; hence, it is fair to think of the definition of $V|_{\mathcal{K}^m}$ as repeated differentiation. With this in mind, the above definition imitates the definition of polynomials of degree $m$. Hence, finite-type invariants can be considered as "polynomials" on the space of knots.

As described in the section "Basic facts", finite-type invariants are plenty and powerful and they carry a rich algebraic structure and are deeply related to Lie algebras. There are several constructions for a "universal finite-type invariant" and those are related to conformal field theory, the Chern–Simons–Witten topological quantum field theory, and Drinfel'd's theory of associators and quasi-Hopf algebras (see the section "The proofs of the fundamental theorem"). Finite-type invariants have been studied extensively (see the section "Some further directions") and generalized in several directions (see the section "Beyond knots"). But the first question on finite-type invariants remains unanswered:

**Problem 2** *Honest polynomials are dense in the space of functions. Are finite-type invariants dense within the space of all knot invariants? Do they separate knots?*

In a similar way, one may define finite-type invariants of framed knots (and ask the same questions).

## Basic Facts

### Classical Knot Polynomials

The first (nontrivial!) thing to notice is that there are plenty of finite-type invariants and they are at least as powerful as all the standard knot polynomials combined (finite-type invariants are like polynomials on the space of knots; the standard phrase "knot polynomials" refers to a different thing – knot invariants with polynomial values):

**Theorem 3** (Bar-Natan 1995, Birman-Lin 1993). *Let $J(K)(q)$ be the Jones polynomial of a knot $K$ (it is a Laurent polynomial in a variable $q$). Consider the power series expansion $J(K)(e^x) = \sum_{m=0}^{\infty} V_m(K)x^m$. Then each coefficient $V_m(K)$ is a finite-type knot invariant (thus, the Jones polynomial can be reconstructed from finite-type information).*

A similar theorem holds for the Alexander–Conway, HOMFLY-PT, and Kauffman polynomials (Bar-Natan 1995), and indeed, for arbitrary Reshetikhin–Turaev invariants (Reshetikhin and Turaev 1990, Lin 1991), although it is still unknown if the signature of a knot can be expressed in terms of its finite-type invariants.

### Chord Diagrams and the Fundamental Theorem

The top derivatives of a multivariable polynomial form a system of constants which determine the polynomial up to polynomials of lower degree. Likewise the $m$th derivative $V^{(m)} := V(\times \overset{m}{\cdots} \times)$ of a type $m$ invariant $V$ is a constant (for $V(\times \overset{m}{\cdots} \overcrossing\times) - V(\times \overset{m}{\cdots} \undercrossing\times) = V(\times \overset{m+1}{\cdots} \times) = 0$ so $V^{(m)}$ is blind to 3D topology), and likewise $V^{(m)}$ determines $V$ up to invariants of lower type. Hence, a primary tool in the study of finite-type invariants is the study of the "top derivative" $V^{(m)}$, also known as "the weight system of $V$."

Blind to 3D topology, $V^{(m)}$ only sees the combinatorics of the circle that parametrizes an $m$-singular knot. On this circle, there are $m$ pairs of points that are pairwise identified in the image; one indicates those by drawing a circle with $m$ chords marked (an "$m$-chord diagram") (see Figure 1).

**Definition 4** Let $\mathcal{D}_m$ denote the space of all formal linear combinations with rational coefficients of $m$-chord diagrams. Let $\mathcal{A}_m^r$ be the quotient of $\mathcal{D}_m$ by all $4T$ and $FI$ relations as drawn in Figure 2 (full details are given in, e.g., Bar-Natan (1995)), and let $\hat{\mathcal{A}}^r$ be the graded completion of $\mathcal{A} := \bigoplus_m \mathcal{A}_m^r$. Let $\mathcal{A}_m, \mathcal{A}$, and $\hat{\mathcal{A}}$ be the same as $\mathcal{A}_m^r, \mathcal{A}^r$, and $\hat{\mathcal{A}}^r$ but without imposing the $FI$ relations.

**Theorem 5** (The fundamental theorem)

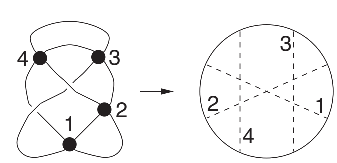

**Figure 1** A 4-singular knot and its corresponding chord diagram.

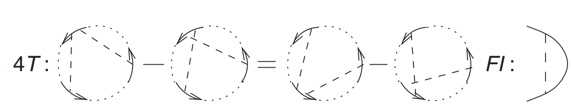

**Figure 2** The 4T and FI relations.

- (*Easy part*). *If V is a rational valued type m-invariant then* $V^{(m)}$ *defines a linear functional on* $\mathcal{A}^r_m$. *If in addition* $V^{(m)} \equiv 0$, *then V is of type* $m-1$.
- (*Hard part*). *For any linear functional W on* $\mathcal{A}^r_m$, *there is a rational valued type m invariant V so that* $V^{(m)} = W$.

Thus, to a large extent, the study of finite-type invariants is reduced to the finite (though super-exponential in $m$) algebraic study of $\mathcal{A}^r_m$. A similar theorem reduces the study of finite-type invariants of framed knots to the study of $\mathcal{A}_m$.

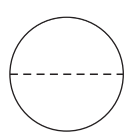
### The Structure of $\mathcal{A}$

Knots can be multiplied (the "connected sum" operation) and knot invariants can be multiplied. This structure interacts well with finite-type invariants and induces the following structure on $\mathcal{A}^r$ and $\mathcal{A}$:

**Theorem 6** (Kontsevich 1993, Bar-Natan 1995, Willerton 1996, Chmutov *et al.* 1994). $\mathcal{A}^r$ *and* $\mathcal{A}$ *are commutative and cocommutative graded bialgebras* (*i.e.*, *each carries a commutative product and a compatible cocommutative coproduct*). *Thus*, *both* $\mathcal{A}^r$ *and* $\mathcal{A}$ *are graded polynomial algebras over their spaces of primitives*, $\mathcal{P}^r = \oplus_m \mathcal{P}^r_m$ *and* $\mathcal{P} = \oplus_m \mathcal{P}_m$.

Framed knots differ from knots only by a single integer parameter (the "self-linking," itself a type 1 invariant). Thus, $\mathcal{P}^r$ and $\mathcal{P}$ are also closely related.

**Theorem 7** (Bar-Natan 1995). $\mathcal{P} = \mathcal{P}^r \oplus \langle \theta \rangle$, *where* $\theta$ *is the unique 1-chord diagram*:



### Bounds and Computational Results

Table 1 shows the number of type $m$-invariants of knots and framed knots modulo type $m-1$ invariants ($\dim \mathcal{A}^r_m$ and $\dim \mathcal{A}_m$) and the number of multiplicative generators of the algebra $\mathcal{A}$ in degree $m$ ($\dim \mathcal{P}_m$) for $m \le 12$. Some further tabulated results are in Bar-Natan (1996).

Little is known about these dimensions for large $m$. There is an explicit conjecture in Broadhurst (1997), but no progress has been made in the direction of proving or disproving it. The best asymptotic bounds available are the following.

**Theorem 8** *For large m*, $\dim \mathcal{P}_m > e^{c\sqrt{m}}$ (*for any fixed* $c < \pi\sqrt{2/3}$) *and* $\dim \mathcal{A}_m < 6^m m! \sqrt{m}/\pi^{2m}$ (Stoimenow 1998, Zagier 2001).

### Jacobi Diagrams and the Relation with Lie Algebras

Much of the richness of finite-type invariants stems from their relationship with Lie algebras. Theorem 9 below suggests this relationship on an abstract level, Theorem 10 makes that relationship concrete, and Theorem 12 makes it a bit deeper.

**Theorem 9** (Bar-Natan 1995). *The algebra* $\mathcal{A}$ *is isomorphic to the algebra* $\mathcal{A}^t$ *generated by "Jacobi diagrams in a circle"* (*chord diagrams that are also allowed to have oriented internal trivalent vertices*) *modulo the AS, STU, and IHX relations* (see Figure 3).

Thinking of trivalent vertices as graphical analogs of the Lie bracket, the AS relation becomes the anti-commutativity of the bracket, STU becomes the equation $[x, y] = xy - yx$, and IHX becomes the Jacobi identity. This analogy is made concrete within the proof of the following:

**Theorem 10** (Bar-Natan 1995). *Given a finite-dimensional metrized Lie algebra* $\mathfrak{g}$ (*e.g.*, *any semi-simple Lie algebra*), *there is a map* $\mathcal{T}_{\mathfrak{g}} : \mathcal{A} \to \mathcal{U}(\mathfrak{g})^{\mathfrak{g}}$ *defined on* $\mathcal{A}$ *and taking values in the invariant part* $\mathcal{U}(\mathfrak{g})^{\mathfrak{g}}$ *of the universal enveloping algebra* $\mathcal{U}(\mathfrak{g})$ *of* $\mathfrak{g}$. *Given also a finite-dimensional representation R of* $\mathfrak{g}$ *there is a linear functional* $W_{\mathfrak{g},R} : \mathcal{A} \to \mathbb{Q}$.

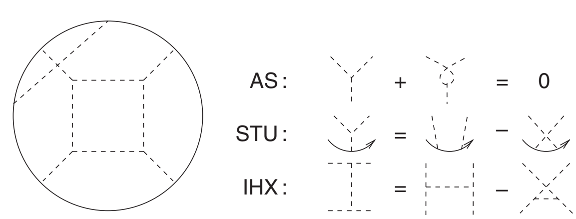


**Figure 3** A Jacobi diagram in a circle and the AS, STU, and IHX relations.

**Table 1** Some dimensions of spaces of finite type invariants

| $m$ | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $\dim \mathcal{A}^r_m$ | 1 | 0 | 1 | 1 | 3 | 4 | 9 | 14 | 27 | 44 | 80 | 132 | 232 |
| $\dim \mathcal{A}_m$ | 1 | 1 | 2 | 3 | 6 | 10 | 19 | 33 | 60 | 104 | 184 | 316 | 548 |
| $\dim \mathcal{P}_m$ | 0 | 1 | 1 | 1 | 2 | 3 | 5 | 8 | 12 | 18 | 27 | 39 | 55 |

Source: Bar-Natan (1995); Kneissler (1997).

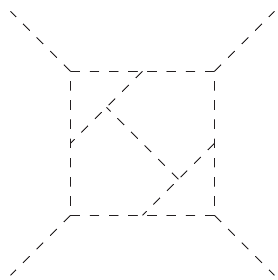

**Figure 4** A free Jacobi diagram.

The last assertion along with Theorem 5 show that associated with any $\mathfrak{g}$, $R$, and $m$, there is a weight system and hence a knot invariant. Thus, knots are unexpectedly linked with Lie algebras.

The hope (Bar-Natan 1995) that all finite-type invariants arise in this way was dashed by Vogel (1997, 1999) and Lieberum (1999). But finite-type invariants that do not arise in this way remain rare and not well understood.

The Poincaré–Birkhoff–Witt (PBW) theorem of the theory of Lie algebras says that the obvious "symmetrization" map $\chi_{\mathfrak{g}}: \mathcal{S}(\mathfrak{g}) \to \mathcal{U}(\mathfrak{g})$ from the symmetric algebra $\mathcal{S}(\mathfrak{g})$ of a Lie algebra $\mathfrak{g}$ to its universal enveloping algebra $\mathcal{U}(\mathfrak{g})$ is a $\mathfrak{g}$-module isomorphism. The following definition and theorem form a diagrammatic counterpart of this theorem:

**Definition 11** Let $\mathcal{B}$ be the space of formal linear combinations of "free Jacobi diagrams" (Jacobi diagrams as before, but with unmarked univalent ends ("legs") replacing the circle; see an example in Figure 4), modulo the AS and IHX relations of before. Let $\chi: \mathcal{B} \to \mathcal{A}$ be the symmetrization map which maps a $k$-legged free Jacobi diagram to the average of the $k$! ways of planting these legs along a circle.

**Theorem 12** (Diagrammatic PBW; Kontsevich 1993, Bar-Natan 1995). *$\chi$ is an isomorphism of vector spaces. Furthermore, fixing a metrized $\mathfrak{g}$ there is a commutative square as in* Figure 5.

Note that $\mathcal{B}$ can be graded (by half the number of vertices in a Jacobi diagram) and that $\chi$ respects degrees so it extends to an isomorphism $\chi: \hat{\mathcal{B}} \to \hat{\mathcal{A}}$ of graded completions.

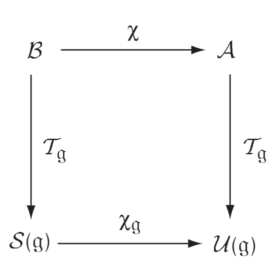

**Figure 5** The diagrammatic PBW isomorphism and its classical counterpart.

## Proofs of the Fundamental Theorem

The heart of all known proofs of Theorem 5 is always a construction of a "universal finite-type invariant" (see below); it is simple to show that the existence of a universal finite-type invariant is equivalent to Theorem 5.

**Definition 13** A universal finite-type invariant is a map $Z: \{\text{knots}\} \to \hat{\mathcal{A}}^r$ whose extension to singular knots satisfies $Z(K) = D + (\text{higher degrees})$ whenever a singular knot $K$ and a chord diagram $D$ are related as discussed before.

### The Kontsevich Integral

The first construction of a universal finite-type invariant was given by Kontsevich (1993) (see also Bar-Natan (1995) and Chmutov and Duzhin (2001)). It is known as "the Kontsevich integral" and up to a normalization factor it is given by

$$Z_1(K) = \sum_{m=0}^{\infty} \frac{1}{(2\pi i)^m} \int\!\!\!\!\!\!\sum_{\substack{t_1<\cdots<t_m \\ P=\{(z_i,z_i')\}}} (-1)^{\#P_\downarrow} D_P \bigwedge_{i=1}^{m} \frac{dz_i - dz_i'}{z_i - z_i'}$$

where the relationship between the knot $K$, the pairing $P$, the real variables $t_i$, the complex variables $z_i$ and $z_i'$, and the chord diagram $D_P$ is summarized in Figure 6 (the symbol $\int\!\!\!\!\!\!\sum$ means "sum over all discrete variables and integrate over all continuous variables.")

The Kontsevich integral arises from studying the holonomy of the Knizhnik–Zamolodchikov equation of conformal field theory (Knizhnik and Zamolodchikov 1984). When evaluating $Z_1$, one encounters multiple $\zeta$-numbers (Le-Murakami 1995) in a substantial way, and the proof that the end result is rational is quite involved (Le-Murakami 1996) and relies on deep results about associators and quasitriangular quasi-Hopf algebras (Drinfel'd 1990, 1991). Employing the same techniques, in Le-Murakami

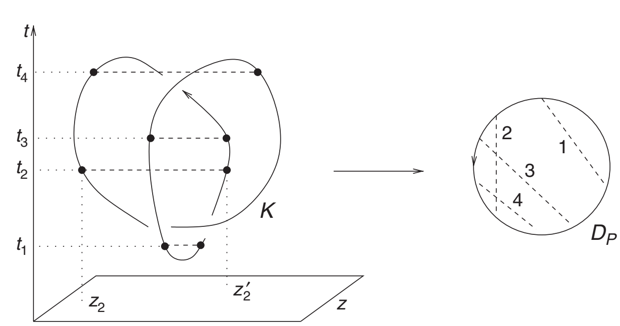

**Figure 6** The key ingredients of the Kontsevich integral.

(1996), it is also shown that the composition of $W_{\mathfrak{g},R} \circ Z_1$ precisely reproduces the Reshetikhin–Turaev invariants (Reshetikhin and Turaev 1990).

### Perturbative Chern–Simons–Witten Theory and Configuration Space Integrals

Historically, the first approach to the construction of a universal finite-type invariant was to use perturbation theory with the Chern–Simons–Witten topological quantum field theory; this is also how the relationship with Lie algebras first arose. But taming the integrals involved turned out to be difficult and working constructions using this approach appeared only a bit later.

In short, one writes a perturbative expansion for the large $k$ asymptotics of the Chern–Simons–Witten path integral for some metrized Lie algebra $\mathfrak{g}$ with a Wilson loop in some representation $R$ of $\mathfrak{g}$,

$$\int_{\mathfrak{g}\text{-connections}} \mathcal{D}A \, \mathrm{tr}_R \, \mathrm{hol}_K(A) \times \exp\left[\frac{\mathrm{i}k}{4\pi}\int_{\mathbb{R}^3} \mathrm{tr}\left(A \wedge \mathrm{d}A + \frac{2}{3} A \wedge A \wedge A\right)\right]$$

The result is of the form

$$\sum_{D:\ \text{Feynman diagram}} W_{\mathfrak{g}(D),R} \sum\!\!\!\!\!\!\int \mathcal{E}(D)$$

where $\mathcal{E}(D)$ is a very messy integral expression and the diagrams $D$ as well as the weights $W_{\mathfrak{g}(D),R}$ were already discussed before. Replacing $W_{\mathfrak{g}(D),R}$ by simply $D$ in the above formula, we get an expression with values in $\hat{\mathcal{A}}$:

$$Z_2(K) := \sum_D D \sum\!\!\!\!\!\!\int \mathcal{E}(D) \in \hat{\mathcal{A}}$$

For formal reasons $Z_2(K)$ ought to be a universal finite-type invariant, and after much work taming the $\mathcal{E}(D)$ factors and after multiplying by a further framing-dependent renormalization term $Z^{\text{anomaly}}$, the result is indeed a universal finite-type invariant.

Upon further inspection, the $\mathcal{E}(D)$ factors can be reinterpreted as integrals of certain spherical volume forms on certain (compactified) configuration spaces (Bott–Taubes 1994). These integrals can be further interpreted as counting certain "tinker toy constructions" built on top of $K$ (Thurston 1995). The latter viewpoint makes the construction of $Z_2$ visually appealing (Bar-Natan 2000), but there is no satisfactory write-up of this perspective yet.

We note that the precise form of the renormalization term $Z^{\text{anomaly}}$ remains an open problem. An appealing conjecture is that $Z^{\text{anomaly}} = \exp(1/2)\ominus$. If this is true then $Z_2 = Z_1$ (Poirier 1999); but the conjecture is only verified up to degree 6 (Lescop 2001) (there is also an unconfirmed verification to all orders (Yang 1997)).

The most important open problem about perturbative Chern–Simons–Witten theory is not directly about finite-type invariants, but it is nevertheless worthwhile to recall it here:

**Problem 14** *Does the perturbative expansion of the Chern–Simons–Witten theory converge* (*or is asymptotic to*) *the exact solution due to Witten (1989) and Reshetikhin and Turaev* (1990) *when the parameter k converges to infinity?*

### Associators and Trivalent Graphs

There is also an entirely algebraic approach for the construction of a universal finite-type invariant $Z_3$. The idea is to find some algebraic context within which knot theory is finitely presented – that is, presented by finitely many generators subject to finitely many relations. If the algebraic context at hand is compatible with the definitions of finite-type invariants and of chord diagrams, one may hope to define $Z_3$ by defining it on the generators in such a way that the relations are satisfied. Thus, the problem of defining $Z_3$ is reduced to finding finitely many elements of $\mathcal{A}$-like spaces which solve certain finitely many equations.

A concrete realization of this idea is in Le-Murakami (1996) and Bar-Natan (1997) (following ideas from Drinfel'd (1990, 1991) on quasitriangular quasi-Hopf algebras). The relevant "algebraic context" is a category with certain extra operations, and within it, knot theory is generated by just two elements, the braiding ⤫ and the re-association ⟋. Thus, to define $Z_3$ it is enough to find $R = Z_3(⤫)$ and "an associator" $\Phi = Z_3(⟋)$ which satisfy certain normalization conditions as well as the pentagon and hexagon equations:

$$\Phi^{123} \cdot (1\Delta 1)(\Phi) \cdot \Phi^{234} = (\Delta 11)(\Phi) \cdot (11\Delta)(\Phi)$$

$$(\Delta 1)(R^{\pm}) = \Phi^{123}(R^{\pm})^{23}(\Phi^{-1})^{132}(R^{\pm})^{13}\Phi^{312}$$

As it turns out, the solution for $R$ is easy and nearly canonical. But finding an associator $\Phi$ is rather difficult. There is a closed-form integral expression $\Phi^{KZ}$ due to Drinfel'd (1990) but one encounters the same not-too-well-understood multiple $\zeta$ numbers. There is a rather complicated iterative procedure for finding an associator (Drienfel'd 1991, Bar-Natan 1998). On a computer it had been used to find an associator up to degree 7. There is also closed-form associator that works only with the Lie superalgebra gl(1|1) (Lieberum 2002). But it remains an open

problem to find a closed-form formula for a rational associator (existence by Drienfel'd (1991) and Bar- Natan (1998)).

On the positive side, we should note that the end result, the invariant $Z_3$, is independent of the choice of $\Phi$ and that $Z_3 = Z_1$.

There is an alternative (more symmetric and intrinsically three dimensional, but less well-documented) description of the theory of associators in terms of knotted trivalent graphs (Bar-Natan and Thurston). There ought to be a perturbative invariant associated with knotted trivalent graphs in the spirit of the last subsection and such an invariant should lead to a simple proof that $Z_2 = Z_3 = Z_1$. But the $\mathcal{E}(D)$ factors remain untamed in this case.

#### Step-by-Step Integration

The last approach for proving the fundamental theorem is the most natural and historically the first. But here it is last because it is yet to lead to an actual proof. A weight system $W : \mathcal{A}^r_m \to \mathbb{Q}$ is an invariant of $m$-singular knots. We want to show that it is the $m$th derivative of an invariant $V$ of nonsingular knots. It is natural to try to integrate $W$ step by step, first finding an invariant $V^{m-1}$ of $(m-1)$-singular knots whose derivative in the sense of [1] is $W$, then an invariant $V^{m-2}$ of $(m-2)$-singular knots whose derivative is $V^{m-1}$, and so on all the way up to an invariant $V^0 = V$ whose $m$th derivative will then be $W$. If proven, the following conjecture would imply that such an inductive procedure can be made to work:

**Conjecture 15** (*Hutchings 1998*). *If $V^r$ is a once-integrable invariant of $r$-singular knots, then it is also twice integrable. That is, if there is an invariant $V^{r-1}$ of $(r-1)$-singular knots whose derivative is $V^r$, then there is an invariant $V^{r-2}$ of $(r-2)$-singular knots whose second derivative is $V^r$.*

Hutchings (1998) reduced this conjecture to a certain appealing topological statement and further to a certain combinatorial-algebraic statement about the vanishing of a certain homology group $H^1$ which is probably related to Kontsevich's graph homology complex (Kontsevich 1994) (Kontsevich's $H^0$ is $\mathcal{A}$, so this is all in the spirit of many deformation theory problems where $H^0$ enumerates infinitesimal deformations and $H^1$ is the obstruction to globalization). Hutchings (1998) was also able to prove the vanishing of $H^1$ (and hence reprove the fundamental theorem) in the simpler case of braids. But no further progress has been made along these lines since then.

## Some Further Directions

We would like to touch upon a number of significant further directions in the theory of finite-type invariants and describe each of those only briefly; the reader is referred to the "Further reading" section for more information.

#### The Original "Vassiliev" Perspective

V A Vassiliev came to the study of finite-type knot invariants by studying the infinite-dimensional space of all immersions of a circle into $\mathbb{R}^3$ and the topology of the "discriminant," the locus of all singular immersions within the latter space (Vassiliev 1990, 1992). Vassiliev studied the topology of the complement of the discriminant (the space of embeddings) using a certain spectral sequence and found that certain terms in it correspond to finite-type invariants. This later got related to the Goodwillie calculus and back to the configuration spaces discussed in the last section. See Volic (2004).

#### Interdependent Modifications

The standard definition of finite-type invariants is based on modifying a knot by replacing over (or under) crossings with under (or over) crossings. Goussarov (1998) generalized this by allowing arbitrary modifications done to a knot – just take any segment of the knot and move it anywhere else in space. The resulting new "finite-type" theory turns out to be equivalent to the old one though with a factor of 2 applied to the grading (so an "old" type $m$ invariant is a "new" type $2m$ invariant and vice versa). (see also Bar-Natan (2001) and Conant (2003)).

#### $n$-Equivalence, Commutators, and Claspers

While little is known about the overall power of finite-type invariants, much is known about the power of type $n$-invariants for any given $n$. Goussarov (1993) defined the notion of $n$-equivalence: two knots are said to be "$n$-equivalent" if all their type $n$-invariants are the same. This equivalence relation is well understood both in terms of commutator subgroups of the pure braid group (Stanford 1998, Ng and Stanford 1999) and in terms of Habiro's calculus of surgery over "claspers" (Habiro 2000) (the latter calculus also gives a topological explanation for the appearance of Jacobi diagrams). In particular, already Goussarov (1993) shows that the set of equivalence classes of knots modulo $n$-equivalence is a finitely generated abelian group $G_n$ under the operation of connected sum, and the rank of that group is equal to the dimension of the space of type $n$-invariants.

Ng (1998) has shown that ribbon knots generate an index 2 subgroup of $G_n$.

### Polynomiality and Gauss Sums

Goussarov (1998) (see also Goussarov–Polyak–Viro (2001)) found an intriguing way to compute finite-type invariants from a Gauss diagram presentation of a knot, showing in particular that finite-type invariants grow as polynomials in the number of crossings $n$ and can be computed in polynomial time in $n$ (though actual computer programs are still missing!).

Gauss diagrams are obtained from knot diagrams in much of the same way as Chord diagrams are obtained from singular knots, except all crossings are counted and not just the double points, and certain over/under and sign information is associated with each crossing/chord so that the knot diagram can be recovered from its Gauss diagram. In the example below (**Figure 8**), we also dashed a subdiagram of the Gauss diagram equivalent to the chord diagram shown in **Figure 7**.

If $G$ is a Gauss diagram and $D$ is a chord diagram, then let $\langle D, G\rangle$ be the number of subdiagrams of $G$ equivalent to $D$, counted with appropriate signs (to be precise, we also need to base the diagrams involved and count subdiagrams that respect the basing).

**Theorem 16** (Goussarov 1998, Goussarov *et al.* 2000). *If $V$ is a type $m$ invariant, then there are finitely many (based) chord diagrams $D_i$ with at most $m$ chords and rational numbers $\alpha_i$ so that $V(K) = \sum_i \alpha_i \langle D_i, G\rangle$ whenever $G$ is a Gauss diagram representing a knot $K$.*

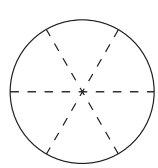

**Figure 7** A chord diagram.

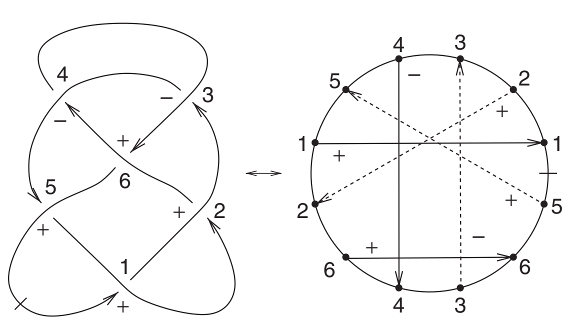

**Figure 8** A knot and its Gauss diagram.

### Computing the Kontsevich Integral

While the Kontsevich integral $Z_1$ is a cornerstone of the theory of finite-type invariants, it has been computed for surprisingly few knots. Even for the unknot, the result is nontrivial:

**Theorem 17** ("Wheels," Bar-Natan *et al.* 2000, 2003). *The framed Kontsevich integral of the unknot, $Z_1^F(\bigcirc)$, expressed in terms of diagrams in $\hat{\mathcal{B}}$, is given by $\Omega = \exp_{\cup}\sum_{n=1}^{\infty} b_{2n}\omega_{2n}$, where the "modified Bernoulli numbers" $b_{2n}$ are defined by the power series expansion $\sum_{n=0}^{\infty} b_{2n}x^{2n} = (1/2)\log(\sinh x/2)/(x/2)$, the "2n-wheel" $\omega_{2n}$ is the free Jacobi diagram made of a 2n-gon with 2n legs (so, e.g., $\omega_6 =$ ), and where* $\exp_{\cup}$ *means "exponential in the disjoint union sense."*

Closed-form formulas have also been given for the Kontsevich integral of framed unknots, the Hopf link and Hopf chains.

Theorem 17 has a companion that utilizes the same element $\Omega$, the "wheeling" theorem (Bar-Natan *et al.* 2000, 2003). The wheeling theorem "upgrades" the vector space isomorphism $\chi: \mathcal{B} \to \mathcal{A}$ to an algebra isomorphism and is related to the Duflo isomorphism of the theory of Lie algebras. It is amusing to note that the wheeling theorem (and hence Duflo's theorem in the metrized case) follows using finite-type techniques from the "$1 + 1 = 2$ on an abacus" identity (**Figure 9**).

### Taming the Kontsevich Integral

While explicit calculations are rare, there is a nice structure theorem for the values of the Kontsevich integral, saying that for a knot $K$ and up to any fixed number of loops in the Jacobi diagrams, $\chi^{-1}Z_1(K)$ can be described by finitely many rational functions (with denominators powers of the Alexander polynomial) which dictate the placement of the legs. This structure theorem was conjectured in Rozansky (2003), proven in Kricker (2000), and partially generalized to links in Garoufalidis and Kricker (2004).

### The Rozansky–Witten Theory

One way to construct linear functionals on $\mathcal{A}$ (and hence finite-type invariants) is using Lie algebras and representations as discussed earlier; much of our insight about $\mathcal{A}$ comes this way. But there is another construction for such functionals (and hence invariants), due to Rozansky and Witten (1997), using contractions of curvature tensors on hyper-Kähler

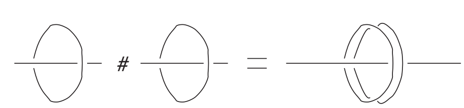

**Figure 9** A knot theoretic $1 + 1 = 2$.

manifolds. Very little is known about the Rozansky–Witten approach; in particular, it is not known if it is stronger or weaker than the Lie algebraic approach. For an application of the Rozansky–Witten theory back to hyper-Kähler geometry check Hitchin and Sawon (2001), and for a unification of the Rozansky–Witten approach with the Lie algebraic approach (albeit at a categorical level) check Roberts and Willeton (in preparation).

### The Melvin–Morton Conjecture and the Volume Conjecture

The Melvin–Morton conjecture (stated Melvin and Morton (1995), proven Bar-Natan and Garoufalidis (1996)) says that the Alexander polynomial can be read off certain coefficients of the colored Jones polynomial. The Kashaev–Murakami–Murakami volume conjecture (stated Kashaev (1997) and J Murakami and H Murakami (2001), unproven) says that a certain asymptotic growth rate of the colored Jones polynomial is the hyperbolic volume of the knot complement.

Both conjectures are not directly about finite-type invariants but both have ramifications to the theory of finite-type invariants. The Melvin–Morton conjecture was first proven using finite-type invariants and several later proofs and generalizations (see (Bar-Natan)) also involve finite-type invariants. The volume conjecture would imply, in particular, that the hyperbolic volume of a knot complement can be read from that knot's finite-type invariants, and hence finite-type invariants would be at least as strong as the volume invariant.

A particularly noteworthy result and direction for further research is Gukov's (preprint) recent unification of these two conjectures under the Chern–Simons umbrella (along with some relations to three-dimensional quantum gravity).

## Beyond Knots

For lack of space, we have restricted ourselves here to a discussion of finite-type invariants of knots. But the basic "differentiation" idea of the first section calls for generalization, and indeed it has been generalized extensively. We will only make a few quick comments.

Finite-type invariants of homotopy links (links where each component is allowed to move across itself freely) and of braids are extremely well behaved. They separate, they all come from Lie algebraic constructions and in the case of braids, step-by-step integration as discussed previously works (for homotopy links the issue was not studied).

Finite-type invariants of 3-manifolds and especially of integral and rational homology spheres have been studied extensively and the picture is nearly a complete parallel of the picture for knots. There are several competing definitions of finite-type invariants, and they all agree up to regrading. There are weight systems and they are linear functionals on a space $\mathcal{A}(\emptyset)$ which is a close cousin of $\mathcal{A}$ and $\mathcal{B}$ and is related to Lie algebras and hyper-Kähler manifolds in a similar way. There is a notion of a "universal" invariant, and there are several constructions; they all agree or are conjectured to agree, and they are related to the Chern–Simons–Witten theory.

Finite-type invariants were studied for several other types of topological objects, including knots within other manifolds, higher-dimensional knots, virtual knots, plane curves and doodles and more (see Bar-Natan).

# Finite-Type Invariants of 3-Manifolds

**T T Q Lê**, Georgia Institute of Technology, Atlanta, GA, USA

## Introduction

### Physics Background and Motivation

Suppose $G$ is a semisimple compact Lie group and $M$ a closed oriented 3-manifold. Witten (1989) defined quantum invariants by the path integral over all $G$-connections $A$:

$$Z(M, G; k) := \int \exp(\sqrt{-1}k\, \mathrm{CS}(A))\mathcal{D}A$$

where $k$ is an integer and $\mathrm{CS}(A)$ is the Chern–Simons functional,

$$\mathrm{CS}(A) = \frac{1}{4\pi}\int_M \mathrm{tr}\left(A \wedge \mathrm{d}A + \frac{2}{3}A^3\right)$$

The path integral is not mathematically rigorous. According to the stationary-phase approximation in quantum field theory, in the limit $k \to \infty$ the path integral decomposes as a sum of contributions from the flat connections:

$$Z(M, G; k) \sim \sum_{\text{flat connections } f} Z^{(f)}(M, G; k) \quad \text{as } k \to \infty$$

Each contribution is $\exp(2\pi\sqrt{-1}\,k\,\mathrm{CS}(f))$ times a power series in $1/k$. The contribution from the trivial connection is important, especially for rational homology 3-spheres, and the coefficients of the powers $(1/k)^n$, calculated using $(n+1)$-loop Feynman diagrams by quantum field theory techniques, are known as perturbative invariants.

### Mathematical Theories

A mathematically rigorous theory of quantum invariants $Z(M, G\,; k)$ was pioneered by Reshetikhin and Turaev in 1990 (see Turaev (1994)). A number-theoretical expansion of the quantum invariants into power series that should correspond to the perturbative invariants was given by Ohtsuki (in the case of $\mathrm{sl}_2$, and general simple Lie algebras by the author) in 1994. This led him to introducing finite-type invariant (FTI) theory for 3-manifolds. A universal perturbative invariant was constructed by Le–Murakami–Ohtsuki (LMO) in 1995; it is universal for both finite-type invariants and quantum invariants, at least for homology 3-spheres. Rozansky in 1996 defined perturbative invariants using Gaussian integral, very close in the spirit to the original physics point of view. Later Habiro (for $\mathrm{sl}_2$ and Habiro and the author for all simple Lie algebras) found a finer expansion of quantum invariants, known as the cyclotomic expansion, but no physics origin is known for the cyclotomic expansion. The cyclotomic expansion helps to show that the LMO invariant dominates all quantum invariants for homology 3-spheres.

The purpose of this article is to give an overview of the mathematical theory of finite-type and perturbative invariants of 3-manifolds.

### Conventions and Notations

All vector spaces are assumed to be over the ground field $\mathbb{Q}$ of rational numbers, unless otherwise stated. For a graded space $A$, let $\mathrm{Gr}_n A$ be the subspace of grading $n$ and $\mathrm{Gr}_{\leq n}A$ the subspace of grading $\leq n$. For $x \in A$, let $\mathrm{Gr}_n x$ and $\mathrm{Gr}_{\leq n}x$ be the projections of $x$ onto, respectively, $\mathrm{Gr}_n A$ and $\mathrm{Gr}_{\leq n}A$.

All 3-manifolds are supposed to be closed and oriented. A 3-manifold $M$ is an integral homology 3-sphere ($\mathbb{Z}$HS) if $H_1(M, \mathbb{Z}) = 0$; it is a rational homology 3-sphere ($\mathbb{Q}$HS) if $H_1(M, \mathbb{Q}) = 0$. For a framed link $L$ in a 3-manifold $M$ denote $M_L$ the 3-manifold obtained from $M$ by surgery along $L$ (see e.g., Turaev (1994)).

## Finite-Type Invariants

After its introduction by Ohtsuki in 1994, the theory of FTIs of 3-manifolds has been developed rapidly by many authors. Later Goussarov and Habiro independently introduced clasper calculus, or $Y$-surgery, which provides a powerful geometric technique and deep insight in the theory. $Y$-surgery, corresponding to the commutator in group theory, naturally gives rise to 3-valent graphs.

### Generality on FTIs

**Decreasing filtration** In a theory of FTIs, one considers a class of objects, and a "good" decreasing filtration $\mathcal{F}_0 \supset \mathcal{F}_1 \supset \mathcal{F}_2 \supset \cdots$ on the vector space $\mathcal{F} = \mathcal{F}_0$ spanned by these objects. An invariant of the objects with values in a vector space is of order less than or equal to $n$ if its restriction to $\mathcal{F}_{n+1}$ is 0; it is of finite type if it is of order $\le n$ for some $n$. An invariant has order $n$ if it is of order $\le n$ but not $\le n-1$. Good here means at least the space of FTI of each order is finite dimensional. It is desirable to have an algorithm of polynomial time to calculate every FTI. In addition, one wants the set of FTIs to separate the objects (completeness).

The space of invariants of order $\le n$ can be identified with the dual space of $\mathcal{F}_0/\mathcal{F}_{n+1}$; its subspace $\mathcal{F}_n/\mathcal{F}_{n+1}$ is isomorphic to the space of invariants of order $\le n$ modulo the space of invariants of order $\le n-1$. Informally, one can say that $\mathcal{F}_n/\mathcal{F}_{n+1}$ is more or less the set of invariants of order $n$.

**Elementary moves, the knot case** Usually the filtrations are defined using "independent elementary moves." For the class of knots the elementary move is given by crossing change. Any two knots can be connected by a finite sequence of such moves. The idea is if $K, K' \in \mathcal{F}_n$, the $n$th term of the filtration, then $K - K' \in \mathcal{F}_{n+1}$, where $K'$ is obtained from $K$ by an elementary move. Formal definition is as follows. Suppose $S$ is a set of double points of a knot diagram $D$. Let

$$[D, S] = \sum_{S' \subset S} (-1)^{\#S'} D_{S'}$$

where the sum is over all subsets $S'$ of $S$, including the empty set, $D_{S'}$ is the knot obtained by changing the crossing at every point in $S'$, and $\#S'$ is the number of elements of $S'$. Then $\mathcal{F}_n$ is the vector space spanned by all elements of the form $[D, S]$ with $\#S = n$. For the knot case, the Kontsevich integral is an invariant that is universal for all FTIs (see Bar-Natan (1995)).

### Ohtsuki's Definition of FTIs for $\mathbb{Z}$HS

An elementary move here is a surgery along a knot: $M \to M_K$, where $K$ is a framed knot in a $\mathbb{Z}$HS $M$. A collection of moves corresponds to surgery on a framed link. To always remain in the class of $\mathbb{Z}$HS we need to restrict ourselves to unit-framed and algebraically split links, that is, framed links in $\mathbb{Z}$HS each component of which has framing $\pm 1$ and the linking number of every two components is 0. It is easy to prove that a link $L$ in a $\mathbb{Z}$HS $M$ is unit-framed and algebraically split if and only if $M_{L'}$ is a $\mathbb{Z}$HS for every sublink $L'$ of $L$. For a unit-framed, algebraically split link $L$ in a $\mathbb{Z}$HS $M$ define

$$[M, L] = \sum_{L' \subset L} (-1)^{|\#L'|} M_{L'}$$

which is an element in the vector space $\mathcal{M}$ freely spanned by $\mathbb{Z}$HS.

For a non-negative integer $n$ let $\mathcal{F}_n^{\mathrm{AS}}$ be the subspace of $\mathcal{M}$ spanned by $[M, L]$ with $\#L = n$. Then the descending filtration $\mathcal{M} = \mathcal{F}_0^{\mathrm{AS}} \supset \mathcal{F}_1^{\mathrm{AS}} \supset \mathcal{F}_2^{\mathrm{AS}} \supset \cdots$ defines a theory of FTIs on the class of $\mathbb{Z}$HS.

**Theorem 1**

(i) (Ohtsuki) *The dimension of* $\mathcal{F}_n(\mathcal{M})$ *is finite for every* $n$.
(ii) (Garoufalidis–Ohtsuki) *One has* $\mathcal{F}_{3n+1}(\mathcal{M}) = \mathcal{F}_{3n+2}(\mathcal{M}) = \mathcal{F}_{3n+3}(\mathcal{M})$.

The orders of FTIs in this theory are multiples of 3. The first nontrivial invariant, which is the only (up to scalar) invariant of degree 3, is the Casson invariant.

### The Goussarov–Habiro Definition

**$Y$-surgery or clasper surgery** Consider the standard $Y$-graph $Y$ and a small neighborhood $N(Y)$ of it in the standard $\mathbb{R}^2$ (see Figure 1). Denote by $L(Y)$ the six-component framed link diagram in $N(Y) \subset \mathbb{R}^3$, each component of which has framing 0 in $\mathbb{R}^3$ (see Figure 1).

A framed $Y$-graph $C$ in a 3-manifold $M$ is the image of an embedding of $N(Y)$ into $M$. The surgery of $M$ along the image of the six-component link $L(Y)$ is called a $Y$-surgery along $C$, denoted by $M_C$. If one of the leaves bounds a disk in $M$ whose interior is disjoint from the graph, then $M_C$ is homeomorphic to $M$.

Matveev in 1987 proved that two 3-manifolds $M$ and $M'$ are related by a finite sequence of $Y$-surgeries if and only if there is an isomorphism from $H_1(M, \mathbb{Z})$ onto $H_1(M', \mathbb{Z})$ preserving the

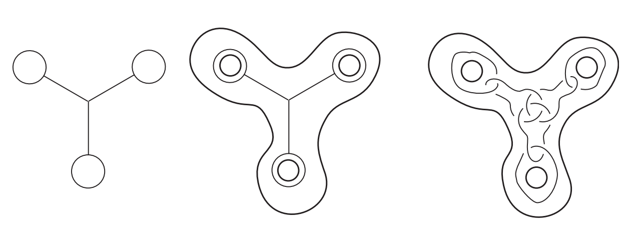

**Figure 1** Y-graph.

linking form on the torsion group. It is natural to partition the class of 3-manifolds into subclasses of the same $H_1$ and the same linking form.

**Goussarov–Habiro filtrations** For a 3-manifold $M$ denote by $\mathcal{M}(M)$ the vector space spanned by all 3-manifolds with $H_1$ and linking form the same as those of $M$. Define, for a set $S$ of $Y$-graphs in $M$, $[M,S] = \sum_{S' \subset S} (-1)^{\#S'} M_{S'}$, and $\mathcal{F}_n^Y \mathcal{M}(M)$ the vector space spanned by all $[N,S]$ such that $N$ is in $\mathcal{M}(M)$ and $\#S = n$. The following theorem of Goussarov and Habiro (Goussarov 1999, Garoufalidis *et al.* 2001, Habiro 2000) shows that the FTI theory based on $Y$-surgery is the same as the one of Ohtsuki in the case of $\mathbb{Z}$HS.

**Theorem 2** *For the case* $\mathcal{M} = \mathcal{M}(S^3)$, *one has* $\mathcal{F}_{2n-1}^Y = \mathcal{F}_{2n}^Y = \mathcal{F}_{3n}^{AS}$.

### The Fundamental Theorem of FTIs of $\mathbb{Z}$HS

**Jacobi diagrams** A closed Jacobi diagram is a vertex-oriented trivalent graph, that is, a graph for which the degree of each vertex is equal to 3 and a cyclic order of the three half-edges at every vertex is fixed. Here, multiple edges and self-loops are allowed. In pictures, the orientation at a vertex is the clockwise orientation, unless otherwise stated. The "degree" of Jacobi diagram is half the number of its vertices.

Let $\mathrm{Gr}_n\mathcal{A}(\emptyset), n \geq 0$, be the vector space spanned by all closed Jacobi diagrams of degree $n$, modulo the antisymmetry (AS) and Jacobi (IHX) relations (see Figure 2).

**The universal weight map $W$** Suppose $D$ is a closed Jacobi diagram of degree $n$. Embedding $D$ into $\mathbb{R}^3 \subset S^3$ arbitrarily and then projecting down onto $\mathbb{R}^2$ in general position, one can describe $D$ by a diagram, with over/under-crossing information at every double point just as in the case of a link diagram. We can assume that the orientation at every vertex of $D$ is given by a clockwise cyclic order. From the image of $D$, construct a set $G$ of $2n$ $Y$-graphs as in

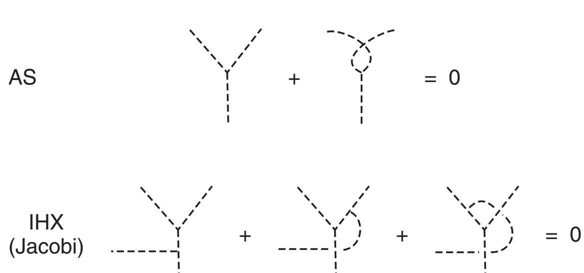

**Figure 2** The AS and IHX relations.

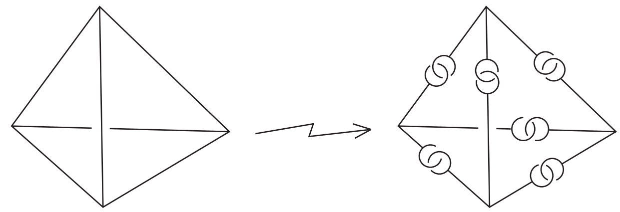

**Figure 3** The weight map.

Figure 3. Here only the cores of a $Y$-graph are drawn, with the convention that each framed $Y$-graph is a small neighborhood of its core in $\mathbb{R}^2$.

If $G'$ is a proper subset of $G$, then in $G'$ there is a $Y$-graph, one of the leaves of which bounds a disk, hence $S^3_{G'} = S^3$. Thus, $W(D) := [S^3, G] = S^3_G - S^3$. By definition, $W(D) \in \mathcal{F}_{2n}^Y$; it might depend on the embedding of $D$ into $\mathbb{R}^3$, but one can show that $W(D)$ is well defined in $\mathcal{F}_{2n}^Y/\mathcal{F}_{2n+1}^Y$. The map $W$ was first constructed by Garoufalidis and Ohtsuki in the framework of $\mathcal{F}^{AS}$.

#### Fundamental theorem

**Theorem 3** (Lê *et al.* 1998, Lê 1997). *The map $W$ descends to a well-defined linear map* $W : \mathrm{Gr}_n\mathcal{A}(\emptyset) \to \mathcal{F}_{2n}^Y/\mathcal{F}_{2n+1}^Y$ *and moreover, is an isomorphism between the vector spaces* $\mathrm{Gr}_n\mathcal{A}(\emptyset)$ *and* $\mathcal{F}_{2n}^Y/\mathcal{F}_{2n+1}^Y$, *for* $\mathcal{M} = \mathcal{M}(S^3)$.

The theorem essentially says that the set of invariants of degree $2n$ is dual to the space of closed Jacobi diagram $\mathrm{Gr}_n\mathcal{A}(\emptyset)$. The proof is based on the LMO invariant (see the next section).

A $\mathbb{Q}$-valued invariant $I$ of order $\leq 2n$ restricts to a linear map from $\mathcal{F}_{2n}/\mathcal{F}_{2n+1}$ to $\mathbb{Q}$. The composition of $I$ and $W$ is a functional on $\mathrm{Gr}_n\mathcal{A}(\emptyset)$ called the "weight system" of $I$. The theorem shows that every linear functional on $\mathrm{Gr}_{\leq n}\mathcal{A}(\emptyset)$ is the weight of an invariant of order $\leq 2n$.

**Relation to knot invariants** Under the map that sends an (unframed) knot $K \subset S^3$ to the $\mathbb{Z}$HS obtained by surgery along $K$ with framing 1, an invariant of degree $\leq 2n$ (in the $\mathcal{F}^Y$ theory) of $\mathbb{Z}$HS pulls back to an invariant of order $\leq 2n$ of knots. This was conjectured by Garoufalidis and proved by Habegger.

**Other classes of rational homology 3-spheres** Actually, the theorem was first proved in the framework of $\mathcal{F}^{AS}$. Clasper surgery theory allows Habiro (2000) to generalize the fundamental theorem to $\mathbb{Q}$HS: for $M$ a $\mathbb{Q}$HS, the universal weight map $W : \mathrm{Gr}_n \mathcal{A}(\emptyset) \to \mathcal{F}_{2n}\mathcal{M}(M)/\mathcal{F}_{2n+1}\mathcal{M}(M)$, defined similarly as

in the case of $\mathbb{Z}$HS, is an isomorphism, and $\mathcal{F}_{2n-1}\mathcal{M}(M) = \mathcal{F}_{2n}\mathcal{M}(M)$.

**Other filtrations and approaches** Other equivalent filtrations were introduced (and compared) by Garoufalidis, Garoufalidis and Levine (1997), and Garoufalidis–Goussarov–Polyak (2001). Of importance is the one using subgroups of mapping class groups in Garoufalidis and Levine (1997). A theory of $n$-equivalence was constructed by Goussarov and Habiro that encompasses many geometric aspects of FTIs of 3-manifolds (Habiro 2000, Goussarov 1999). Cochran and Melvin (2000) extended the original Ohtsuki definition to manifolds with homology, using algebraically split links, but the filtrations are different from those of Goussarov–Habiro.

## The Le–Murakami–Ohtsuki Invariant

### Jacobi Diagrams

An open Jacobi diagram is a vertex-oriented uni–trivalent graph, that is, a graph with univalent and trivalent vertices together with a cyclic ordering of the edges incident to the trivalent vertices. A univalent vertex is also called "a leg." The degree of an open Jacobi diagram is half the number of vertices (trivalent and univalent). A Jacobi diagram based on $X$, a compact oriented 1-manifold, is a graph $D$ together with a decomposition $D = X \cup \Gamma$, such that $D$ is the result of gluing all the legs of an open Jacobi diagram $\Gamma$ to distinct interior points of $X$. The degree of $D$, by definition, is the degree of $\Gamma$. In Figure 4 $X$ is depicted by bold lines. Let $\mathcal{A}^f(X)$ be the space of Jacobi diagrams based on $X$ modulo the usual antisymmetry, Jacobi and the new STU relations. The completion of $\mathcal{A}^f(X)$ with respect to degree is denoted by $\mathcal{A}(X)$.

When $X$ is a set of $m$-ordered oriented intervals, denote $\mathcal{A}(X)$ by $\mathcal{P}_m$, which has a natural algebra structure where the product $DD'$ of two Jacobi diagrams is defined by stacking $D$ on top of $D'$ (concatenating the corresponding oriented intervals). When $X$ is a set of $m$-ordered oriented circles, denote $\mathcal{A}(X)$ by $\mathcal{A}_m$. By identifying the two endpoints of each interval, one gets a map $pr : \mathcal{P}_m \to \mathcal{A}_m$, which is an isomorphism if $m = 1$ (see Bar-Natan (1995)).

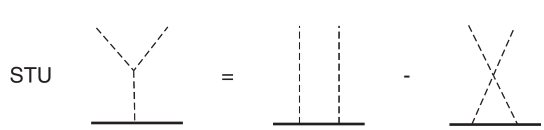

**Figure 4** The STU relation.

For $x \in \mathcal{A}_m$ and $y \in \mathcal{A}_1$, the connected sum is defined by $x\#_m y := pr((pr^{-1}x)(pr^{-1}y)^{\otimes m})$, where $(pr^{-1}y)^{\otimes m}$ is the element in $\mathcal{P}_m$ with $pr^{-1}y$ on each oriented interval.

**Symmetrization maps** Let $\mathcal{B}_m$ be the vector space spanned by open Jacobi diagrams whose legs are labeled by elements of $\{1, 2, \ldots, m\}$, modulo the antisymmetry and Jacobi relations. One can define an analog of the Poincare–Birkhoff–Witt isomorphism $\chi : \mathcal{B}_m \to \mathcal{P}_m$ as follows. For a diagram $D$, $\chi(D)$ is obtained by taking the average over all possible ways of ordering the legs labeled by $j$ and attaching them to the $j$th oriented interval. It is known that $\chi$ is a vector space isomorphism (Bar-Natan (1995)).

### The Framed Kontsevich Integral of Links

For an $m$-component framed link $L \subset \mathbb{R}^3$, the (framed version of the) Kontsevich integral $Z(L)$ is an invariant taking values in $\mathcal{A}_m$ (see, e.g., Ohtsuki (2002)). Let $\nu := Z(K)$, when $K$ is the unknot with framing 0, and $\check{Z}(L) := Z(L)\#_m\nu$. An explicit formula for $\nu$ is given in Bar-Natan *et al.* (2003).

### Removing Solid Loops: The Maps $\iota_n$

Suppose $x \in \mathcal{B}_m$ is an open Jacobi diagram with legs labeled by $\{1, \ldots, m\}$. If the number of vertices of any label is different from $2n$, or if the degree of $D > (m+1)n$, we set $\iota_n(D) = 0$. Otherwise, partitioning the $2n$ vertices of each label into $n$ pairs and identifying points in each pair, from $x$ we get a trivalent graph which may contain some isolated loops (no vertices) and which depends on the partition. Replacing each isolated loop by a factor $-2n$, and summing up over all partitions, we get $\iota_n(D) \in \mathrm{Gr}_{\leq n}\mathcal{A}(\emptyset)$.

For $x \in \mathcal{A}_m$, choose $y \in \mathcal{P}_m$ such that $pr(y) = x$. Using the isomorphism $\chi$ we pull back $\chi^{-1}y \in \mathcal{B}_m$. Define $\iota_n(x) := \iota_n(\chi^{-1}y)$. One can prove that $\iota_n(x)$ does not depend on the choice of the preimage $y$ of $x$. Note that $\iota_n$ lowers the degree by $nm$.

### Definition of the Le–Murakami–Ohtsuki Invariant $Z^{\mathrm{LMO}}$

In $\mathcal{A}(\emptyset) := \prod_{n=0}^{\infty} \mathrm{Gr}_n\mathcal{A}(\emptyset)$ let the product of two Jacobi diagrams be their disjoint union. In addition, define the coproduct $\Delta(D) = 1 \otimes D + D \otimes 1$ for $D$ a connected Jacobi diagram. Then $\mathcal{A}(\emptyset)$ is a commutative cocommutative graded Hopf algebra.

For the unknot $U_\pm$ with framing $\pm 1$, one has $\iota_n(\check{Z}(U_\pm)) = (\mp 1)^n + (\text{terms of degree} \geq 1)$; hence, their inverses exist. Suppose the linking matrix of an

oriented framed link $L \subset \mathbb{R}^3$ has $\sigma_+$ positive eigenvalues and $\sigma_-$ negative eigenvalues. Define

$$\Omega_n(L) = \frac{\iota_n(\check{Z}(L))}{(\iota_n(\check{Z}(U_+)))^{\sigma_+}(\iota_n(\check{Z}(U_-)))^{\sigma_-}} \in \mathrm{Grad}_{\leq n}(\mathcal{A}(\emptyset)) \qquad [1]$$

**Theorem 4** (Lê *et al.* 1998). *$\Omega_n(L)$ is an invariant of the 3-manifold $M = S^3_L$.*

We can combine all the $\Omega_n$ to get a better invariant:

$$Z^{\mathrm{LMO}}(M) := 1 + \mathrm{Grad}_1(\Omega_1(M)) + \cdots + \mathrm{Grad}_n(\Omega_n(M)) + \cdots \in \mathcal{A}(\emptyset)$$

For $M$ a $\mathbb{Q}$HS, we also define

$$\hat{Z}^{\mathrm{LMO}}(M) := 1 + \frac{\mathrm{Grad}_1(\Omega_1(M))}{d(M)} + \cdots + \frac{\mathrm{Grad}_n(\Omega_n(M))}{d(M)^n} + \cdots$$

where $d(M)$ is the cardinality of $H_1(M, \mathbb{Z})$.

**Proposition 1** (Lê *et al.* 1998). *Both $Z^{\mathrm{LMO}}(M)$ and $\hat{Z}^{\mathrm{LMO}}(M)$ (when defined) are group-like elements, that is,*

$$\Delta(Z^{\mathrm{LMO}}(M)) = Z^{\mathrm{LMO}}(M) \otimes Z^{\mathrm{LMO}}(M)$$
$$\Delta(\hat{Z}^{\mathrm{LMO}}(M)) = \hat{Z}^{\mathrm{LMO}}(M) \otimes \hat{Z}^{\mathrm{LMO}}(M)$$

*Moreover, $\hat{Z}^{\mathrm{LMO}}(M_1 \# M_2) = \hat{Z}^{\mathrm{LMO}}(M_1) \times \hat{Z}^{\mathrm{LMO}}(M_2)$.*

### Universality Properties of the LMO Invariant

Let us restrict ourselves to the case of $\mathbb{Z}$HS.

**Theorem 5** (Lê 1997). *The less than or equal to $n$ degree part $\mathrm{Gr}_{\leq n} Z^{\mathrm{LMO}}$ is an invariant of degree $2n$. Any invariant of degree $\leq 2n$ is a composition $w(\mathrm{Gr}_{\leq n} Z^{\mathrm{LMO}})$, where $w : \mathrm{Gr}_{\leq n}\mathcal{A}(\emptyset) \to \mathbb{Q}$ is a linear map.*

Clasper calculus (or $Y$-surgery) theory allows Habiro to extend the theorem to rational homology 3-spheres.

### The Arhus Integral

The Arhus integral (ca. 1998) of Bar-Natan, Garoufalidis, Rozansky and Thurston, based on a theory of formal integration, calculates the LMO invariant of rational homology 3-spheres. The formal integration theory has a conceptual flavor and helps to relate the LMO invariant to perturbative expansions of quantum invariants. We give here the definition for the case when one does surgery on a knot $K$ with nonzero framing $b$. The link case is similar (see Bar-Natan *et al.* (2002a, b)).

When $K$ is a knot, $\check{Z}(K)$ is an element of $\mathcal{A}_1 \equiv \mathcal{P}_1 \equiv \mathcal{B}_1$. Note that $\mathcal{B}_1$ is an algebra where the product is the disjoint union $\sqcup$. Since the framing is $b$, one has

$$\check{Z}(K) = \exp_{\sqcup}(b\, w_1/2) \sqcup Y$$

where $w_1$ is the "dashed interval" (the only connected open Jacobi diagram without trivalent vertex), and $Y$ is an element in $\mathcal{B}$ every term of which must have at least one trivalent vertex. For uni–trivalent graphs $C, D \in \mathcal{B}_1$ let

$$\langle C, D\rangle = \begin{cases} 0 & \text{if the numbers of legs of } C, D \text{ are different} \\ \text{sum of all ways to glue legs of } C \text{ and } D \text{ together} \end{cases}$$

One defines $\int^{FG} \check{Z}(K) := \langle \exp_{\sqcup}(-w_1/2b), Y\rangle$. Then

$$\int^{FG} \check{Z}(K) = \sum_{n=0}^{\infty} \frac{\mathrm{Gr}_n(\iota_n \check{Z}(K))}{(-b)^n}$$

Hence,

$$\hat{Z}^{\mathrm{LMO}}(S^3_K) = \frac{\int^{FG} \check{Z}(K)}{\int^{FG} \check{Z}(U_{\mathrm{sign}(b)})}$$

### Other Approaches

Another construction of a universal perturbative invariant based on integrations over configuration spaces, closer to the original physics approach but harder to calculate because of the lack of a surgery formula, was developed by Axelrod and Singer, Kontsevich, Bott and Cattaneo, Kuperberg and Thurston (see Axelred and Singer (1992), Bott and Cattaneo (1998)).

## Quantum Invariants and Perturbative Expansion

Fix a simple (complex) Lie algebra $\mathfrak{g}$ of finite dimension. Using the quantized enveloping algebra of $\mathfrak{g}$ one can define quantum link and 3-manifold invariants. We recall here the definition, adapted for the case of roots lattice (projective group case).

Here our $q$ is equal to $q^2$ in the text book (Jantzen 1995). Fix a root system of $\mathfrak{g}$. Let $X, X_+, Y$ denote respectively the weight lattice, the set of dominant weights, and the root lattice. We normalize the invariant scalar product in the real vector space of the weight lattice so that the length of any short root is $\sqrt{2}$.

### Quantum Link Invariants

Suppose $L$ is a framed oriented link with $m$-ordered components, then the quantum invariant $J_L(\lambda_1, \ldots, \lambda_m)$ is a Laurent polynomial in $q^{1/2D}$, where $\lambda_1, \ldots, \lambda_m$ are dominant weights, standing for the simple $\mathfrak{g}$-modules of highest weights $\lambda_1, \ldots, \lambda_m$, and $D$ is the determinant of the Cartan matrix of $\mathfrak{g}$ (see, e.g., Turaev (1994) and Lê (1996)). The Jones polynomial is the case when $\mathfrak{g} = \mathrm{sl}_2$ and all the $\lambda_i$'s are the highest weights of the fundamental representation. For the unknot $U$ with zero framing, one has (here $\rho$ is the half-sum of all positive roots)

$$J_U(\lambda) = \prod_{\text{positive roots } \alpha} \frac{q^{(\lambda+\rho|\alpha)/2} - q^{-(\lambda+\rho|\alpha)/2}}{q^{(\rho|\alpha)/2} - q^{-(\rho|\alpha)/2}}$$

We will also use another normalization of the quantum invariant:

$$Q_L(\lambda_1, \ldots, \lambda_m) := J_L(\lambda_1, \ldots, \lambda_m) \times \prod_{j=1}^{m} J_U(\lambda_j)$$

This definition is good only for $\lambda_j \in X_+$. Note that each $\lambda \in X$ is either fixed by an element of the Weyl group under the dot action (see Humphreys (1978)) or can be moved to $X_+$ by the dot action. We define $Q_L(\lambda_1, \ldots, \lambda_m)$ for arbitrary $\lambda_j \in X$ by requiring that $Q_L(\lambda_1, \ldots, \lambda_m) = 0$ if one of the $\lambda_j$'s is fixed by an element of the Weyl group, and that $Q_L(\lambda_1, \ldots, \lambda_m)$ is component-wise invariant under the dot action of the Weyl group, that is, for every $w_1, \ldots, w_m$ in the Weyl group,

$$Q_L(w_1 \cdot \lambda_1, \ldots, w_m \cdot \lambda_m) = Q_L(\lambda_1 \ldots, \lambda_m)$$

**Proposition 2** (Lê 1996). *Suppose $\lambda_1, \ldots, \lambda_m$ are in the root lattice $Y$.*

(i) *(Integrality) Then $Q_L(\lambda_1, \ldots, \lambda_m) \in \mathbb{Z}[q^{\pm 1}]$, (no fractional power).*
(ii) *(Periodicity) When $q$ is an $r$th root of 1, then $Q_L(\lambda_1, \ldots, \lambda_m)$ is invariant under the action of the lattice group $rY$, that is, for $y_1, \ldots, y_m \in Y$, $Q_L(\lambda_1, \ldots, \lambda_m) = Q_L(\lambda_1 + ry_1, \ldots, \lambda_m + ry_m)$.*

### Quantum 3-Manifold Invariants

Although the infinite sum $\sum_{\lambda_j \in Y} Q_L(\lambda_1, \ldots, \lambda_m)$ does not have a meaning, heuristic ideas show that it is invariant under the second Kirby move, and hence almost defines a 3-manifold invariant. The problem is to regularize the infinite sum. One solution is based on the fact that at $r$th roots of unity, $Q_L(\lambda_1, \ldots, \lambda_m)$ is periodic, so we should use the sum with $\lambda_j$'s run over a fundamental set $P_r$ of the action of $rY$, where

$$P_r := \{x = c_1\alpha_1 + \cdots + c_\ell\alpha_\ell \mid 0 \le c_1, \ldots, c_\ell < r\}$$

Here $\alpha_1, \ldots, \alpha_\ell$ are basis roots. For a root $\xi$ of unity of order $r$, let

$$F_L(\xi) = \sum_{\lambda_j \in (P_r \cap Y)} Q_L(\lambda_1, \ldots, \lambda_m)|_{q=\xi}$$

If $F_{U_\pm}(\xi) \neq 0$, define

$$\tau_L(\xi) := \frac{F_L(\xi)}{(F_{U_+}(\xi))^{\sigma_+}(F_{U_-}(\xi))^{\sigma_-}}$$

Recall that $D$ is the determinant of the Cartan matrix. Let $d$ be the maximum of the absolute values of entries of the Cartan matrix outside the diagonal.

**Theorem 6** (Lê 2003)

(i) *If the order $r$ of $\xi$ is coprime with d$D$, then $F_{U_\pm}(\xi) \neq 0$.*
(ii) *If $F_{U_\pm}(\xi) \neq 0$ then $\tau_M^{P\mathfrak{g}}(\xi) := \tau_L(\xi)$ is an invariant of the 3-manifold $M = S^3_L$.*

**Remark 1** The version presented here corresponds to projective groups. It was defined by Kirby and Melvin for $\mathrm{sl}_2$, Kohno and Takata for $\mathrm{sl}_n$, and by Lê (2003) for arbitrary simple Lie algebra. When $r$ is coprime with d$D$, there is also an associated modular category that generates a topological quantum field theory. In most texts in literature, say Kirillov (1996) and Turaev (1994), another version $\tau^{\mathfrak{g}}$ was defined. The reason we choose $\tau^{P\mathfrak{g}}$ is: it has nice integrality and eventually perturbative expansion. For relations between the version $\tau^{P\mathfrak{g}}$ and the usual $\tau^{\mathfrak{g}}$, see Lê (2003).

**Examples** When $M$ is the Poincaré sphere and $\mathfrak{g} = \mathrm{sl}_2$,

$$\tau_M^{Psl_2}(q) = \frac{1}{1-q}\sum_{n=0}^{\infty} q^n(1-q^{n+1}) \times (1-q^{n+2}) \ldots (1-q^{2n+1})$$

Here $q$ is a root of unity, and the sum is easily seen to be finite.

**Integrality** The following theorem was proved for $\mathfrak{g} = \mathrm{sl}_2$ by Murakami (1995) and for $\mathfrak{g} = \mathrm{sl}_n$ by Takata–Yokota and Masbaum–Wenzl (using ideas of J Roberts) and for arbitrary simple Lie algebras by Lê (2003).

**Theorem 7** *Suppose the order $r$ of $\xi$ is a prime big enough, then $\tau_M^{P\mathfrak{g}}(\xi)$ is in $\mathbb{Z}[\xi] = \mathbb{Z}[\exp(2\pi i/r)]$.*

### Perturbative Expansion

Unlike the link case, quantum 3-manifold invariants can be defined only at certain roots of unity. In general, there is no analytic extension of the function $\tau_M^{P\mathfrak{g}}$ around $q=1$. In perturbative theory, we want to expand the function $\tau_M^{\mathfrak{g}}$ around $q=1$ into power series. For $\mathbb{Q}$HS, Ohtsuki (for $\mathfrak{g}=\mathrm{sl}_2$) and then the present author (for all other simple Lie algebras) showed that there is a number-theoretical expansion of $\tau_M^{P\mathfrak{g}}$ around $q=1$ in the following sense.

Suppose $r$ is a big enough prime, and $\xi=\exp(2\pi i/r)$. By the integrality (Theorem 7),

$$\tau_M^{P\mathfrak{g}}(\xi)\in\mathbb{Z}[\xi]=\mathbb{Z}[q]/(1+q+q^2+\cdots+q^{r-1})$$

Choose a representative $f(q)\in\mathbb{Z}[q]$ of $\tau_M^{P\mathfrak{g}}(\xi)$. Formally substitute $q=(q-1)+1$ in $f(q)$:

$$f(q)=c_{r,0}+c_{r,1}(q-1)+\cdots+c_{r,n-2}(q-1)^{n-2}$$

The integers $c_{r,n}$ depend on $r$ and the representative $f(q)$. It is easy to see that $c_{r,n}$ (mod $r$) does not depend on the representative $f(q)$ and hence is an invariant of $\mathbb{Q}$HS. The dependence on $r$ is a big drawback. The theorem below says that there is a rational number $c_n$, not depending on $r$, such that $c_{r,n}$ (mod $r$) is the reduction of either $c_n$ or $-c_n$ modulo $r$, for sufficiently large prime $r$. It is easy to see that if such $c_n$ exists, it must be unique. Let $s$ be the number of positive roots of $\mathfrak{g}$. Recall that $\ell$ is the rank of $\mathfrak{g}$.

**Theorem 8** *For every $\mathbb{Q}$HS $M$, there is a sequence of numbers*

$$c_n\in\mathbb{Z}\left[\frac{1}{(2n+2s)!|H_1(M,\mathbb{Z})|}\right]$$

*such that for sufficiently large prime $r$*

$$c_{r,n}\equiv\left(\frac{|H_1(M,\mathbb{Z})|}{r}\right)^{\ell}c_n\ (\mathrm{mod}\ r)$$

*where*

$$\left(\frac{|H_1(M,\mathbb{Z})|}{r}\right)=\pm1$$

*is the Legendre symbol. Moreover, $c_n$ is an invariant of order $\le 2n$.*

The series $\mathrm{t}_M^{P\mathfrak{g}}(q-1):=\sum_{n=0}^{\infty}c_n(q-1)^n$, called the Ohtsuki series, can be considered as the perturbative expansion of the function $\tau_M^{P\mathfrak{g}}$ at $q=1$. For actual calculation of $\mathrm{t}_M^{P\mathfrak{g}}(q-1)$, see Lê (2003), Ohtsuki (2002), and Rozansky (1997).

**Recovery from the LMO invariant** It is known that for any metrized Lie algebra $\mathfrak{g}$, there is a linear map $W_{\mathfrak{g}}:\mathrm{Gr}_n\mathcal{A}(\emptyset)\to\mathbb{Q}$ (see Bar-Natan (1995)).

**Theorem 9** *One has*

$$\sum_{n=0}^{\infty}W_{\mathfrak{g}}(\mathrm{Gr}_nZ^{\mathrm{LMO}})\,h^n=\mathrm{t}_M^{P\mathfrak{g}}(q-1)|_{q=e^h}$$

This shows that the Ohtsuki series $\mathrm{t}_M^{P\mathfrak{g}}(q-1)$ can be recovered from, and hence totally determined by, the LMO invariant. The theorem was proved by Ohtsuki for $\mathrm{sl}_2$. For other simple Lie algebras, the theorem follows from the Arhus integral (see Bar-Natan *et al.* (2002a, b) and Ohtsuki (2002)).

### Rozansky's Gaussian Integral

Rozansky (1997) gave a definition of the Ohtsuki series using formal Gaussian integral in the important work. The work is only for $\mathrm{sl}_2$, but can be generalized to other Lie algebras; it is closer to the original physics ideas of perturbative invariants.

## Cyclotomic Expansion

### The Habiro Ring

Let us define the Habiro ring $\widehat{\mathbb{Z}[q]}$ by

$$\widehat{\mathbb{Z}[q]}:=\lim_{\leftarrow n}\mathbb{Z}[q]/((1-q)(1-q^2)\ldots(1-q^n))$$

Habiro (2002) called it the cyclotomic completion of $\mathbb{Z}[q]$. Formally, $\widehat{\mathbb{Z}[q]}$ is the set of all series of the form

$$f(q)=\sum_{n=0}^{\infty}f_n(q)(1-q)(1-q^2)\ldots(1-q^n)$$
$$f_n(q)\in\mathbb{Z}[q]$$

Suppose $U$ is the set of roots of 1. If $\xi\in U$ then $(1-\xi)(1-\xi^2)\cdots(1-\xi^n)=0$ if $n$ is big enough; hence, one can define $f(\xi)$ for $f\in\widehat{\mathbb{Z}[q]}$. One can consider every $f\in\widehat{\mathbb{Z}[q]}$ as a function with domain $U$. Note that $f(\xi)\in\mathbb{Z}[\xi]$ is always an algebraic integer. It turns out that $\widehat{\mathbb{Z}[q]}$ has remarkable properties, and plays an important role in quantum topology.

Note that the formal derivative of $(1-q)(1-q^2)\ldots(1-q^n)$ is divisible by $(1-q)(1-q^2)\ldots(1-q^k)$ with $k>(n-1)/2$. This means every element $f\in\widehat{\mathbb{Z}[q]}$ has a derivative $f'\in\widehat{\mathbb{Z}[q]}$, and hence derivatives of all orders in $\widehat{\mathbb{Z}[q]}$. One can then associate to $f\in\widehat{\mathbb{Z}[q]}$ its Taylor series at a root $\xi$ of 1:

$$T_\xi(f):=\sum_{n=0}^{\infty}\frac{f^{(n)}(\xi)}{n!}(q-\xi)^n$$

which can also be obtained by noticing that $(1-q)(1-q^2)\ldots(1-q^n)$ is divisible by $(q-\xi)^k$ if $n$ is bigger than $k$ times the order of $\xi$. Thus, one has a map $T_\xi:\widehat{\mathbb{Z}[q]}\to\mathbb{Z}[\xi][[q-\xi]]$.

**Theorem 10** (Habiro 2004)

(i) *For each root of unity* $\xi$, *the map* $T_\xi$ *is injective, that is, a function in* $\widehat{\mathbb{Z}[q]}$ *is determined by its Taylor expansion at a point in the domain U.*
(ii) *if* $f(\xi) = g(\xi)$ *at infinitely many roots* $\xi$ *of prime power orders, then* $f = g$ *in* $\widehat{\mathbb{Z}[q]}$.

One important consequence is that $\widehat{\mathbb{Z}[q]}$ is an integral domain, since we have the embedding $T_1 : \widehat{\mathbb{Z}[q]} \hookrightarrow \mathbb{Z}[[q-1]]$.

In general the Taylor series $T_1 f$ has 0 convergence radius. However, one can speak about $p$-adic convergence to $f(\xi)$ in the following sense. Suppose the order $r$ of $\xi$ is a power of prime, $r = p^k$. Then it is known that $(\xi - 1)^n$ is divisible by $p^m$ if $n > mk$. Hence, $T_1 f(\xi)$ converges in the $p$-adic topology, and it can be easily shown that the limit is exactly $f(\xi)$.

The above properties suggest considering $\widehat{\mathbb{Z}[q]}$ as a class of "analytic functions" with domain $U$.

#### Quantum Invariants as an Element of $\widehat{\mathbb{Z}[q]}$

It was proved, by Habiro for $sl_2$ and by Habiro with the present author for general simple Lie algebras, that quantum invariants of $\mathbb{Z}$HSs belong to $\widehat{\mathbb{Z}[q]}$ and thus have remarkable integrality properties:

**Theorem 11**

(i) *For every* $\mathbb{Z}$HS *M, there is an invariant* $I_M^{\mathfrak{g}} \in \widehat{\mathbb{Z}[q]}$ *such that if* $\xi$ *is a root of unity for which the quantum invariant* $\tau_M^{P\mathfrak{g}}(\xi)$ *can be defined, then* $I_M^{\mathfrak{g}}(\xi) = \tau_M^{P\mathfrak{g}}(\xi)$.
(ii) *The Ohtsuki series is equal to the Taylor series of* $I_M^{\mathfrak{g}}$ *at 1.*

**Corollary 1** *Suppose M is a* $\mathbb{Z}$HS.

(i) *For every root of unity* $\xi$, *the quantum invariant at* $\xi$ *is an algebraic integer,* $\tau_M^{\mathfrak{g}}(\xi) \in \mathbb{Z}[\xi]$. (*No restriction on the order of* $\xi$ *is required.*)
(ii) *The Ohtsuki series* $t_M^{P\mathfrak{g}}(q-1)$ *has integer coefficients. If* $\xi$ *is a root of order* $r = p^k$, *where p is prime, then the Ohtsuki series at* $\xi$ *converges p-adically to the quantum invariant at* $\xi$.
(iii) *The quantum invariant* $\tau_M^{P\mathfrak{g}}$ *is determined by values at infinitely many roots of prime power orders and also determined by its Ohtsuki series.*
(iv) *The* LMO *invariant totally determines the quantum invariants* $\tau_M^{P\mathfrak{g}}$.

Part (ii) was conjectured by R Lawrence for $sl_2$ and first proved by Rozansky (also for $sl_2$). Part (iv) follows from the fact that the LMO invariant determines the Ohtsuki series; it exhibits another universality property of the LMO invariant.

# Floer Homology

**P B Kronheimer**, Harvard University, Cambridge, MA, USA

## Introduction

Morse theory allows one to reconstruct the homology of a compact manifold $B$ from data obtained from the gradient flow of a function $f: B \to \mathbb{R}$, the Morse function. The term "Floer homology" is used to describe homology groups that arise from carrying out the same construction, but in a setting where the space $B$ is replaced by an infinite-dimensional manifold (a space of maps, or a space of configurations for a gauge theory), and where the gradient trajectories of the Morse function correspond to solutions of an elliptic differential equation. There are two important types of such homology theories that have been extensively developed, and the study of both was initiated in the 1980s by Andreas Floer. In the first type, the elliptic equation that arises is a Cauchy–Riemann equation, whose solutions are pseudoholomorphic maps from a two-dimensional domain into a symplectic manifold. In the second type, the elliptic equation is an equation of gauge theory on a 4-manifold: either the anti-self-dual Yang–Mills equations or the Seiberg–Witten equations. Important antecedents of Floer's work included work of Conley, Zehnder, and others on the symplectic fixed-point problem, and Witten's ideas about Morse theory.

This article describes the background material from Morse theory before discussing Floer homology of Cauchy–Riemann type and its application to the Arnol'd conjecture in symplectic topology. Floer homology in the context of four-dimensional gauge theories is discussed more briefly.

## Morse Theory

Let $B$ be a smooth, compact manifold and $f: B \to \mathbb{R}$ a smooth function. A critical point $p$ of $f$ is said to be nondegenerate if the Hessian of $f$ is a nonsingular operator on $T_pB$. The function $f$ is a Morse function if all its critical points are nondegenerate. In the presence of a Riemannian metric $g$ on $B$, the derivative $\mathrm{d}f$ becomes a vector field, the gradient $\nabla f$, and we can consider the downward gradient-flow equation for a path $x(s)$ in $B$:

$$\frac{\mathrm{d}x}{\mathrm{d}s} = -\nabla f(x)$$

If $p$ and $q$ are nondegenerate critical points, let us write $M(p,q)$ for the space of solutions $x(s)$ satisfying

$$\lim_{s\to-\infty} x(s) = p$$
$$\lim_{s\to+\infty} x(s) = q$$

To understand the structure of $M(p,q)$, consider the linearization of the gradient-flow equation at a solution $x \in M(p,q)$. This is a linear equation for a vector field $X$ along the path $x$ in $B$, and takes the form

$$\nabla_{\partial/\partial s} X = -\nabla\nabla f(X) \qquad [1]$$

where $\nabla\nabla f$ is the covariant derivative of the gradient $\nabla f$, an operator on tangent vectors. Let $\epsilon_x$ be the dimension of the space of solutions $X$ to this linear equation, with the boundary conditions $\lim_{s\to\pm\infty} X(s) = 0$, and let $\epsilon'_x$ be the dimension of the space of solutions to the adjoint equation

$$\nabla_{\partial/\partial s} X = +\nabla\nabla f(X)$$

We say that the trajectory $x$ is "regular" if $\epsilon'_x = 0$. In this case, the trajectory space $M(p,q)$ has the structure of smooth manifold near $x$: its dimension is $\epsilon_x$ and its tangent space is the space of solutions $X$ to [1]. The gradient flow is said to be Morse–Smale if all trajectories between critical points are regular. If $f$ is any Morse function, one can always choose the metric $g$ so that the corresponding flow is Morse–Smale. (It is also the case that one can leave $g$ fixed and perturb $f$ to achieve the same effect.)

In the Morse–Smale case, each $M(p,q)$ is a smooth manifold. The dimension of $M(p,q)$ in the neighborhood of a trajectory $x$ depends only on $p$ and $q$, not otherwise on $x$. Indeed, even without the regularity condition, the index of eqn [1], namely the difference $\epsilon_x - \epsilon'_x$, is given by

$$\epsilon_x - \epsilon'_x = \mathrm{index}(p) - \mathrm{index}(q)$$

where $\mathrm{index}(p)$ denotes the number of negative eigenvalues (counting multiplicity) of the Hessian at $p$. In the Morse–Smale case therefore, the dimension of $M(p,q)$ is given by $\mathrm{index}(p) - \mathrm{index}(q)$. If $x(s)$ is a solution of the gradient-flow equation, then so is the reparametrized trajectory $x(s+c)$; and this is different from $x(s)$ as long as $p \neq q$. Let us denote by $\breve{M}(p,q)$ the quotient of $M(p,q)$ by the action of $\mathbb{R}$ given by these reparametrizations. We have

$$\dim \breve{M}(p,q) = \mathrm{index}(p) - \mathrm{index}(q) - 1 \quad (p \neq q)$$

as long as the trajectory space is nonempty.

Let $\mathbb{F}_2$ denote the field with two elements. The Morse complex of a Morse–Smale gradient flow, with coefficients in $\mathbb{F}_2$, is defined as follows. For each $i$, let $C_i(f)$ be the finite-dimensional vector space over $\mathbb{F}_2$ having a basis

$$e_{p_1}, \ldots, e_{p_{r_i}}$$

indexed by the critical points $p_1, \ldots, p_{r_i}$ with index $i$. For each pair of critical points $p$ and $q$ with indices $i$ and $i-1$ respectively, let $\delta_{pq} \in \mathbb{F}_2$ denote the number of points in the zero-dimensional manifold $\breve{M}(p,q)$, counted mod 2:

$$\delta_{pq} = \#\breve{M}(p,q) \pmod 2$$

The Morse–Smale condition ensures that the zero-dimensional space $\breve{M}(p,q)$ is finite, so this definition is satisfactory. Define a differential

$$\delta : C_i(f) \to C_{i-1}(f)$$

by

$$\delta(e_p) = \sum_{\mathrm{index}(q)=i-1} \delta_{pq} e_q$$

The first important fact is that $\delta$ really is a differential: as long as the flow is Morse–Smale, we have

$$\text{the composite } \delta \circ \delta : C_i(f) \to C_{i-2}(f) \text{ is zero} \qquad [2]$$

We can therefore construct the homology of the complex $(C_*(f), \delta)$. This is the Morse homology:

$$H_i(f) = \frac{\ker(\delta : C_i(f) \to C_{i-1}(f))}{\mathrm{im}(\delta : C_{i+1}(f) \to C_i(f))} \qquad [3]$$

The proof of [2] is as follows. Suppose that $p$ has index $i$ and $r$ is a critical point with index $i-2$, and consider $\breve{M}(p,r)$, which has dimension 1. The key step is to understand that $\breve{M}(p,r)$ is noncompact, and that its ends correspond to "broken trajectories": pairs $(x_1, x_2)$ (modulo reparametrization), where $x_1$ is a gradient trajectory from $p$ to some $q$ of index $i-1$, and $x_2$ is a trajectory from $q$ to $r$. The number of ends is thus $\sum_q \delta_{qr}\delta_{pq}$. Since the number of ends of a 1-manifold is even, this sum is zero in $\mathbb{F}_2$. This sum is also the matrix entry of $\delta \circ \delta$ from $e_p$ to $e_r$; so $\delta \circ \delta = 0$.

The main result about Morse homology in finite dimensions is the following:

**Theorem 1** *The Morse homology $H_i(f)$ is isomorphic to the ordinary homology of the compact manifold $B$ with coefficients $\mathbb{F}_2$: the group $H_i(B; \mathbb{F}_2)$.*

This result can be proved by first showing that $H_i(f)$ depends only on $B$, not on the choice of $f$ or the metric. (This step can be accomplished by examining a nonautonomous flow of the form $\mathrm{d}x/\mathrm{d}s = -\nabla f(s,x)$.) Then one can examine the Morse complex in the case of a self-indexing Morse function (where the value of $f$ at the critical points is a monotone-increasing function of their index). In the self-indexing case, the unstable manifolds of the critical points give rise to a cell decomposition of the manifold $B$, and the Morse complex is easily identified with the cellular chain complex for this cell decomposition.

The sum of the dimensions of the Morse homology groups cannot be larger than the sum of the dimensions of the chain groups $C_i(f)$, which is the total number of critical points. The above theorem therefore implies the following basic version of the "Morse inequalities":

**Corollary 2** *The number of critical points of a Morse function $f: B \to \mathbb{R}$ cannot be less than $\sum_i \dim H_i(B; \mathbb{F}_2)$.*

The Morse complex can be refined in various ways. For example, one can use integer coefficients in place of coefficients $\mathbb{F}_2$ by taking account of orientations of the spaces of trajectories. One can also introduce Morse theory with coefficients in a local system, and in both these cases a version of the above theorem continues to hold. One can also study the Morse complex of a multivalued Morse function: that is, one can start with closed 1-form $\alpha$ on $B$, with nontrivial periods, and study the flow generated by the corresponding vector field $-g^{-1}\alpha$. Such a theory was developed by Novikov.

The Morse complex can be generalized in a different direction, replacing $f$ by a functional

related to a geometric problem. The canonical example of this (and one of the very few cases in which the theory works as in the finite-dimensional case) is the case that $B = LW$ is the space of loops $u : S^1 \to W$ in a Riemannian manifold $W$ and $f$ is the "energy function," $f_E(u) = \int (du/dt)^2\, dt$. If the Morse–Smale condition holds, then the Morse homology $H_i(f_E)$ computes the homology of $LW$, as expected. Critical points of $f_E$ are geodesics, and the relationship between geodesics and the topology of $LW$, for which Corollary 2 provides a prototype, is an idea with many applications.

For the energy functional, the downward gradient-flow equation is a parabolic equation (the ordinary heat equation if the target space is Euclidean), and a solution to the flow exists for each choice of initial condition. Floer homology can be loosely characterized as the Morse theory of certain variational problems for which the gradient-flow equation is not parabolic, but elliptic of first order: the important models are the Cauchy–Riemann equation in dimension 2, the anti-self-dual Yang–Mills equations in dimension 4, or the closely related Seiberg–Witten equations. For an elliptic equation, one does not expect to solve the Cauchy problem with arbitrary initial condition; so with Floer homology, one is studying a functional for which the gradient flow is not everywhere defined. However, to define the Morse complex, the important thing is only that we have a good understanding of the trajectory spaces $M(p, q)$, which will now be solution spaces for an elliptic problem of geometric origin. The proof of Theorem 1 depends very much on the fact that the flow is everywhere defined: this theorem will therefore fail for the Morse complexes arising in Floer theory, and one must look elsewhere for a means to compute the Morse homology groups.

Before discussing Floer homology in more specific terms, we shall describe the problem in symplectic geometry that motivated its development.

## The Arnol'd Conjecture

A symplectic manifold of dimension $2n$ is a smooth manifold $W$ equipped with a 2-form $\omega$ which is closed and nondegenerate. On a symplectic manifold, one can associate to each smooth function $H : W \to \mathbb{R}$ a vector field $X_H$ on $W$: the vector field is characterized by the property that

$$\omega(X_H, V) = dH(V)$$

for all vector fields $V$. In this situation, one refers to $H$ as the Hamiltonian and $X_H$ as the corresponding Hamiltonian vector field. If $W$ is compact, or if $X_H$ is otherwise complete, then this vector field generates a flow $\phi_t : W \to W (t \in \mathbb{R})$. We also wish to consider the case that $H$ is time dependent: we suppose that $H_t : W \to \mathbb{R}$ is a Hamiltonian which varies smoothly with $t \in \mathbb{R}$ and is periodic, in that $H_{t+1} = H_t$. In this case, there is a time-dependent Hamiltonian vector field $X_t$, and we can consider the flow $\phi_t$ that it generates: so for $x \in W$, the path $\phi_t(x)$ will be the solution to

$$\frac{d}{dt}\phi_t(x) = X_t(x) \qquad [4]$$

with initial condition $\phi_0(x) = x$. The Arnol'd conjecture, in one formulation, concerns the 1-periodic solutions to this equation, or equivalently the fixed points of $\phi_1 : W \to W$. A fixed point $x$ with $\phi_1(x) = x$ is called nondegenerate if $d\phi_1 : T_xX \to T_xX$ does not have 1 as an eigenvalue. With this understood, one version of the conjecture states:

**Conjecture 3** Suppose $W$ is compact and let $H_t$ be any 1-periodic, time-dependent Hamiltonian. If the fixed points of $\phi_1$ are all nondegenerate, then the number of fixed points is not less than the sum of the Betti numbers of the manifold $W$.

There is another, more general version of this conjecture. Let $L \subset W$ be a closed Lagrangian submanifold: that is, an $n$-dimensional submanifold such that the restriction of $\omega$ to $L$ as a 2-form is identically zero. Let $L' \subset W$ be another Lagrangian, obtained from $L$ by a Hamiltonian isotopy: that is, $L'$ is $\phi_1(L)$, for some flow $\phi_t$ generated by a time-dependent Hamiltonian $H_t$ as above.

**Question 4** If $L$ and $L'$ intersect transversely, is it always true that the number of intersection points of $L$ and $L'$ is at least the sum of the Betti numbers of the manifold $L$:

$$\#(L \cap L') \geq \sum_i \operatorname{rank} H_i(L)?$$

This is phrased as a question rather than a conjecture, because the answer is certainly "no" in some cases. For example, $L$ might be a circle contained in a small disk in a symplectic 2-manifold, in which case there is no reason why $\phi_1$ should not move the disk to be completely disjoint from itself. Nevertheless, with extra hypotheses, it is known that the answer is often "yes."

We can exhibit Conjecture 3 as a special case of Question 4, as follows. Given a symplectic manifold $(V, \omega)$, we can form the product $W = V \times V$, with the symplectic form $\omega_W = -p_1^*\omega + p_2^*\omega$, where the $p_i$ are the two projections. The result of this definition is

that the diagonal in $V \times V$ is a Lagrangian submanifold,

$$L \subset W = V \times V$$

for this symplectic form. Let $H_t$ be a time-dependent Hamiltonian on $V$, and let $\phi_t : V \to V$ be the flow. Then $H_t \circ p_2$ is a time-dependent Hamiltonian generating a flow on $W$. For the flow on $W$, the image $L'$ of the diagonal $L \subset W$ at time 1 is the graph of $\phi_1 : V \to V$. Thus, $(L \cap L')$ can be identified with the set of fixed points of $\phi_1$ in $V$, and an affirmative answer to Question 4 for $L \subset W$ implies Conjecture 3 for $V$.

Conjecture 3 and Question 4 can both be extended to the case of isolated degenerate fixed points of $\phi_1$ for Conjecture 3, or to the case of isolated, nontransverse intersections for Question 4. For example, one can ask whether, in the nontransverse case, the sum of the intersection multiplicities can ever be less than the sum of the Betti numbers.

## Morse Theory and the Arnol'd Conjecture

The Arnol'd conjecture, and the related Question 4, can both be studied by reformulating them as questions about the number of critical points of a carefully chosen functional.

We begin with the situation addressed by Conjecture 3. For simplicity, we suppose that $\pi_2(W)$ is zero. Let $\mathcal{B}$ be the space of smooth, null-homotopic loops in $W$:

$$\mathcal{B} = \{u : S^1 \to W | u \text{ is smooth and null homotopic}\}$$

This is a smooth, infinite-dimensional manifold. There is a natural functional $f_0 : \mathcal{B} \to \mathbb{R}$, the symplectic action, defined as

$$f_0(u) = \int_{D^2} v^*(\omega)$$

where $v : D^2 \to W$ is any extension of the map $u : S^1 \to W$. The extension $v$ exists because $u$ is null homotopic, and the value of $f_0$ is independent of the choice of $v$ because $\pi_2(W) = 0$. This functional can be modified in the presence of a periodic Hamiltonian. Introduce a coordinate $t$ on $S^1$ with period 1, and so regard $u$ as a periodic function of $t$. Write the Hamiltonian as $H_t$ as before, and define

$$f(u) = f_0(u) + \int_0^1 H_t(u(t))\,\mathrm{d}t$$

To compute the first variation of $f$, consider a one-parameter family of loops $u_s(t) = u(s,t)$ parametrized by $s \in \mathbb{R}$. We compute

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}s} f(u_s) &= \int_0^1 \omega\left(\frac{\partial u}{\partial s}, \frac{\partial u}{\partial t}\right) \mathrm{d}t + \int_0^1 \mathrm{d}H_t\left(\frac{\partial u}{\partial s}\right) \mathrm{d}t \\ &= \int_0^1 \omega\left(\frac{\partial u}{\partial s}, \frac{\partial u}{\partial t} - X_t(u)\right) \mathrm{d}t \end{aligned}$$

using the relationship between $\mathrm{d}H_t$ and $X_t$. Thus, a loop $u \in \mathcal{B}$ is a critical point of $f : \mathcal{B} \to \mathbb{R}$ if and only if it is a solution of the equation

$$\frac{\mathrm{d}u}{\mathrm{d}t} = X_t(u(t)) \qquad [5]$$

This means that there is a one-to-one correspondence between these critical points and certain 1-periodic solutions of eqn [4]: these in turn correspond to fixed points $p$ of $\phi_1$ with the additional property that the path $\phi_t(p)$ from $p$ to $p$ is null homotopic.

To consider the formal gradient flow of the functional $f$, on must introduce a metric on $\mathcal{B}$. A Riemannian metric $g$ on the symplectic manifold $(W, \omega)$ is compatible with $\omega$ if there is an almost-complex structure $J : TW \to TW$ such that $\omega(X, Y) = g(JX, Y)$ for all tangent vectors $X$ and $Y$ at any point of $W$. Let $g_t$ be a 1-periodic family of compatible Riemannian metrics on $W$. Using these, on can define an inner product on the tangent bundle of $\mathcal{B}$ by the formula

$$\langle U, V \rangle = \int_0^1 g_t(U(t), V(t))\,\mathrm{d}t$$

in which $U$ and $V$ are tangent vectors at $u \in \mathcal{B}$, regarded as vector fields along the loop $u$ in $W$. We can rewrite the above formula for the variation of $f$ in terms of this inner product:

$$\left\langle \frac{\partial u}{\partial s}, J_t\left(\frac{\partial u}{\partial t} - X_t(u)\right)\right\rangle$$

where $J_t$ is the almost-complex structure corresponding to $g_t$. Formally then, a one-parameter family of loops $u(s,t)$ is a solution of the downward gradient-flow equations for the functional $f$ with respect to this metric, if $u$ satisfies the differential equation

$$\frac{\partial u}{\partial s} + J_t\left(\frac{\partial u}{\partial t} - X_t(u)\right) = 0 \qquad [6]$$

In the absence of the term $X_t$, and with $W$ replaced by $\mathbb{C}^n$ with the standard $J$, this equation becomes the Cauchy–Riemann equation $\mathrm{d}u/\mathrm{d}\bar{z} = 0$, for a function $u$ of the complex variable $z = s + \mathrm{i}t$, periodic in $t$.

Let us now suppose we are in the situation of Conjecture 3, so $W$ is closed, and the fixed points of $\phi_1$ are nondegenerate. As we have seen, each fixed point $p$ of $\phi_1$ corresponds to a 1-periodic solution $u_p$ of eqn [5], a critical point of $f$. For each pair of fixed points $p$ and $q$, introduce $M(p,q)$ as the space of solutions of the formal gradient-flow equations of $f$, running from $p$ to $q$: that is, $M(p,q)$ is the space of maps $u:\mathbb{R}\times S^1\to W$ satisfying eqn [6], with

$$\lim_{s\to-\infty} u(s,t) = u_p(t)$$
$$\lim_{s\to+\infty} u(s,t) = u_q(t)$$

With these definitions in place, one can follow the same sequence of steps that we outlined previously in the context of finite-dimensional Morse theory, to construct the Morse complex. First, if $u$ belongs to $M(p,q)$, we can consider the linearization at $u$ of eqns [6], to obtain the counterpart of eqn [1]. These are linear equations for a vector field $U(s,t)$ along $u$ in $W$, and take the form

$$\nabla_{\partial/\partial s}U + J_t\nabla_{\partial/\partial t}U + h(U) = 0 \qquad [7]$$

where $h$ is a linear operator of order zero. Let $\epsilon_u$ denote the dimension of the space solutions $U$ which decay at $s=\pm\infty$, and let $\epsilon_u'$ denote the dimension of the space of solutions of the formal adjoint equation. Elliptic theory for the Cauchy–Riemann equation, and the nondegeneracy condition for $u_p$ and $u_q$, mean that the operator that appears on the left-hand side of the equation is Fredholm: so both $\epsilon_u$ and $\epsilon_u'$ are finite, and the index $\epsilon_u-\epsilon_u'$ is deformation invariant. This index depends only on $p$ and $q$: we give it a name,

$$\epsilon_u - \epsilon_u' = \mathrm{index}(p,q)$$

As before, $u$ is said to be regular if $\epsilon_u'$ is zero. For suitable choice of the almost-complex structures $J_t$ (or equivalently the metrics $g_t$), the Morse–Smale condition will hold: that is, the trajectories in all spaces $M(p,q)$ are regular. In this case, each $M(p,q)$ is a smooth manifold and has dimension index$(p,q)$ if it is nonempty.

The "relative index" index$(p,q)$ plays the role of the difference of the Morse indices in the finite-dimensional case. It can be defined whether or not $M(p,q)$ is empty by considering an equation such as [7] along an arbitrary path $u(s,t)$. In general, there is no natural way to define the "index" of $p$: if we wish, we can select one fixed point $p_0$ and declare it to have index zero; we can then define index$(p)$ as index$(p,p_0)$. Alternatively, we can regard the critical points as indexed by an affine copy of $\mathbb{Z}$ (without a preferred zero).

Imitating the construction of the Morse complex, we define a vector space $\mathrm{CF}_*$ over $\mathbb{F}_2$ as having a basis consisting of elements $e_p$ indexed by the fixed points $p$. We then define $\delta:\mathrm{CF}_*\to\mathrm{CF}_*$ by

$$\delta e_p = \sum_{\mathrm{index}(p,q)=1} \delta_{pq} e_q$$

where $\delta_{pq}$ is defined by counting points in $\breve{M}(p,q)$ as before. The vector space $\mathrm{CF}_*$ is $\mathbb{Z}$-graded if we make a choice of critical point $p_0$ to have index zero; otherwise, $\mathrm{CF}_*$ has an "affine" $\mathbb{Z}$-grading. The map $\delta$ maps $\mathrm{CF}_i$ into $\mathrm{CF}_{i-1}$.

To show that $\delta$ is well defined, and to show that $\delta\circ\delta=0$, one must show that the zero-dimensional spaces $\breve{M}(p,q)$ are compact, and that the ends of the one-dimensional spaces $\breve{M}(p,r)$ correspond bijectively to broken trajectories, as in the finite-dimensional case. Both of these desired properties hold, under the Morse–Smale conditions; but this is a very special feature of the specific problem. Without the hypothesis that $\pi_2(W)$ is zero, additional noncompactness can arise from the following "bubbling" phenomenon. There could be a sequence of solutions $u^i\in M(p,q)$ to eqns [6], and a point $(s_0,t_0)$ in $\mathbb{R}\times S^1$, such that for suitable constants $\epsilon_i$ converging to zero, the rescaled solutions

$$\tilde{u}^i(\sigma,\tau) = u^i(s_0+\epsilon_i\sigma, t_0+\epsilon_i\tau)$$

converge on compact subsets of the plane $\mathbb{R}^2$ to a nonconstant pseudoholomorphic map $\tilde{u}:\mathbb{CP}^1\to W$, or more precisely a solution of the equation

$$\frac{\partial\tilde{u}}{\partial\sigma} + J_{t_0}\left(\frac{\partial\tilde{u}}{\partial\tau}\right) = 0$$

(In the original coordinates, the derivatives of the $u^i$ would grow like $1/\epsilon_i$ near $(s_0,t_0)$.) A pseudoholomorphic sphere always has nontrivial homology class (and therefore nontrivial homotopy class); so this sort of noncompactness does not occur when $\pi_2(W)=0$.

Granted the compactness results, the proof that $\delta\circ\delta=0$ runs as before, and we can construct a Floer homology group,

$$\mathrm{HF}_* = \ker(\delta)/\mathrm{im}(\delta)$$

Unlike the Morse homology of the energy functional, the Floer homology does not yield the ordinary homology of $\mathcal{B}$. To compute it, one first shows that it depends only on the symplectic manifold $(W,\omega)$, not on the choice of Hamiltonian $H_t$ or metrics $g_t$: this step is similar to the proof that the finite-dimensional Morse homology $H_*(f)$ does not depend on the Morse function. Once one has

established this independence, $HF_*$ can be computed by examining a special case. Floer did this by taking the Hamiltonian to be independent of $t$ and equal to a small negative multiple $-\eta h$ of a fixed Morse function $h : W \to \mathbb{R}$ on the symplectic manifold. If the multiple $\eta \in \mathbb{R}$ is small enough, the only fixed points of $\phi_1$ are the stationary points of the flow, and these are exactly the critical points of $h$. Furthermore the only index-1 solutions of eqn [6] for small $\eta$ are the solutions $u(s,t)$ with no $t$ dependence; and these are the solutions of $du/ds = -\eta\nabla h$, the downward gradient flow of $h$, scaled by $\eta$. In this case therefore, the Floer complex $CF_*$ is precisely the Morse complex $C_*(h)$ of the Morse function $h$, and Theorem 1 yields:

**Theorem 5** *For a periodic, time-dependent Hamiltonian $H_t$ on a closed symplectic manifold $(W, \omega)$ with $\pi_2(W) = 0$, the Floer homology $HF_*$ is isomorphic to the ordinary homology of $W$ with $\mathbb{F}_2$ coefficients, $H_*(W; \mathbb{F}_2)$.*

Because the generators of $CF_*$ correspond to fixed points $p$ of $\phi_1$ such that the path $\phi_t(p)$ is null homotopic, the number of these fixed points is not less than the dimension of $HF_*$, and therefore not less than $\sum_i \dim H_i(W; \mathbb{F}_2)$ because of the above result. The sum of the mod 2 Betti numbers is at least as large as the sum of the ordinary Betti numbers (the dimensions of the rational homology groups); so one deduces, following Floer,

**Corollary 6** *The Arnol'd conjecture (Conjecture 3) holds for symplectic manifolds $(W, \omega)$ satisfying the additional condition $\pi_2(W) = 0$.*

Orientations can be introduced rather as in the case of finite-dimensional Morse theory, allowing one to define Floer groups with arbitrary coefficients.

The Arnol'd conjecture is now known to hold in complete generality, without the hypothesis on $\pi_2$. The proof has been achieved by successive extensions of the Floer homology technique. When $\pi_2(W)$ is nonzero, the space $\mathcal{B}$ is not simply connected. The first complication that arises is that the symplectic action functional $f_0$, and therefore $f$ also, is multivalued. This is not an obstacle initially, because $\nabla f$ is still well defined, and the spaces $M(p,q)$ of gradient trajectories can still be assumed to satisfy the Morse–Smale condition: this is the type of Morse theory considered by Novikov, as mentioned above. Because $\pi_1(\mathcal{B})$ is nontrivial, $M(p,q)$ is a union of parts $M_z(p,q)$, one for each homotopy class of paths from $p$ to $q$. For each homotopy class $z$, we have the index $\text{index}_z(p,q)$, which is the dimension of $M_z(p,q)$.

The spaces $M_z(p,q)$ may now have additional noncompactness, due to the presence of pseudo-holomorphic spheres $\tilde{u} : \mathbb{CP}^1 \to W$. The simplest manifestation is when a sequence $u^i$ in $M_z(p,q)$ "bubbles off" a single such sphere at a point $(s_0, t_0)$, and converges elsewhere to a smooth trajectory $u'$ in $M_{z'}(p,q)$, belonging to a different homotopy class. Let $\sigma$ be the homology class of the sphere $\tilde{u}$. Because the sphere has positive area, the pairing of $\sigma$ with the de Rham class $[\omega]$ is positive: $\langle[\omega], \sigma\rangle > 0$. The indices are related by

$$\text{index}_{z'}(p,q) = \text{index}_z(p,q) - 2\langle c_1(W), \sigma\rangle$$

where $c_1(W) \in H^2(W; \mathbb{Z})$ is the first Chern class of a compatible almost-complex structure. The symplectic manifold is said to be "monotone" if, in real cohomology, $c_1(W)$ is a positive multiple of $[\omega]$. In the monotone case, we always have $\text{index}_{z'}(p,q) < \text{index}_z(p,q)$, and no bubbling off can occur for trajectory spaces $M_z(p,q)$ of index 2 or less: the above formula either makes $M_{z'}(p,q)$ a space of negative dimension (in which case it is empty) or a zero-dimensional space (in which case one has to exploit an additional transversality argument, to show that the holomorphic spheres belonging to classes $\sigma$ with $\langle c_1(W), \sigma\rangle = 1$ cannot intersect one of the loops $u_p$ in $W$). Since the construction of $HF_*$ involves only the trajectories of indices 1 and 2, the construction goes through with minor changes. Because $\text{index}_z(p,q)$ depends on the path $z$, the group $HF_*$ will no longer be $\mathbb{Z}$-graded: the grading is defined only modulo $2d$, where $d$ is the smallest nonzero value of $\langle c_1(W), \sigma\rangle$ for spherical classes $\sigma$.

In the case that $W$ is not monotone, additional techniques are needed to deal with the essential noncompactness of the trajectory spaces. These techniques involve (amongst other things) multi-valued perturbations on orbifolds – a strategy that requires the use of rational coefficients in order to perform the necessary averaging. For this reason, in the monotone case, the Arnol'd conjecture is known to hold only in its original form: with the ordinary (rational) Betti numbers.

To address Question 4 for Lagrangian intersections, a closely related Floer homology theory is used. Assume $L$ is connected, and introduce the space of smooth paths joining $L$ to $L'$:

$$\begin{aligned}&\Omega(W; L, L')\\&\quad = \{u : [0,1] \to W \mid u(0) \in L, u(1) \in L'\}\end{aligned}$$

Fix a point $x_0$ in $L$, and let $u_0$ be the path $u_0(t) = \phi_t(x_0)$. Let $\mathcal{B}$ be the connected component

of $\Omega(W; L, L')$ containing $u_0$. On $\mathcal{B}$ we have a symplectic action functional, defined as

$$f(u) = \int_{[0,1]\times[0,1]} v^*(\omega)$$

where $v : [0,1] \times [0,1] \to W$ is a path in $\mathcal{B}$ with $v(0,t) = u_0(t)$ and $v(1,t) = u(t)$. The symplectic action is single valued if $\pi_2(W, L)$ is trivial (even though this condition does not guarantee that $\mathcal{B}$ is simply connected). The critical points of $f$ correspond to constant paths whose image in $W$ is an intersection point of $L$ and $L'$ (though not all such constant paths belong to the connected component $\mathcal{B}$). If we fix a one-parameter family of compatible metrics $g_t$ and almost-complex structures $J_t$ on $W$, then we can consider the downward gradient trajectories of the functional. These are maps

$$u : \mathbb{R} \times [0,1] \to W$$

satisfying the Cauchy–Riemann equation

$$\frac{\partial u}{\partial s} + J_t\left(\frac{\partial u}{\partial t}\right) = 0$$

with boundary conditions $u(s,0) \in L$ and $u(s,1) \in L'$. With coefficients $\mathbb{F}_2$, a Morse complex can be constructed much as in the case just considered. If $\pi_2(W,L)$ is trivial, then the Floer homology group $\mathrm{HF}_*$ obtained as the homology of this Morse complex is isomorphic to $H_*(L; \mathbb{F}_2)$; and as a corollary, Question 4 has an affirmative answer in this case.

Without the hypothesis that $\pi_2(W,L)$ is trivial, one does not expect an affirmative answer to Question 4 in all cases. There is a "monotone" case, in which $\mathrm{HF}_*$ can always be defined; but it is not always isomorphic to $H_*(L; \mathbb{F}_2)$: instead, there is a spectral sequence relating the two. In the general case, there is once again the need to use rational coefficients in place of mod 2 coefficients, in order to deal with the orbifold nature of the trajectory spaces that appear. This raises the question of orientability for the trajectory spaces. In contrast to the Morse theory for Hamiltonian diffeomorphisms, there is an obstruction to orientability, involving spin structures on $L$ and $W$. Even when the trajectory spaces are orientable, there are further obstructions to the existence of a Morse differential satisfying $\delta \circ \delta = 0$. The theory of these obstructions is developed in Fukaya *et al.* (2000). There are still open questions in this area.

## Instanton Floer Homology

A "Floer homology theory" for 3-manifolds should assign to each 3-manifold $Y$ (satisfying perhaps some additional topological requirements) a group, say $\mathrm{HF}(Y)$. Furthermore, given a four-dimensional cobordism $W$ from $Y_1$ to $Y_2$, the theory should provide a corresponding homomorphism of groups, from $\mathrm{HF}(Y_1)$ to $\mathrm{HF}(Y_2)$. These homomorphisms should satisfy the natural composition law for composite cobordisms. One can formulate this by considering the category in which an object is a closed, connected, oriented 3-manifold $Y$, and in which the morphisms from $Y_1$ to $Y_2$ are the oriented four-dimensional cobordisms, considered up to diffeomorphism. A Floer homology theory is then a functor from this category (perhaps with some additional decorations or restrictions) to the category of groups. Such a functor was constructed by Floer (1988a), at least for the full subcategory of homology 3-spheres (manifolds $Y$ with $H_1 \times (Y; \mathbb{Z}) = 0$). We outline the construction.

Let $P \to Y$ be a principal SU(2) bundle (necessarily trivial). Let $\mathcal{A}$ denote the space of SU(2) connections in the bundle $P$, and let $A_0$ be any chosen basepoint in $\mathcal{A}$. Any other $A \in \mathcal{A}$ can be written as $A_0 + a$, for some 1-form $a$ with values in the adjoint bundle $\mathrm{ad}(P)$ whose fiber is the Lie algebra $\mathfrak{su}(2)$. So $\mathcal{A}$ is an affine space,

$$\mathcal{A} = A_0 + \Omega^1(Y; \mathrm{ad}(P))$$

and we can identify the tangent space $T_A\mathcal{A}$ at any $A$ with $\Omega^1(Y; \mathrm{ad}(P))$. The Chern–Simons functional is a smooth function

$$\mathrm{CS} : \mathcal{A} \to \mathbb{R}$$

depending on our choice of a reference connection $A_0$. It can be defined by stating that its derivative at $A \in \mathcal{A}$ is the linear map $T_A\mathcal{A} \to \mathbb{R}$ given by

$$a \mapsto -\int_Y \mathrm{tr}(a \wedge F_A)$$

where $F_A$ denotes the curvature of $A$, as an $\mathrm{ad}(P)$-valued 2-form on $Y$, and tr denotes the trace of a matrix-valued 3-form. If we equip $Y$ with a Riemannian metric, then we have the $L^2$ inner product on $\Omega^1(Y; \mathrm{ad}(P))$, with respect to which we can consider the gradient of CS. The formal downward gradient-flow equation on $\mathcal{A}$ is then

$$(\mathrm{d}/\mathrm{d}s)A = - * F_A \qquad [8]$$

where $*$ is the Hodge star on $Y$. If $A(s)$ is a solution defined on an interval $[s_1, s_2]$, then we can form the corresponding four-dimensional connection $\boldsymbol{A}$ on $[s_1, s_2] \times Y$, and eqn [8] implies that $\boldsymbol{A}$ is a solution of the anti-self-dual Yang–Mills equation, $F^+_{\boldsymbol{A}} = 0$. Here $F^+_{\boldsymbol{A}}$ is the self-dual part of the curvature 2-form on the cylinder. The critical points of CS are the flat connections on $Y$, with $F_A = 0$.

Let $\mathcal{G}$ denote the gauge group, by which we mean the group of automorphisms of $P$. When a trivialization of $P$ is chosen, $\mathcal{G}$ becomes the group of smooth maps $g: Y \to SU(2)$. A connection $A \in \mathcal{A}$ is irreducible if its stabilizer in $\mathcal{G}$ consists only of the constant gauge transformations $\pm 1$. The functional CS is invariant only under the identity component of $\mathcal{G}$: it descends to a function $CS: \mathcal{A}/\mathcal{G} \to \mathbb{R}/(4\pi^2\mathbb{Z})$. If we choose a basepoint in $Y$, then the gauge-equivalence classes of flat connections in $\mathcal{A}$ are in one-to-one correspondence with conjugacy classes of representations,

$$\rho : \pi_1(Y) \to SU(2)$$

Given representations $\rho$ and $\sigma$, we write $M(\rho, \sigma)$ for the quotient by $\mathcal{G}$ of the space of trajectories $A(s)$ which satisfy the gradient-flow equation [8] and which are asymptotic to flat connections belonging to the classes $\rho$ and $\sigma$ as $s \to \pm\infty$. There is a purely four-dimensional interpretation of $M(\rho, \sigma)$: it can be identified with the moduli space of solutions $\boldsymbol{A}$ to the anti-self-dual Yang–Mills equation, or "instantons," on $\mathbb{R} \times Y$, satisfying the same asymptotic conditions.

One defines the "instanton Floer homology" of $Y$, roughly speaking, as the Morse homology arising from the functional CS. In the case that $Y$ is a homology 3-sphere, Floer defined $I_*(Y)$ as the homology $H_*(C, \delta)$ of a complex $C$ whose generators correspond to the irreducible representations $\rho$, and whose differential $\delta$ is defined in terms of the one-dimensional components of the moduli spaces $M(\rho, \sigma)$. To carry out the construction of $I_*(Y)$, it is necessary to perturb the functional CS to achieve a Morse–Smale condition: this is done by adding a function $f: \mathcal{A} \to \mathbb{R}$ defined in terms of the holonomy of connections along families of loops in $Y$. The group $\mathcal{G}$ is not connected, and for given $\rho$ and $\sigma$, the moduli space $M(\rho, \sigma)$ has components differing in dimension by multiples of 8. For this reason, $I_*(Y)$ is a $\mathbb{Z}/8$-graded homology theory. It is a topological invariant of $Y$, and is functorial for cobordisms, in the manner outlined at the beginning of this section.

Various extensions have been made, to allow the definition of $I_*(Y)$ for 3-manifolds with nontrivial $H_1$, and to incorporate the reducible representations. Although there have been some successes (Donaldson 2002), a completely satisfactory general theory has not been constructed. The main difficulties stem from the noncompactness of the instanton moduli spaces (a bubbling phenomenon) and the interaction of this bubbling with the reducible solutions.

The instanton Floer theory for 3-manifolds is closely tied up with Donaldson's polynomial invariants of closed 4-manifolds, which are also defined using the anti-self-dual Yang–Mills equations.

## Seiberg–Witten Floer Homology

Seiberg–Witten Floer homology can be defined in a manner very similar to the instanton case. Again, we start with a Riemannian 3-manifold $Y$, equipped now with a spin$^c$ structure $\mathfrak{s}$: a rank-2 Hermitian vector bundle $S \to Y$ together with a Clifford multiplication $\rho: \Lambda^*(Y) \to \mathrm{End}(S)$. The configuration space $\mathcal{C}$ is defined as the space of pairs $(A, \Phi)$, where $A$ is a spin$^c$ connection and $\Phi$ is a section of $S$. In place of the Chern–Simons functional considered above, we have the Chern–Simons–Dirac functional $CSD: \mathcal{C} \to \mathbb{R}$ defined by

$$CSD(A, \Phi) = \frac{1}{4} CS(\mathrm{tr}(A)) + \frac{1}{2} \int_Y \langle \Phi, D_A \Phi \rangle \, d\mu$$

where $\mathrm{tr}(A)$ denotes the connection induced by $A$ on the line bundle $\Lambda^2 S$ and $D_A$ is the Dirac operator for the connection $A$. The functional is invariant again under the identity component of the gauge group $\mathcal{G}$, which this time is the group of maps $g: Y \to S^1$, acting as automorphisms of $S$. The critical points are the solutions $(A, \Phi)$ to the three-dimensional "Seiberg–Witten equations,"

$$\tfrac{1}{2}\rho(F_{\mathrm{tr}(A)}) - (\Phi\Phi^*)_0 = 0$$
$$D_A \Phi = 0$$

in which the subscript 0 denotes the traceless part of the endomorphism. If $\alpha$ and $\beta$ are gauge-equivalence classes of critical points, then we write $M(\alpha, \beta)$ for the quotient by $\mathcal{G}$ of the space of gradient trajectories from $\alpha$ to $\beta$.

As in the instanton case, $M(\alpha, \beta)$ has a four-dimensional interpretation: it is the quotient by the four-dimensional gauge group of a space of solutions $(\boldsymbol{A}, \boldsymbol{\Phi})$ on $\mathbb{R} \times Y$ to the four-dimensional Seiberg–Witten equations:

$$\tfrac{1}{2}\rho\left(F^+_{\mathrm{tr}(\boldsymbol{A})}\right) - (\boldsymbol{\Phi}\boldsymbol{\Phi}^*)_0 = 0$$
$$D^+_{\boldsymbol{A}} \boldsymbol{\Phi} = 0$$

Here $\boldsymbol{\Phi}$ is a section of the summand $S^+$ of the four-dimensional spin$^c$ bundle $S = S^+ \oplus S^-$, and $D^+_{\boldsymbol{A}}: \Gamma(S^+) \to \Gamma(S^-)$ is the four-dimensional Dirac operator.

The action of the gauge group on $\mathcal{C}$ is free except at configurations with $\Phi = 0$. These reducible configurations have an $S^1$ stabilizer. Reducible critical points of CSD correspond to flat connections in the line bundle $\Lambda^2 S$. We can now distinguish two cases, according to whether $c_1(S)$ is a torsion class or not.

If $c_1(S)$ is not a torsion class, then there are no flat connections in $\Lambda^2 S$, so all critical points are irreducible. In this case, there is a straightforward Floer-type Morse theory for the functional CSD on

the space $\mathcal{C}/\mathcal{G}$: for generators of our complex we take the gauge-equivalence classes of critical points, and we use the one-dimensional trajectory spaces $M(\alpha, \beta)$ to define the boundary map. The resulting Morse homology group is denoted $\mathrm{HM}_*(Y, \mathfrak{s})$. It has a canonical $\mathbb{Z}/2$-grading, and is a topological invariant of $Y$ and its spin$^c$ structure.

If $c_1(S)$ is torsion, the theory is more complex. There will be reducible critical points, and one cannot exclude these from the Morse complex and still obtain a topological invariant of $Y$. One may incorporate the reducible critical points in two different ways, that are in a sense dual to one another; and there is a third homology theory that one can define, using the reducibles alone. Thus, one can construct three Floer groups associated to $Y$ with the spin$^c$ structure $\mathfrak{s}$. The resulting theory closely resembles the Heegaard Floer homology that is described next.

## Heegaard Floer Homology and Other Floer Theories

Heegaard Floer homology is a Floer homology theory for 3-manifolds that is formally similar to Seiberg–Witten Floer homology, and conjecturally isomorphic to it. Unlike the instanton and Seiberg–Witten theories, its construction, due to Ozsváth and Szabó, does not use gauge theory. Instead, one begins with a decomposition of the 3-manifold into two handlebodies with common boundary $\Sigma$, and one studies a symplectic manifold $s^g\Sigma$, the configuration space of $g$-tuples of points on $\Sigma$, where $g$ denotes the genus. The Heegaard Floer groups are then defined by a variant of the construction used for Lagrangian intersections (see the section "Morse theory and the Arnol'd conjecture"), applied to a particular pair of Lagrangian tori in $s^g\Sigma$.

As in the case of Seiberg–Witten theory, Heegaard Floer homology assigns to each oriented 3-manifold $Y$ three different Floer groups, $\mathrm{HF}^+(Y), \mathrm{HF}^-(Y)$, and $\mathrm{HF}^\infty(Y)$, related by a long exact sequence:

$$\cdots \to \mathrm{HF}^+(Y) \to \mathrm{HF}^-(Y) \to \mathrm{HF}^\infty(Y) \to \mathrm{HF}^+(Y) \to \cdots$$

The first two groups are dual, in that there is a nondegenerate pairing between $\mathrm{HF}^+(Y)$ and $\mathrm{HF}^-(-Y)$, where $-Y$ denotes the same 3-manifold with opposite orientation. If $W$ is an oriented four-dimensional cobordism from $Y_1$ to $Y_2$, then there are associated functorial maps

$$\mathcal{F}^+(W) : \mathrm{HF}^+(Y_1) \to \mathrm{HF}^+(Y_2)$$
$$\mathcal{F}^-(W) : \mathrm{HF}^-(Y_1) \to \mathrm{HF}^-(Y_2)$$
$$\mathcal{F}^\infty(W) : \mathrm{HF}^\infty(Y_1) \to \mathrm{HF}^\infty(Y_2)$$

In addition, if the intersection form of $W$ is not negative semidefinite, there is a map

$$\mathcal{F}(W) : \mathrm{HF}^-(Y_1) \to \mathrm{HF}^+(Y_2)$$

As a special case, one can start with a closed 4-manifold $X$, and consider the cobordism $W$ from $S^3$ to $S^3$ obtained from $X$ by removing two 4-balls. In this case, the map

$$\mathcal{F}(W) : \mathrm{HF}^-(S^3) \to \mathrm{HF}^+(S^3)$$

encodes a diffeomorphism invariant of the original 4-manifold $X$. This invariant is conjectured to be equivalent to the Seiberg–Witten invariants of $X$.

Heegaard Floer homology, and its cousin Seiberg–Witten Floer homology, have been applied successfully to settle long-standing problems in topology, particularly questions related to surgery on knots. An example of such an application is the theorem of Kronheimer *et al.* that one cannot obtain the projective space $\mathbb{RP}^3$ by surgery on a nontrivial knot in the 3-sphere.

In these and other applications of both Heegaard and Seiberg–Witten Floer homology, two key properties of the homology groups play an important part. The first is a nonvanishing theorem, which shows, for example, that these Floer groups can distinguish $S^1 \times S^2$ from any other manifold with the same homology. The second is a long exact sequence, which relates the Floer groups of the manifolds obtained by three different surgeries on a knot. The latter property is shared by the instanton Floer groups, as was shown by Floer (Braam and Donaldson 1995).

Other Floer-type theories have been considered, not all of which arise from a gradient flow, but in which the boundary map of the complex is obtained by counting solutions to a geometric differential equation. At the time of writing, Floer homology is an area of very active development.

# Fluid Mechanics: Numerical Methods

**J-L Guermond**, Université de Paris Sud, Orsay, France

The objective of this article is to give an overview of some advanced numerical methods commonly used in fluid mechanics. The focus is set primarily on finite-element methods and finite-volume methods.

## Fluid Mechanics Models

Let $\Omega$ be a domain in $\mathbb{R}^d (d=2,3)$ with boundary $\partial\Omega$ and outer unit normal $\boldsymbol{n}$. $\Omega$ is assumed to be occupied by a fluid. The basic equations governing fluid flows are derived from three conservation principles: *conservation of mass*, *momentum*, *and energy*. Denoting the density by $\rho$, the velocity by $\boldsymbol{u}$, and the mass specific internal energy by $e_i$, these equations are

$$\partial_t \rho + \nabla\cdot(\rho\boldsymbol{u}) = 0 \qquad [1]$$

$$\partial_t(\rho\boldsymbol{u}) + \nabla\cdot(\rho\boldsymbol{u}\otimes\boldsymbol{u}) = \nabla\cdot\boldsymbol{\sigma} + \rho\boldsymbol{f} \qquad [2]$$

$$\partial_t(\rho e_i) + \nabla\cdot(\rho\boldsymbol{u}e_i) = \boldsymbol{\sigma}:\boldsymbol{\varepsilon} + q_{\mathrm{T}} - \nabla\cdot\boldsymbol{j}_T \qquad [3]$$

where $\boldsymbol{\sigma}$ is the *stress tensor*, $\boldsymbol{\varepsilon} = (1/2)(\nabla\boldsymbol{u} + \nabla\boldsymbol{u})^{\mathrm{T}}$ is the *strain tensor*, $\boldsymbol{f}$ is a body force per unit mass (gravity is a typical example), $q_T$ is a volume source (it may model chemical reactions, Joule effects, radioactive decay, etc.), and $\boldsymbol{j}_T$ is the heat flux. In addition to the above three fundamental conservation equations, one may also have to add $L$ equations that account for the conservation of other quantities, say $\phi_\ell, 1 \le \ell \le L$. These quantities may, for example, be the concentration of constituents in an alloy, the turbulent kinetic energy, the mass fractions of various chemical species by unit volume, etc. All these conservation equations take the following form:

$$\partial_t(\rho\phi_\ell) + \nabla\cdot(\rho\boldsymbol{u}\phi_\ell) = q_{\phi_\ell} - \nabla\cdot\boldsymbol{j}_{\phi_\ell}, \quad 1 \le \ell \le L \qquad [4]$$

Henceforth, the index $\ell$ is dropped to alleviate the notation.

The above set of equations must be supplemented with initial and boundary conditions. Typical initial conditions are $\rho_{|t=0} = \rho_0$, $\boldsymbol{u}_{|t=0} = \boldsymbol{u}_0$, and $\phi_{|t=0} = \phi_0$. Boundary conditions are usually classified into two types: the *essential boundary conditions* and the *natural boundary conditions*. Natural conditions impose fluxes at the boundary. Typical examples are

$$(\boldsymbol{\sigma}\cdot\boldsymbol{n} + \mathcal{R}\cdot\boldsymbol{u})_{|\partial\Omega} = \boldsymbol{a_u}$$

$$(\boldsymbol{j}_T\cdot\boldsymbol{n} + r_T e_i)_{|\partial\Omega} = a_T$$

and

$$(\boldsymbol{j}_\phi\cdot\boldsymbol{n} + r_\phi\phi)_{|\partial\Omega} = a_\phi$$

The quantities $\mathcal{R}$, $r_T$, $r_\phi$, $\boldsymbol{a_u}$, $a_T$, $a_\phi$ are given. Essential boundary conditions consist of enforcing boundary values on the dependent variables. One typical example is the so-called *no-slip boundary condition*: $\boldsymbol{u}_{|\partial\Omega} = 0$.

The above system of conservation laws is closed by adding three constitutive equations whose purpose is to relate each field $\boldsymbol{\sigma}$, $\boldsymbol{j}_T$, and $\boldsymbol{j}_\phi$ to the fields $\rho$, $\boldsymbol{u}$, and $\phi$. They account for microscopic properties of the fluid and thus must be frame-independent. Depending on the constitutive equations and

adequate hypotheses on time and space scales, various models are obtained. An important class of fluid model is one for which the stress tensor is a linear function of the strain tensor, yielding the so-called Newtonian fluid model:

$$\boldsymbol{\sigma} = (-p + \lambda \nabla \cdot \boldsymbol{u})\boldsymbol{I} + 2\mu\boldsymbol{\varepsilon} \qquad [5]$$

Here $p$ is the pressure, $\boldsymbol{I}$ is the identity matrix, and $\lambda$ and $\mu$ are viscosity coefficients. Still assuming linearity, common models for heat and solute fluxes consist of assuming

$$\boldsymbol{j}_T = -\kappa \nabla T, \qquad \boldsymbol{j}_\phi = -D\nabla\phi \qquad [6]$$

where $T$ is the temperature. These are the so-called Fourier's law and Fick's law, respectively.

Having introduced two new quantities, namely the pressure $p$ and the temperature $T$, two new scalar relations are needed to close the system. These are the state equations. One admissible assumption consists of setting $\rho = \rho(p, T)$. Another usual additional hypothesis consists of assuming that the variations in the internal energy are proportional to those in the temperature, that is, $\partial e_i = c_P \partial T$.

Let us now simplify the above models by assuming that $\rho$ is constant. Then, mass conservation implies that the flow is incompressible, that is, $\nabla \cdot \boldsymbol{u} = 0$. Let us further assume that neither $\lambda, \mu$, nor $p$ depend on $e_i$. Then, upon abusing the notation and still denoting by $p$ the ratio $p/\rho$, the above set of assumptions yields the so-called incompressible Navier–Stokes equations:

$$\nabla \cdot \boldsymbol{u} = 0 \qquad [7]$$

$$\partial_t \boldsymbol{u} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} - \nu \Delta \boldsymbol{u} + \nabla p = \boldsymbol{f} \qquad [8]$$

As a result, the mass and momentum conservation equations are independent of that of the energy and those of the solutes:

$$\rho c_P(\partial_t T + \boldsymbol{u} \cdot \nabla T) - \nabla \cdot (\kappa \nabla T) = 2\mu\boldsymbol{\varepsilon} : \boldsymbol{\varepsilon} + q_T \qquad [9]$$

$$\partial_t \phi + \boldsymbol{u} \cdot \nabla \phi - \frac{1}{\rho} \nabla \cdot (D \nabla \phi) = \frac{1}{\rho} q_\phi \qquad [10]$$

Another model allowing for a weak dependency of $\rho$ on the temperature, while still enforcing incompressibility, consists of setting $\rho = \rho_0(1 - \beta(T - T_0))$. If buoyancy effects induced by gravity are important, it is then possible to account for them by setting $\boldsymbol{f} = \rho_0 g(1 - \beta(T - T_0))$, where $g$ is the gravitational acceleration, yielding the so-called Boussinesq model.

Variations on these themes are numerous and a wide range of fluids can be modeled by using nonlinear constitutive laws and nonlinear state laws. For the purpose of numerical simulations, however, it is important to focus on simplified models.

## The Building Blocks

From the above considerations we now extract a small set of elementary problems which constitute the building blocks of most numerical methods in fluid mechanics.

### Elliptic Equations

By taking the divergence of the momentum equation [8] and assuming $\boldsymbol{u}$ to be known and renaming $p$ to $\phi$, one obtains the Poisson equation

$$-\Delta \phi = f \qquad [11]$$

where $f$ is a given source term. This equation plays a key role in the computation of the pressure when solving the Navier–Stokes equations; see [54b]. Assuming that adequate boundary conditions are enforced, this model equation is the prototype for the class of the so-called elliptic equations. A simple generalization of the Poisson equation consists of the advection–diffusion equation

$$\boldsymbol{u} \cdot \nabla \phi - \nabla \cdot (\kappa \nabla \phi) = f \qquad [12]$$

where $\kappa > 0$. Admissible boundary conditions are $(\kappa \partial_n \phi + r\phi)_{|\partial\Omega} = a$, $r \geq 0$, or $\phi_{|\partial\Omega} = a$. This type of equation is obtained by neglecting the time derivative in the heat equation [9] or in the solute conservation equation [10]. Mathematically speaking, [12] is also elliptic since its properties (in particular, the way the boundary conditions must be enforced) are controlled by the second-order derivatives. For the sake of simplicity, assume that $\boldsymbol{u} = 0$ in the above equation and that the boundary condition is $\phi_{|\partial\Omega} = 0$, then it is possible to show that $\phi$ solves [12] if and only if $\phi$ minimizes the functional

$$\mathcal{J}(\psi) = \int_\Omega (|\nabla \psi|^2 - f\psi)\, \mathrm{d}\boldsymbol{x}$$

where $|\cdot|$ is the Euclidean norm and $\psi$ spans

$$H = \left\{ \psi; \int_\Omega |\nabla \psi|^2 \, \mathrm{d}\boldsymbol{x} < \infty; \psi_{|\partial\Omega} = 0 \right\} \qquad [13]$$

Writing the first-order optimality condition for this optimization problem yields

$$\int_\Omega \nabla \phi \cdot \nabla \psi = \int_\Omega \boldsymbol{f} \psi$$

for all $\psi \in H$. This is the so-called variational formulation of [12]. When $\boldsymbol{u}$ is not zero, no variational principle holds but a similar way to

reformulate [12] consists of multiplying the equation by arbitrary functions in $H$ and integrating by parts the second-order term to give

$$\int_\Omega (\boldsymbol{u}\cdot\nabla\phi)\psi + \kappa\nabla\phi\cdot\nabla\psi = \int_\Omega f\psi, \quad \forall\psi\in H \qquad [14]$$

This is the so-called weak formulation of [12]. Weak and variational formulations are the starting point for finite-element approximations.

### Stokes Equations

Another elementary building block is deduced from [8] by assuming that the time derivative and the nonlinear term are both small. The corresponding model is the so-called Stokes equations,

$$-\nu\Delta\boldsymbol{u} + \nabla p = \boldsymbol{f} \qquad [15]$$

$$\nabla\cdot\boldsymbol{u} = 0 \qquad [16]$$

Assume for the sake of simplicity that the no-slip boundary condition is enforced: $\boldsymbol{u}_{|\partial\Omega}=\boldsymbol{0}$. Introduce the Lagrangian functional

$$\mathcal{L}(\boldsymbol{v},q) = \int_\Omega (\nabla\boldsymbol{u}:\nabla\boldsymbol{v} - q\nabla\cdot\boldsymbol{v} - \boldsymbol{f}\cdot\boldsymbol{v})\,\mathrm{d}\boldsymbol{x}$$

Set

$$\boldsymbol{X} = \left\{\boldsymbol{v};\int_\Omega |\nabla\boldsymbol{v}|^2\,\mathrm{d}\boldsymbol{x} < \infty; \boldsymbol{v}_{|\partial\Omega} = 0\right\}$$
$$M = \left\{q;\int_\Omega q^2\,\mathrm{d}\boldsymbol{x} < \infty\right\}$$

Then, the pair $(\boldsymbol{u},p)\in\boldsymbol{X}\times M$ solves the Stokes equations if and only if it is a saddle point of $\mathcal{L}$, that is,

$$\mathcal{L}(\boldsymbol{u},q) \le \mathcal{L}(\boldsymbol{u},p) \le \mathcal{L}(\boldsymbol{v},p), \quad \forall(\boldsymbol{v},q)\in\boldsymbol{X}\times M \qquad [17]$$

In other words, the pressure $p$ is the Lagrange multiplier of the incompressibility constraint $\nabla\cdot\boldsymbol{u}=0$. Realizing this fact helps to understand the nature of the Stokes equations, specially when it comes to constructing discrete approximations. A variational formulation of the Stokes equations is obtained by writing the first-order optimality condition, namely:

$$\int_\Omega (\nu\nabla\boldsymbol{u}:\nabla\boldsymbol{v} - p\nabla\cdot\boldsymbol{v} - \boldsymbol{f}\cdot\boldsymbol{v})\,\mathrm{d}\boldsymbol{x} = 0 \quad \forall\boldsymbol{v}\in\boldsymbol{X}$$
$$\int_\Omega q\nabla\cdot\boldsymbol{u}\,\mathrm{d}\boldsymbol{x} = 0 \quad \forall q\in M$$

When the nonlinear term is not zero in the momentum equation, or when this term is linearized, there is no saddle point, but a weak formulation is obtained by multiplying the momentum equation by arbitrary functions $\boldsymbol{v}$ in $\boldsymbol{X}$ and integrating by parts the Laplacian, and by multiplying the mass equation by arbitrary functions $q$ in $M$:

$$\int_\Omega ((\boldsymbol{u}\cdot\nabla\boldsymbol{u})\cdot\boldsymbol{v} + \nu\nabla\boldsymbol{u}:\nabla\boldsymbol{v} - p\nabla\cdot\boldsymbol{v})\,\mathrm{d}\boldsymbol{x} = \int_\Omega \boldsymbol{f}\cdot\boldsymbol{v} \qquad [18]$$

$$\int_\Omega q\nabla\boldsymbol{u} = 0 \qquad [19]$$

### Parabolic Equations

The class of elliptic equations generalizes to that of the parabolic equations when time is accounted for:

$$\partial_t\phi + \boldsymbol{u}\cdot\nabla\phi - \nabla\cdot(\kappa\nabla\phi) = f, \quad \phi_{|t=0} = \phi_0 \qquad [20]$$

Fundamentally, this equation has many similarities with the elliptic equation

$$\alpha\phi + \boldsymbol{u}\cdot\nabla\phi - \nabla\cdot(\kappa\nabla\phi) = f \qquad [21]$$

where $\alpha > 0$. In particular, the set of boundary conditions that are admissible for [20] and [21] are identical, that is, it is legitimate to enforce $(\kappa\partial_n\phi + r\phi)_{|\partial\Omega} = a, r\ge 0$, or $\phi_{|\partial\Omega} = a$. Moreover, solving [21] is always a building block of any algorithm solving [20]. The important fact to remember here is that if a good approximation technique for solving [21] is at hand, then extending it to solve [20] is usually straightforward.

### Hyperbolic Equations

When $\kappa/UL\to 0$, where $U$ is the reference velocity scale and $L$ is the reference length scale, [20] degenerates into the so-called transport equation

$$\partial_t\phi + \boldsymbol{u}\cdot\nabla\phi = f \qquad [22]$$

This is the prototypical example for the class of hyperbolic equations. For this equation to be well-posed, it is necessary to enforce an initial condition $\phi_{|t=0} = \phi_0$ and an inflow boundary condition, that is, $\phi_{|\partial\Omega^-} = a$, where $\partial\Omega^- = \{\boldsymbol{x}\in\partial\Omega; (\boldsymbol{u}\cdot\boldsymbol{n})(\boldsymbol{x}) < 0\}$ is the so-called *inflow boundary* of the domain. To better understand the nature of this equation, introduce the characteristic lines $\boldsymbol{X}(x,s;t)$ of $\boldsymbol{u}(\boldsymbol{x},t)$ defined as follows:

$$\begin{aligned} \mathrm{d}_t\boldsymbol{X}(x,s;t) &= \boldsymbol{u}(\boldsymbol{X}(x,s;t),t) \\ \boldsymbol{X}(x,s;s) &= \boldsymbol{x} \end{aligned} \qquad [23]$$

If $\boldsymbol{u}$ is continuous with respect to $t$ and Lipschitz with respect to $\boldsymbol{x}$, this ordinary differential equation has a unique solution. Furthermore, [22] becomes

$$\mathrm{d}_t[\phi(\boldsymbol{X}(\boldsymbol{x},s;t),t)] = f(\boldsymbol{X}(\boldsymbol{x},s;t),t) \qquad [24]$$

Then

$$\phi(\boldsymbol{x},t) = \phi_0(\boldsymbol{X}(\boldsymbol{x},t;0)) + \int_0^t f(\boldsymbol{X}(\boldsymbol{x},t;\tau),\tau)\,\mathrm{d}\tau$$

provided $\boldsymbol{X}(\boldsymbol{x},t;\tau) \in \Omega$ for all $\tau \in [0,t]$. This shows that the concept of characteristic curves is important to construct an approximation to [22].

## Meshes

The starting point of every approximation technique for solving any of the above model problems consists of defining a mesh of $\Omega$ on which the approximate solution is defined. To avoid having to account for curved boundaries, let us assume that the domain $\Omega$ is a two-dimensional polygon (resp. three-dimensional polyhedron). A mesh of $\Omega$, say $\mathcal{T}_h$, is a partition of $\Omega$ into small cells, hereafter assumed to be simple convex polygons in two dimensions (resp. polyhedrons in three dimensions), say triangles or quadrangles (resp. tetrahedrons or cuboids). Moreover, this partition is usually assumed to be such that if two different cells have a nonempty intersection, then the intersection is a vertex, or an entire edge, or an entire face. The left panel of Figure 1 shows a mesh satisfying the above requirement. The mesh in the right panel is not admissible.

## Finite Elements: Interpolation

The finite-element method is foremost an interpolation technique. The goal of this section is to illustrate this idea by giving examples.

Let $\mathcal{T}_h = \{K_m\}_{1\le m\le N_{\mathrm{el}}}$ be a mesh composed of $N_{\mathrm{el}}$ simplices, that is, triangles in two dimensions or tetrahedrons in three dimensions. Consider the following vector spaces of functions:

$$V_h = \{v_h \in \mathcal{C}^0(\bar{\Omega}); v_{h|K_m} \in \mathbb{P}_k, 1 \le m \le N_{\mathrm{el}}\} \quad [25]$$

where $\mathbb{P}_k$ denotes the space of polynomials of global degree at most $k$. $V_h$ is called a *finite-element approximation space*. We now construct a basis for $V_h$.

Given a simplex $K_m$ in $\mathbb{R}^d$, let $\boldsymbol{v}_n$ be a vertex of $K_m$, let $F_n$ be the face of $K_m$ opposite to $\boldsymbol{v}_n$, and

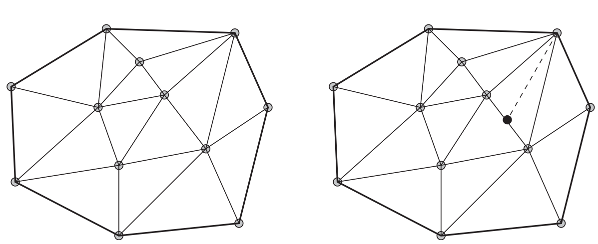

**Figure 1** Admissible (left) and nonadmissible (right) meshes.

define $\boldsymbol{n}_n$ to be the outward normal to $F_n, 1 \le n \le d+1$. Define the *barycentric coordinates*

$$\lambda_n(\boldsymbol{x}) = 1 - \frac{(\boldsymbol{x}-\boldsymbol{v}_n)\cdot \boldsymbol{n}_n}{(\boldsymbol{v}_l-\boldsymbol{v}_n)\cdot\boldsymbol{n}_n}, \quad 1 \le n \le d+1 \quad [26]$$

where $\boldsymbol{v}_l$ is an arbitrary vertex in $F_n$ (the definition of $\lambda_n$ is clearly independent of $\boldsymbol{v}_l$ provided $\boldsymbol{v}_l$ belongs to $F_n$). The barycentric coordinate $\lambda_n$ is an affine function; it is equal to 1 at $\boldsymbol{v}_n$ and vanishes on $F_n$; its level sets are hyperplanes parallel to $F_n$. The barycenter of $K_m$ has barycentric coordinates

$$\left(\frac{1}{d+1},\ldots,\frac{1}{d+1}\right)$$

The barycentric coordinates satisfy the following properties: for all $\boldsymbol{x} \in K_m, 0 \le \lambda_n(\boldsymbol{x}) \le 1$, and for all $\boldsymbol{x} \in \mathbb{R}^d$,

$$\sum_{n=1}^{d+1} \lambda_n(\boldsymbol{x}) = 1 \quad \text{and} \quad \sum_{n=1}^{d+1} \lambda_n(\boldsymbol{x})(\boldsymbol{x}-\boldsymbol{v}_n) = 0$$

Consider the set of nodes $\{\boldsymbol{a}_{n,m}\}_{1\le n\le n_{\mathrm{sh}}}$ of $K_m$ with barycentric coordinates

$$\left(\frac{i_0}{k},\ldots,\frac{i_d}{k}\right), \quad 0 \le i_0,\ldots,\, i_d \le k,\; i_0+\cdots+i_d = k$$

These points are called the *Lagrange nodes* of $K_m$. It is clear that there are $n_{\mathrm{sh}} = (1/2)(k+1)(k+2)$ of these points in two dimensions and $n_{\mathrm{sh}} = (1/6)(k+1)(k+2)(k+3)$ in three dimensions. It is remarkable that $n_{\mathrm{sh}} = \dim \mathbb{P}_k$.

Let $\{\boldsymbol{b}_1,\ldots,\boldsymbol{b}_N\} = \bigcup_{K_m\in\mathcal{T}_h}\{\boldsymbol{a}_{1,m},\ldots,\boldsymbol{a}_{n_{\mathrm{sh}},m}\}$ be the set of all the Lagrange nodes in the mesh. For $K_m \in \mathcal{T}_h$ and $n \in \{1,\ldots,n_{\mathrm{sh}}\}$, let $j(n,m) \in \{1,\ldots,N\}$ be the integer such that $\boldsymbol{a}_{n,m} = \boldsymbol{b}_{j(n,m)}$; $j(n,m)$ is the global index of the Lagrange node $\boldsymbol{a}_{n,m}$. Let $\{\varphi_1,\ldots,\varphi_N\}$ be the set of functions in $V_h$ defined by $\varphi_i(\boldsymbol{b}_j) = \delta_{ij}$, then it can be shown that

$$\{\varphi_1,\ldots,\,\varphi_N\} \text{ is a basis for } V_h \quad [27]$$

The functions $\varphi_i$ are called *global shape functions*. An important property of global shape functions is that their supports are small sets of cells. More precisely, let $i \in \{1,\ldots,N\}$ and let $\mathcal{V}_i = \{m; \exists n; i = j(n,m)\}$ be the set of cell indices to which the node $\boldsymbol{b}_i$ belongs, then the support of $\varphi_i$ is $\bigcup_{m\in\mathcal{V}_i} K_m$. For $k=1$, it is clear that $\varphi_{i\,|\,K_m} = \lambda_n$ for all $m \in \mathcal{V}_i$ and all $n$ such that $i = j(n,m)$, and $\varphi_{i\,|\,K_m} = 0$ otherwise. The graph of such a shape function in two dimensions is shown in the left panel of Figure 2. For $k=2$, enumerate from 1 to $d+1$ the vertices of $K_m$, and enumerate from $d+2$ to $n_{\mathrm{sh}}$ the Lagrange nodes located at the midedges. For a midedge node of index $d+2 \le n \le n_{\mathrm{sh}}$, let $b(n), e(n) \in \{1,\ldots, d+1\}$ be the two indices of the two Lagrange

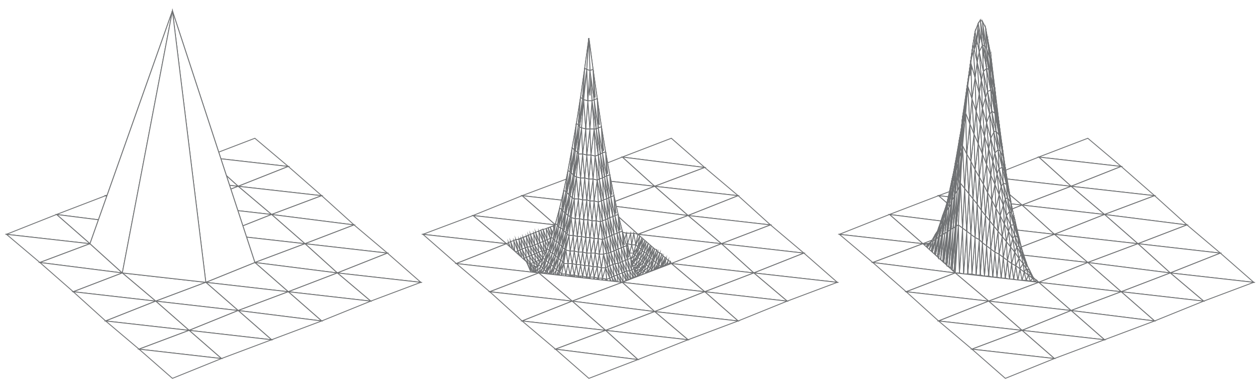

**Figure 2** Two-dimensional Lagrange shape functions: piecewise $\mathbb{P}_1$ (left) and piecewise $\mathbb{P}_2$ (center and right).

nodes at the extremities of the edge in question. Then, the restriction to $K_m$ of a $\mathbb{P}_2$ shape function $\varphi_i$ is

$$\varphi_{i|K_m} = \begin{cases} \lambda_n(2\lambda_n - 1), & \text{if } 1 \le n \le d+1 \\ 4\lambda_{b(n)}\lambda_{e(n)}, & \text{if } d+2 \le n \le n_{\text{sh}} \end{cases} \quad [28]$$

Figure 2 shows the graph of two $\mathbb{P}_2$ shape functions in two dimensions.

Once the space $V_h$ is introduced, it is natural to define the interpolation operator

$$\Pi_h : \mathcal{C}^0(\bar{\Omega}) \ni v \longmapsto \sum_{i=1}^{N} v(\boldsymbol{b}_i)\varphi_i \in V_h \quad [29]$$

This operator is such that for all continuous functions $v$, the restriction of $\Pi_h(v)$ to each mesh cell is a polynomial in $\mathbb{P}_k$ and $\Pi_h(v)$ takes the same values as $v$ at the Lagrange nodes. Moreover, setting $h = \max_{K_m \in \mathcal{T}_h} \operatorname{diam}(K_m)$, and defining

$$\|r\|_{L^p} = \left( \int_\Omega |r|^p \mathrm{d}\boldsymbol{x} \right)^{1/p} \quad \text{for } 1 \le p < \infty$$

the following approximation holds:

$$\|v - \Pi_h(v)\|_{L^p} + h\|\nabla(v - \Pi_h(v))\|_{L^p} \le ch^{k+1}\|v\|_{\mathcal{C}^{k+1}(\bar{\Omega})} \quad [30]$$

where $c$ is a constant that depends on the quality of the mesh. More precisely, for $K_m \in \mathcal{T}_h$, let $\rho_{K_m}$ be the diameter of the largest ball that can be inscribed into $K_m$ and let $h_{K_m}$ be the diameter of $K_m$. Then, $c$ depends on $\sigma = \max_{K_m \in \mathcal{T}_h} h_{K_m}/\rho_{K_m}$. Hence, for the mesh to have good interpolation properties, it is recommended that the cells be not too flat. Families of meshes for which $\sigma$ is bounded uniformly with respect to $h$ as $h \to 0$ are said to be *shape-regular families*.

The above example of finite-element approximation space generalizes easily to meshes composed of quadrangles or cuboids. In this case, the shape functions are piecewise polynomials of partial degree at most $k$. These spaces are usually referred to as $\mathbb{Q}_k$ approximation spaces.

## Finite Elements: Approximation

We show in this section how finite-element approximation spaces can be used to approximate some model problems exhibited in the section "Building blocks."

### Advection–Diffusion

Consider the model problem [21] supplemented with the boundary condition $(\kappa\partial_n\phi + r\phi)_{|\partial\Omega} = g$. Assume $\kappa > 0, \alpha + (1/2)\nabla \cdot \boldsymbol{u} \ge 0$, and $r \ge 0$. Define

$$a(\phi, \psi) = \int_\Omega ((\alpha\phi + \beta \cdot \nabla\phi)\psi + \kappa\nabla\phi \cdot \nabla\psi)\mathrm{d}\boldsymbol{x} + \int_{\partial\Omega} r\phi\psi\mathrm{d}s$$

Then, the weak formulation of [21] is: seek $\phi \in H$ ($H$ defined in [13]) such that for all $\psi \in H$

$$a(\phi, \psi) = \int_\Omega f\psi\mathrm{d}\boldsymbol{x} + \int_{\partial\Omega} g\psi\mathrm{d}s \quad [31]$$

Using the approximation space $V_h$ defined in [25] together with the basis defined in [27], we seek an approximate solution to the above problem in the form $\phi_h = \sum_{i=1}^N U_i\varphi_i \in V_h$. Then, a simple way of approximating [31] consists of seeking $U = (U_1, \ldots, U_N)^{\mathrm{T}} \in \mathbb{R}^N$ such that for all $1 \le i \le N$

$$a(\phi_h, \varphi_i) = \int_\Omega f\varphi_i\mathrm{d}\boldsymbol{x} + \int_{\partial\Omega} g\varphi_i\mathrm{d}s \quad [32]$$

This problem finally amounts to solving the following linear system:

$$\mathcal{A}U = F \quad [33]$$

where $\mathcal{A}_{ij} = a(\varphi_j, \varphi_i)$ and

$$F_i = \int_\Omega f\varphi_i \mathrm{d}\boldsymbol{x} + \int_{\partial\Omega} g\varphi_i \mathrm{d}s$$

The above approximation technique is usually referred to as *the Galerkin method*. The following error estimate can be proved:

$$\|\phi - \phi_h\|_{L^p} + h\|\nabla(\phi - \phi_h)\|_{L^p} \leq ch^{k+1}\|\phi\|_{C^{k+1}(\bar{\Omega})} \quad [34]$$

where, in addition to depending on the shape regularity of the mesh, the constant $c$ also depends on $\kappa$, $\alpha$, and $\beta$.

### Stokes Equations

The line of thought developed above can be used to approximate the Navier–Stokes problem [15]–[16]. Let us assume that the nonlinear term $\boldsymbol{u} \cdot \nabla\boldsymbol{u}$ is linearized in the form $\boldsymbol{v} \cdot \nabla\boldsymbol{u}$, where $\boldsymbol{v}$ is known. Let $\mathcal{T}_h$ be a mesh of $\Omega$, and assume that finite-element approximation spaces have been constructed to approximate the velocity and the pressure, say $\boldsymbol{X}_h$ and $M_h$. Assume for the sake of simplicity that $\boldsymbol{X}_h \subset \boldsymbol{X}$ and $M_h \subset M$. Assume that bases for $\boldsymbol{X}_h$ and $M_h$ are at hand, say $\{\varphi_1, \ldots, \varphi_{N_u}\}$ and $\{\psi_1, \ldots, \psi_{N_p}\}$, respectively. Set

$$a(\boldsymbol{u}, \boldsymbol{\varphi}) = \int_\Omega ((\boldsymbol{v} \cdot \nabla\boldsymbol{u}) \cdot \boldsymbol{\varphi} + \nu\nabla\boldsymbol{u} : \nabla\boldsymbol{\varphi} \mathrm{d}\boldsymbol{x}$$

and

$$b(\boldsymbol{v}, \psi) = -\int_\Omega \psi\nabla \cdot \boldsymbol{v} \mathrm{d}\boldsymbol{x}$$

Then, we seek an approximate velocity $\boldsymbol{u}_h = \sum_{i=1}^{N_u} U_i\boldsymbol{\varphi}_i$ and an approximate pressure $p_h = \sum_{k=1}^{N_p} P_k\psi_k$ such that for all $i \in \{1, \ldots, N_u\}$ and all $k \in \{1, \ldots, N_p\}$ the following holds:

$$a(\boldsymbol{u}_h, \boldsymbol{\varphi}_i) + b(\boldsymbol{\varphi}_i, p_h) = \int_\Omega \boldsymbol{f} \cdot \boldsymbol{\varphi}_i \mathrm{d}\boldsymbol{x} \quad [35]$$

$$b(\boldsymbol{u}_h, \psi_k) = 0 \quad [36]$$

Define the matrix $\mathcal{A} \in \mathbb{R}^{N_u, N_u}$ such that $\mathcal{A}_{ij} = a(\boldsymbol{\varphi}_j, \boldsymbol{\varphi}_i)$. Define the matrix $\mathcal{B} \in \mathbb{R}^{N_p, N_u}$ such that $\mathcal{B}_{ki} = b(\boldsymbol{\varphi}_i, \psi_k)$. Then, the above problem can be recast into the following partitioned linear system:

$$\begin{bmatrix} \mathcal{A} & \mathcal{B}^{\mathrm{T}} \\ \mathcal{B} & 0 \end{bmatrix} \begin{bmatrix} U \\ P \end{bmatrix} = \begin{bmatrix} F \\ 0 \end{bmatrix} \quad [37]$$

where the vector $F \in \mathbb{R}^{N_u}$ is such that $F_i = \int_\Omega \boldsymbol{f} \cdot \boldsymbol{\varphi}_i$.

An important aspect of the above approximation technique is that, for the linear system to be invertible, the matrix $\mathcal{B}^{\mathrm{T}}$ must have full row rank (i.e., $\mathcal{B}$ has full column rank). This amounts to

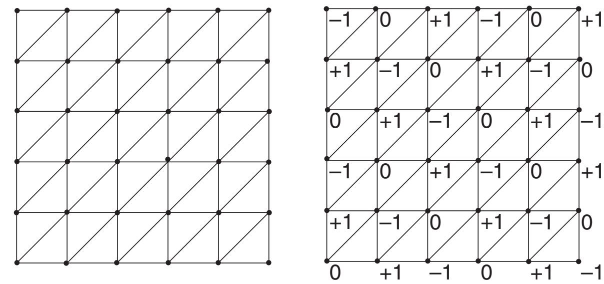

**Figure 3** The $\mathbb{P}_1/\mathbb{P}_1$ finite element: the mesh (left); one pressure spurious mode (right).

$$\exists\beta_h > 0, \quad \inf_{q_h \in M_h} \sup_{\boldsymbol{v}_h \in \boldsymbol{X}_h} \frac{\int_\Omega q_h \nabla \cdot \boldsymbol{v}_h \, \mathrm{d}\boldsymbol{x}}{\|\boldsymbol{v}_h\|_X \|q_h\|_M} \geq \beta_h \quad [38]$$

where

$$\|\boldsymbol{v}_h\|_X^2 = \int_\Omega |\nabla\boldsymbol{v}_h|^2 \mathrm{d}\boldsymbol{x}, \qquad \|q_h\|_M^2 = \int_\Omega q_h^2 \, \mathrm{d}\boldsymbol{x}$$

This nontrivial condition is called the *Ladyženskaja–Babuška–Brezzi condition* (LBB) in the literature. For instance, if $\mathbb{P}_1$ finite elements are used to approximate both the velocity and the pressure, the above condition does not hold, since there are nonzero pressure fields $q_h$ in $M_h$ such that $\int_\Omega q_h \nabla \cdot \boldsymbol{v}_h \mathrm{d}\boldsymbol{x} = 0$ for all $\boldsymbol{v}_h$ in $\boldsymbol{X}_h$. Such fields are called *spurious pressure modes*. An example is shown in Figure 3. The spurious function alternatively takes the values $-1, 0$, and $+1$ at the vertices of the mesh so that its mean value on each cell is zero.

Couples of finite-element spaces satisfying the LBB condition are numerous. For instance, assuming $k \geq 2$, using $\mathbb{P}_k$ finite elements to approximate the velocity and $\mathbb{P}_{k-1}$ finite elements to approximate the pressure is acceptable. Likewise, using $\mathbb{Q}_k$ elements for the velocity and $\mathbb{Q}_{k-1}$ elements for the pressure on meshes composed of quadrangles or cuboids is admissible.

Approximation techniques for which the pressure and the velocity degrees of freedom are not associated with the same nodes are usually called *staggered approximations*. Staggering pressure and velocity unknowns is common in solution methods for the incompressible Stokes and Navier–Stokes equations; see also the subsection "Stokes equations."

## Finite Volumes: Principles

The finite-volume method is an approximation technique whose primary goal is to approximate conservation equations, whether time dependent or

not. Given a mesh, say $\mathcal{T}_h = \{K_m\}_{1\leq m\leq N_{\text{el}}}$, and a conservation equation

$$\alpha\partial_t\phi + \nabla\cdot \boldsymbol{F}(\phi, \nabla\phi, \boldsymbol{x}, t) = f \qquad [39]$$

($\alpha = 0$ if the problem is time independent and $\alpha = 1$ otherwise), the main idea underlying every finite-volume method is to represent the approximate solution by its mean values over the mesh cells $(\phi_{K_1}, \ldots, \phi_{K_{N_{\text{el}}}})^{\text{T}} \in \mathbb{R}^{N_{\text{el}}}$ and to test the conservation equation by the characteristic functions of the mesh cells $\{1_{K_1}, \ldots, 1_{K_{N_{\text{el}}}}\}$. For each cell $K_m \in \mathcal{T}_h$, denote by $\boldsymbol{n}_{K_m}$ the outward unit normal vector and denote by $\mathcal{F}_m$ the set of the faces of $K_m$. The finite-volume approximation to [39] consists of seeking $(\phi_{K_1}, \ldots, \phi_{K_{N_{\text{el}}}})^{\text{T}} \in \mathbb{R}^{N_{\text{el}}}$ such that the function $\phi_h = \sum_{m=1}^{N_{\text{el}}} \phi_{K_m} 1_{K_1 m}$ satisfies the following: for all $1 \leq m \leq N_{\text{el}}$

$$|K_m|\alpha d_t\phi_{K_m}(t) + \sum_{\sigma\in\mathcal{F}_m} F_h^{m,\sigma}(\phi_h, \nabla_h\phi_h, t) = \int_K f\,\mathrm{d}\boldsymbol{x} \qquad [40]$$

where

$$|K_m| = \int_K \mathrm{d}\boldsymbol{x}$$

$\nabla_h\phi_h$ is an approximation of $\nabla\phi$, and $F_h^{m,\sigma}$ is an approximation of

$$\int_\sigma \boldsymbol{F}(\phi, \nabla\phi, \boldsymbol{x}, t)\cdot \boldsymbol{n}_{K_m}\mathrm{d}\boldsymbol{\sigma}$$

The precise definition of the so-called approximate flux $F_h^{m,\sigma}$ depends on the nature of the problem (e.g., elliptic, parabolic, hyperbolic, saddle point) and the desired accuracy. In general, the approximate fluxes are required to satisfy the following two important properties:

1. Conservativity: for $K_m, K_l \in \mathcal{T}_h$ such that $\sigma = K_m \cap K_l, F_h^{m,\sigma} = -F_h^{l,\sigma}$.
2. Consistency: let $\psi$ be the solution to [39], and set

$$\psi_h = \frac{1_{K_1}}{|K_1|}\int_{K_1}\psi\mathrm{d}\boldsymbol{x} + \cdots + \frac{1_{K_{N_{\text{el}}}}}{|K_{N_{\text{el}}}|}\int_{K_{N_{\text{el}}}}\psi\mathrm{d}\boldsymbol{x}$$

then

$$F_h^{m,\sigma}(\psi_h, \nabla_h\psi_h, t) \to \int_\sigma \boldsymbol{F}(\psi, \nabla\psi, \boldsymbol{x}, t)\cdot\boldsymbol{n}\,\mathrm{d}\boldsymbol{\sigma} \text{ as } h\to 0$$

The quantity

$$\left|F_h^{m,\sigma}(\psi_h, \nabla_h\psi_h, t) - \int_\sigma \boldsymbol{F}(\psi, \nabla\psi, \boldsymbol{x}, t)\cdot\boldsymbol{n}\,\mathrm{d}\boldsymbol{\sigma}\right|$$

is called the consistency error.

Note that [40] is a system of ordinary differential equations. This system is usually discretized in time by using standard time-marching techniques such as explicit Euler, Runge–Kutta, etc.

The discretization technique described above is sometimes referred to as *cell-centered finite-volume method*. Another method, called *vertex-centered finite volume* method, consists of using the characteristic functions associated with the vertices of the mesh instead of those associated with the cells.

## Finite Volumes: Examples

In this section we illustrate the ideas introduced above. Three examples are developed: the Poisson equation, the transport equation, and the Stokes equations.

### Poisson Problem

Consider the Poisson equation [11] equipped with the boundary condition $\partial_n\phi_{|\partial\Omega} = a$. To avoid technical details, assume that $\Omega = [0, 1]^d$. Let $\mathcal{K}_h$ be a mesh of $\Omega$ composed of rectangles (or cuboids in three dimensions).

The flux function is $\boldsymbol{F}(\phi, \nabla\phi, \boldsymbol{x}) = -\nabla\phi$; hence, $F_h^{m,\sigma}$ must be a consistent conservative approximation of $-\int_\sigma \boldsymbol{n}_{K_m}\cdot\nabla\phi\,\mathrm{d}\boldsymbol{\sigma}$. Let $\sigma$ be an interior face of the mesh and let $K_m, K_l$ be the two cells such that $\sigma = K_m \cap K_l$. Let $\boldsymbol{x}_{K_m}, \boldsymbol{x}_{K_l}$ be the barycenters of $K_m$ and $K_l$, respectively. Then, an admissible formula for the approximate flux is

$$F_h^{m,\sigma} = -\frac{|\sigma|}{|\boldsymbol{x}_{K_m} - \boldsymbol{x}_{K_l}|}(\phi_{K_l} - \phi_{K_m}) \qquad [41]$$

where $|\sigma| = \int_\sigma \mathrm{d}\boldsymbol{\sigma}$. The consistency error is $\mathcal{O}(h)$ in general, and is $\mathcal{O}(h^2)$ if the mesh is composed of identical cuboids. The conservativity is evident. If $\sigma$ is part of $\partial\Omega$, an admissible formula for the approximate flux is $F_h^{m,\sigma} = -\int_\sigma a\,\mathrm{d}\boldsymbol{\sigma}$. Then, upon defining $\mathcal{F}^i_{K_m} = \mathcal{F}_{K_m}\backslash\partial\Omega$ and $\mathcal{F}^\partial_{K_m} = \mathcal{F}_{K_m}\cap\partial\Omega$, the finite-volume approximation of the Poisson problem is: seek $\phi_h \in \mathbb{R}^{N_{\text{el}}}$ such that for all $1 \leq m \leq N_{\text{el}}$

$$\sum_{\sigma\in\mathcal{F}^i_{K_m}} F_h^{m,\sigma} = \int_{K_m} f\,\mathrm{d}\boldsymbol{x} + \sum_{\sigma\in\mathcal{F}^\partial_{K_m}}\int_\sigma a\,\mathrm{d}\boldsymbol{\sigma} \qquad [42]$$

### Transport Equation

Consider the transport equation

$$\partial_t\phi + \nabla\cdot(\boldsymbol{u}\phi) = f \qquad [43]$$

$$\phi_{|t=0} = \phi_0, \quad \phi_{|\partial\Omega^-} = a \qquad [44]$$

where $\boldsymbol{u}(\boldsymbol{x}, t)$ is a given field in $\mathcal{C}^1(\bar{\Omega}\times[0, T])$. Let $\mathcal{T}_h$ be a mesh of $\Omega$. For the sake of simplicity, let us use the explicit Euler time-stepping to approximate [40].

Let $N$ be positive integer, set $\Delta t = T/N$, set $t^n = n\Delta t$ for $0 \le n \le N$, and partition $[0, T]$ as follows:

$$[0, T] = \bigcup_{n=0}^{N-1} [t^n, t^{n+1}]$$

Denote by $\phi_h^n \in \mathbb{R}^{N_{\mathrm{el}}}$ the finite-volume approximation of $\phi_h(t^n)$. Then, [40] is approximated as follows:

$$\frac{|K_m|}{\Delta t}(\phi_{K_m}^{n+1} - \phi_{K_m}^n) + \sum_{\sigma \in \mathcal{F}_m} F_h^{m,\sigma}(\phi_h, \nabla_h \phi_h, t^n) = \int_K f(\boldsymbol{x}, t^n)\, \mathrm{d}\boldsymbol{x} \qquad [45]$$

where $\phi_{K_m}^0 = \int_{K_m} \phi_0\, \mathrm{d}\boldsymbol{x}$. The approximate flux $F_h^{m,\sigma}$ must be a consistent conservative approximation of $\int_\sigma (\boldsymbol{u} \cdot \boldsymbol{n}_{K_m})\phi\, \mathrm{d}\boldsymbol{\sigma}$. Let $\sigma$ be a face of the mesh and let $K_m, K_l$ be the two cells such that $\sigma = K_m \cap K_l$ (note that if $\sigma$ is on $\partial\Omega, \sigma$ belongs to one cell only and we set $K_m = K_l$). If $\sigma$ is on $\partial\Omega^-$, set

$$F_h^{m,\sigma} = \int_\sigma (\boldsymbol{u} \cdot \boldsymbol{n}_{K_m}) a\, \mathrm{d}\boldsymbol{\sigma} \qquad [46]$$

If $\sigma$ is not on $\partial\Omega^-$, set $u_{m,\sigma}^n = \int_\sigma (\boldsymbol{u} \cdot \boldsymbol{n}_{K_m})\mathrm{d}\boldsymbol{\sigma}$ and define

$$F_h^{m,\sigma} = \begin{cases} \phi_{K_m}^n u_{m,\sigma}^n & \text{if } u_{m,\sigma}^n \ge 0 \\ \phi_{K_l}^n u_{m,\sigma}^n & \text{if } u_{m,\sigma}^n < 0 \end{cases} \qquad [47]$$

The above choice for the approximate flux is usually called the *upwind flux*. It is consistent with the analysis that has been done for [22], that is, information flows along the characteristic lines of the field $\boldsymbol{u}$; see [24]. In other words, the updating of $\phi_{k_m}^{n+1}$ must be done by using the approximate values $\phi_h^n$ coming from the cells that are upstream the flow field.

An important feature of the above approximation technique is that it is $L^\infty$-stable, in the sense that

$$\max_{0 \le n \le N, 1 \le m \le N_{\mathrm{el}}} |\phi_{K_m}^n| \le c(u_0, f)$$

if the two mesh parameters $\Delta t$ and $h$ satisfy the so-called *Courant–Friedrichs–Levy* (CFL) condition $\|\boldsymbol{u}\|_{L^\infty} \Delta t / h \le c(\sigma)$, where $c(\sigma)$ is a constant that depends on the mesh regularity parameter $\sigma = \max_{K_m \in \mathcal{T}_h} h_{K_m}/\rho_{K_m}$. In one dimension, $c(\sigma) = 1$.

### Stokes Equations

To finish this short review of finite-volume methods, we turn our attention to the Stokes problem (15)–(16) equipped with the homogeneous Dirichlet boundary condition $\boldsymbol{u}_{|\partial\Omega} = \boldsymbol{0}$.

Let $\mathcal{T}_h$ be a mesh of $\Omega$ composed of triangles (or tetrahedrons). All the angles in the triangulation are assumed to be acute so that, for all $K \in \mathcal{T}_h$, the intersection of the orthogonal bisectors of the sides of $K$, say $\boldsymbol{x}_K$, is in $K$. We propose a finite-volume approximation for the velocity and a finite-element approximation for the pressure. Let $\{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_d\}$ be a Cartesian basis for $\mathbb{R}^d$. Set $\mathbf{1}_{K_m}^k = 1_{K_m}\boldsymbol{e}_k$ for all $1 \le m \le N_{\mathrm{el}}$ and $1 \le k \le d$; then define

$$\boldsymbol{X}_h = \mathrm{span}\left\{\mathbf{1}_{K_1}^1, \ldots, \mathbf{1}_{K_1}^d, \ldots, \mathbf{1}_{K_{N_{\mathrm{el}}}}^1, \ldots, \mathbf{1}_{K_{N_{\mathrm{el}}}}^d\right\}$$

Let $\{\boldsymbol{b}_1, \ldots, \boldsymbol{b}_{N_v}\}$ be the vertices of the mesh, and let $\{\varphi_1, \ldots, \varphi_{N_v}\}$ be the associated piecewise linear global shape functions. Then, set (see the section "Finite elements: interpolation")

$$N_h = \mathrm{span}\{\varphi_1, \ldots, \varphi_{N_v}\}$$
$$M_h = \{q \in N_h; \int_\Omega q\, \mathrm{d}\boldsymbol{x} = 0\}$$

The approximate problem consists of seeking $(\boldsymbol{u}_{K_1}, \ldots, \boldsymbol{u}_{K_{N_{\mathrm{el}}}}) \in \mathbb{R}^{dN_{\mathrm{el}}}$ and $p_h \in M_h$ such that for all $1 \le m \le N_{\mathrm{el}}, 1 \le k \le d$, and all $1 \le i \le N_v$,

$$\sum_{\sigma \in \mathcal{F}_m} \mathbf{1}_{K_m}^k \cdot \boldsymbol{F}_h^{m,\sigma} + c\left(\mathbf{1}_{K_m}^k, p_h\right) = \int_{K_m} \mathbf{1}_{K_m}^k \cdot \boldsymbol{f} \mathrm{d}\boldsymbol{x} \qquad [48]$$

$$c(\boldsymbol{u}_{K_m}, \varphi_i) = 0 \qquad [49]$$

where

$$c(\boldsymbol{v}_{K_m}, p_h) = \int_{K_m} \boldsymbol{v}_{K_m} \cdot \nabla p_h \mathrm{d}\boldsymbol{x}$$

Moreover,

$$\boldsymbol{F}_h^{m,\sigma} = \begin{cases} \dfrac{\nu|\sigma|}{|\boldsymbol{x}_m - \boldsymbol{x}_l|}(\boldsymbol{u}_{K_m} - \boldsymbol{u}_{K_l}) & \text{if } \sigma = K_m \cap K_l \\ \dfrac{\nu|\sigma|}{d(\boldsymbol{x}_m, \sigma)} \boldsymbol{u}_{K_m} & \text{if } \sigma = K_m \cap \partial\Omega \end{cases}$$

where $d(\boldsymbol{x}_{K_m}, \sigma)$ is the Euclidean distance between $\boldsymbol{x}_{K_m}$ and $\sigma$. This formulation yields a linear system with the same structure as in [37]. Note in particular that

$$\sup_{\boldsymbol{v}_h \in \boldsymbol{X}_h} \frac{c(\boldsymbol{v}_h, p_h)}{\|\boldsymbol{v}_h\|_{L^\infty}} = \|\nabla p_h\|_{L^1} \qquad [50]$$

Since the mean value of $p_h$ is zero, $\|\nabla p_h\|_{L^1}$ is a norm on $M_h$. As a result, an inequality similar to [38] holds. This inequality is a key step to proving that the linear system is wellposed and the approximate solution converges to the exact solution of (15)–(16).

## Projection Methods for Navier–Stokes

In this section we focus on the time approximation of the Navier–Stokes problem:

$$\partial_t \boldsymbol{u} - \nu \Delta \boldsymbol{u} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} + \nabla p = \boldsymbol{f} \qquad [51a]$$

$$\nabla \cdot \boldsymbol{u} = 0 \qquad [51b]$$

$$\boldsymbol{u}_{|\partial\Omega} = 0 \qquad [51c]$$

$$\boldsymbol{u}_{|t=0} = \boldsymbol{u}_0 \qquad [51d]$$

where $\boldsymbol{f}$ is a body force and $\boldsymbol{u}_0$ is a solenoidal velocity field. There are numerous ways to discretize this problem in time, but, undoubtedly, one of the most popular strategies is to use projection methods, sometimes also referred to as *Chorin–Temam methods*.

A projection method is a fractional-step time-marching technique. It is a predictor–corrector strategy aiming at uncoupling viscous diffusion and incompressibility effects. One time step is composed of three substeps: in the first substep, the pressure is made explicit and a provisional velocity field is computed using the momentum equation; in the second substep, the provisional velocity field is projected onto the space of incompressible (solenoidal) vector fields; in the third substep, the pressure is updated.

Let $q > 0$ be an integer and approximate the time derivative of $\boldsymbol{u}$ using a backward difference formula of order $q$. To this end, introduce a positive integer $N$, set $\Delta t = T/N$, set $t^n = n\Delta t$ for $0 \leq n \leq N$, and consider a partitioning of the time interval in the form

$$[0, T] = \bigcup_{n=0}^{N-1} [t^n, t^{n+1}]$$

For all sequences $\boldsymbol{v}_{\Delta t} = (\boldsymbol{v}^0, \boldsymbol{v}^1, \ldots, \boldsymbol{v}^N)$, set

$$D^{(q)}\boldsymbol{v}^{n+1} = \beta_q \boldsymbol{v}^{n+1} - \sum_{j=0}^{q-1} \beta_j \boldsymbol{v}^{n-j} \qquad [52]$$

where $q - 1 \leq n \leq N - 1$. The coefficients $\beta_j$ are such that

$$\frac{1}{\Delta t}(\beta_q \boldsymbol{u}(t^{n+1}) - \sum_{j=0}^{q-1} \beta_j \boldsymbol{u}(t^{n-j}))$$

is a $q$th-order backward difference formula approximating $\partial_t \boldsymbol{u}(t^{n+1})$. For instance,

$$D^{(1)}\boldsymbol{v}^{n+1} = \boldsymbol{v}^{n+1} - \boldsymbol{v}^n$$

$$D^{(2)}\boldsymbol{v}^{n+1} = \tfrac{3}{2}\boldsymbol{v}^{n+1} - 2\boldsymbol{v}^n + \tfrac{1}{2}\boldsymbol{v}^{n-1}$$

Furthermore, for all sequences $\phi_{\Delta t} = (\phi^0, \phi^1, \ldots, \phi^N)$, define

$$\phi^{\star, n+1} = \sum_{j=0}^{q-1} \gamma_j \phi^{n-j} \qquad [53]$$

so that $\sum_{j=0}^{q-1} \gamma_j p(t^{n-j})$ is a $(q-1)$th-order extrapolation of $p(t^{n+1})$. For instance, $p^{\star,n+1} = 0$ for $q = 1, p^{\star,n+1} = p^n$ for $q = 2$, and $p^{\star,n+1} = 2p^n - p^{n-1}$ for $q = 3$. Finally, denote by $(\boldsymbol{u} \cdot \nabla \boldsymbol{u})^{\star,n+1}$ a $q$th-order extrapolation of $(\boldsymbol{u} \cdot \nabla \boldsymbol{u})(t^{n+1})$. For instance,

$$(\boldsymbol{u} \cdot \nabla \boldsymbol{u})^{\star,n+1} = \begin{cases} \boldsymbol{u}^n \cdot \nabla \boldsymbol{u}^n & \text{for } q = 1 \\ 2\boldsymbol{u}^n \cdot \nabla \boldsymbol{u}^n - \boldsymbol{u}^{n-1} \cdot \nabla \boldsymbol{u}^{n-1} & \text{if } q = 2 \end{cases}$$

A general projection algorithm is as follows. Set $\tilde{\boldsymbol{u}}^0 = \boldsymbol{u}_0$ and $\phi^l = 0$ for $0 \leq l \leq q - 1$. If $q > 1$; assume that $\tilde{\boldsymbol{u}}^1, \ldots, \tilde{\boldsymbol{u}}^{q-1}, p^{\star,q}$ and $(\boldsymbol{u} \cdot \nabla \boldsymbol{u})^{\star,q}$ have been initialized properly. For $n \geq q - 1$, seek $\tilde{\boldsymbol{u}}^{n+1}$ such that $\tilde{\boldsymbol{u}}^{n+1}_{|\partial\Omega} = 0$ and

$$\frac{D^{(q)}}{\Delta t}\tilde{\boldsymbol{u}}^{n+1} - \nu \Delta \tilde{\boldsymbol{u}}^{n+1} + \nabla\left(p^{\star,n+1} + \sum_{j=0}^{q-1} \frac{\beta_j}{\Delta t} \phi^{n-j}\right) = \boldsymbol{S}^{n+1} \qquad [54a]$$

where $\boldsymbol{S}^{n+1} = \boldsymbol{f}(t^{n+1}) - (\boldsymbol{u} \cdot \nabla \boldsymbol{u})^{\star,n+1}$. Then solve

$$\Delta \phi^{n+1} = \nabla \cdot \tilde{\boldsymbol{u}}^{n+1}, \qquad \partial_n \phi^{n+1}_{|\partial\Omega} = 0 \qquad [54b]$$

Finally, update the pressure as follows:

$$p^{n+1} = \frac{\beta_q}{\Delta t} \phi^{n+1} + p^{\star,n+1} - \nu \nabla \cdot \tilde{\boldsymbol{u}}^{n+1} \qquad [54c]$$

The algorithm [54a–c] is known in the literature as the rotational form of the pressure-correction method. Upon denoting $u_{\Delta t} = (\boldsymbol{u}(t^0), \ldots, \boldsymbol{u}(t^N))$ and $p_{\Delta t} = (p(t^0), \ldots, p(t^N))$, the above algorithm has been proved to yield the following error estimates:

$$\|u_{\Delta t} - \tilde{\boldsymbol{u}}_{\Delta t}\|_{\ell^2(L^2)} \leq c\Delta t^2$$

$$\|\nabla(u_{\Delta t} - \tilde{\boldsymbol{u}}_{\Delta t})\|_{\ell^2(L^2)} + \|p_{\Delta t} - p_{\Delta t}\|_{\ell^2(L^2)} \leq c\Delta t^{3/2}$$

where $\|\phi_{\Delta t}\|^2_{\ell^2(L^2)} = \Delta t \sum_{n=0}^{N} \int_\Omega |\phi^n|^2 \, d\boldsymbol{x}$.

A simple strategy to initialize the algorithm consists of using $D^{(1)}\boldsymbol{u}^1$ at the first step in [54a]; then using $D^{(2)}\boldsymbol{u}^2$ at the second step, and proceeding likewise until $\tilde{\boldsymbol{u}}^1, \ldots, \tilde{\boldsymbol{u}}^{q-1}$ have all been computed.

At the present time, projection methods count among the few methods that are capable of solving the time-dependent incompressible Navier–Stokes equations in three dimensions on fine meshes within reasonable

computation times. The reason for this success is that the unsplit strategy, which consists of solving

$$\frac{D^{(q)}}{\Delta t}\boldsymbol{u}^{n+1} - \nu\Delta\boldsymbol{u}^{n+1} + \nabla p^{n+1} = \boldsymbol{S}^{n+1} \qquad [55a]$$

$$\nabla \cdot \boldsymbol{u}^{n+1} = 0, \qquad \boldsymbol{u}^{n+1}_{|\partial\Omega} = 0 \qquad [55b]$$

yields a linear system similar to [37], which usually takes far more time to solve than sequentially solving [54a] and [54b]. It is commonly reported in the literature that the ratio of the CPU time for solving [55a]–[55b] to that for solving [54a–c] ranges between 10 to 30.

## Introduction

In the famous 1822 treatise by Jean Baptiste Joseph Fourier, *Théorie analytique de la chaleur*, the *Discours préliminaire* opens with: "Primary causes are unknown to us; but are subject to simple and constant laws, which may be discovered by observation, the study of them being the subject of natural philosophy. Heat, like gravity, penetrates every substance of the universe, its rays occupy all parts of space. The object of our work is to set forth the mathematical laws which this element obeys. The theory of heat will hereafter form one of the most important branches of general physics." After a brief discussion of rational mechanics, he continues with the sentence: "But whatever may be the range of mechanical theories, they do not apply to the effects of heat. These make up a special order of phenomena, which cannot be explained by the principles of motion and equilibria." Fourier goes on with a thorough description of the phenomenology of heat transport and the derivation of the partial differential equation describing heat transport: the heat equation. A large part of the treatise is then devoted to solving the heat equation for various geometries and boundary conditions. Fourier's treatise marks the birth of Fourier analysis. After Boltzmann, Gibbs, and Maxwell and the invention of statistical mechanics in the decades after Fourier's work, we believe that Fourier was wrong and that, in principle, heat transport can and should be explained "by the principles of motion and equilibria," that is, within the formalism of statistical mechanics. But well over a century after the foundations of statistical mechanics were laid down, we still lack a mathematically reasonable derivation of Fourier's law from first principles. Fourier's law describes the macroscopic transport properties of heat, that is, energy, in nonequilibrium systems. Similar laws are valid for the transport of other locally conserved quantities, for example, charge, particle density, momentum, etc. We will not discuss these laws here, except to point out that in none of these cases macroscopic transport laws have been derived from microscopic dynamics. As Peierls once put it: "It seems there is no problem in modern physics for which there are on record as many false starts, and as many theories which overlook some essential feature, as in the problem of the thermal conductivity of [electrically] non-conducting crystals."

## Macroscopic Law

Consider a macroscopic system characterized at some initial time, say $t = 0$, by a nonuniform

temperature profile $T_0(\boldsymbol{r})$. This temperature profile will generate a heat, that is, energy current $\boldsymbol{J}(\boldsymbol{r})$. Due to energy conservation and basic thermodynamics:

$$c_v(T)\frac{\partial}{\partial t}T(\boldsymbol{r},t) = -\nabla\cdot\boldsymbol{J} \qquad [1]$$

where $c_v(T)$ is the specific heat per unit volume. On the other hand, we know that if the temperature profile is uniform, that is, if $T_0(\boldsymbol{r}) \equiv T_0$, there is no current in the system. It is then natural to assume that, for small temperature gradients, the current is given by

$$\boldsymbol{J}(\boldsymbol{r}) = -\kappa(T(\boldsymbol{r}))\nabla T(\boldsymbol{r}) \qquad [2]$$

where $\kappa(T)$ is the conductivity. Here we have assumed that there is no mass flow or other mode of energy transport besides heat conduction (we also ignore, for simplicity, any variations in density or pressure). Equation [2] is normally called as Fourier's law. Putting together eqns [1] and [2], we get the heat equation:

$$c_v(T)\frac{\partial}{\partial t}T(\boldsymbol{r},t) = \nabla\cdot[\kappa(T)\nabla T] \qquad [3]$$

This equation must be completed with suitable boundary conditions. Let us consider two distinct situations in which the heat equation is observed to hold experimentally with high precision:

1. An isolated macroscopic system, for example, a fluid or solid in a domain $\Lambda$ surrounded by effectively adiabatic walls. In this case, eqn [3] is to be solved subject to the initial condition $T(\boldsymbol{r},0) = T_0(\boldsymbol{r})$ and no heat flux across the boundary of $\Lambda$ (denoted by $\partial\Lambda$), that is, $\boldsymbol{n}(\boldsymbol{r})\cdot\nabla T(\boldsymbol{r}) = 0$ if $\boldsymbol{r}\in\partial\Lambda$ with $\boldsymbol{n}$ the normal vector to $\partial\Lambda$ at $\boldsymbol{r}$. As $t\to\infty$, the system reaches a stationary state characterized by a uniform temperature $\bar{T}$ determined by the constancy of the total energy.
2. A system in contact with heat reservoirs. Each reservoir $\alpha$ fixes the temperature of some portion $(\partial\Lambda)_\alpha$ of the boundary $\partial\Lambda$. The rest of the boundary is insulated. When the system reaches a stationary state (again assuming no matter flow), its temperature will be given by the solution of eqn [3] with the left-hand side set equal to zero,

   $$\nabla\cdot\tilde{J}(\boldsymbol{r}) = \nabla\cdot(\kappa\nabla\tilde{T}(\boldsymbol{r})) = 0 \qquad [4]$$

   subject to the boundary condition $\tilde{T}(\boldsymbol{r}) = T_\alpha$ for $\boldsymbol{r}\in(\partial\Lambda)_\alpha$ and no flux across the rest of the boundary.

The simplest geometry for a conducting system is that of a cylindrical slab of height $h$ and cross-sectional area $A$. It can be either a cylindrical container filled with a fluid or a piece of crystalline solid. In both cases, one keeps the lateral surface of the cylinder insulated. If the top and the bottom of the cylinder are also insulated we are in case (1). If one keeps the top and the bottom in contact with thermostats at temperatures $T_\mathrm{h}$ and $T_\mathrm{b}$, respectively, this is (for a fluid) the usual setup for a Benard experiment. To avoid convection, one has to make $T_\mathrm{h} > T_\mathrm{b}$ or keep $|T_\mathrm{h} - T_\mathrm{b}|$ small. Assuming uniformity in the direction perpendicular to the vertical $x$-axis one has, in the stationary state, a temperature profile $\tilde{T}(x)$ with $\tilde{T}(0) = T_\mathrm{b}, \tilde{T}(h) = T_\mathrm{h}$ and $\kappa(\tilde{T})\mathrm{d}\tilde{T}/\mathrm{d}x = \text{const.}$ for $x\in(0,h)$.

In deriving the heat equation, we have implicitly assumed that the system is described fully by specifying its temperature $T(\boldsymbol{r},t)$ everywhere in $\Lambda$. What this means on the microscopic level is that we imagine the system to be in local thermal equilibrium (LTE). Heuristically, we might think of the system as being divided up (mentally) into many little cubes, each large enough to contain very many atoms yet small enough on the macroscopic scale to be accurately described, at a specified time $t$, as a system in equilibrium at temperature $T(\boldsymbol{r}_i,t)$, where $\boldsymbol{r}_i$ is the center of the $i$th cube. For slow variation in space and time, we can then use a continuous description $T(\boldsymbol{r},t)$. The theory of the heat equation is very developed and, together with its generalizations, plays a central role in modern analysis. In particular, one can consider more general boundary conditions. Here we are interested in the derivation of eqn [2] from first principles. This clearly presupposes, as a first fundamental step, a precise definition of the concept of LTE and its justification within the law of mechanics.

## Empirical Argument

A theory of heat conduction has as a goal the computation of the conductivity $\kappa(T)$ for realistic models, or, at the very least, the derivation of behavior of $\kappa(T)$ as a function of $T$. The early analysis was based on "kinetic theory." Its application to heat conduction goes back to the works of Clausius, Maxwell, and Boltzmann, who obtained a theoretical expression for the heat conductivity of gases, $\kappa\sim\sqrt{T}$, independent of the gas density. This agrees with experiment (when the density is not too high) and was a major early achievement of the atomic theory of matter.

### Heat Conduction in Gases

Clausius and Maxwell used the concept of a "mean free path" $\lambda$: the average distance a particle (atom or

molecule) travels between collisions in a gas with particle density $\rho$. Straightforward analysis gives $\lambda \sim 1/\rho\pi\sigma^2$, where $\sigma$ an "effective" hard-core diameter of a particle. They considered a gas with temperature gradient in the $x$-direction and assumed that the gas is (approximately) in local equilibrium with density $\rho$ and temperature $T(x)$. Between collisions, a particle moves a distance $\lambda$ carrying a kinetic energy proportional to $T(x)$ from $x$ to $x + \lambda/\sqrt{3}$, while in the opposite direction the amount carried is proportional to $T(x + \lambda\sqrt{3})$. Taking into account the fact that the speed is proportional to $\sqrt{T}$ the amount of energy $J$ transported per unit area and time across a plane perpendicular to the $x$-axis is approximately

$$J \sim \rho\sqrt{T}\Big[T(x) - T(x + \lambda\sqrt{3})\Big] \sim -\sigma^{-2}\sqrt{T}\frac{\mathrm{d}T}{\mathrm{d}x} \qquad [5]$$

and so $\kappa \sim \sqrt{T}$ independent of $\rho$, in agreement with experiment. It was clear to the founding fathers that starting with a local equilibrium situation the process described above will produce, as time goes on, a deviation from LTE. They reasoned, however, that this deviation from local equilibrium will be small when $(\lambda/T)\mathrm{d}T/\mathrm{d}x \ll 1$, the regime in which Fourier's law is expected to hold, and the above calculation should yield, up to some factor of order unity, the right heat conductivity. To have a more precise theory, one can describe the state of the gas through the probability distribution $f(\boldsymbol{r}, \boldsymbol{p}, t)$ of finding a particle in the volume element $\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{p}$ around the phase space point $(\boldsymbol{r}, \boldsymbol{p})$. Here LTE means that

$$f(\boldsymbol{r}, \boldsymbol{p}, t) \simeq \exp\left(-\frac{p^2}{2mkT(\boldsymbol{r})}\right)$$

where $m$ is the mass of the particles. If one computes the heat flux at a point $\boldsymbol{r}$ by averaging the microscopic energy current at $\boldsymbol{r}$, $j = \rho\boldsymbol{v}(1/2mv^2)$, over $f(\boldsymbol{r}, \boldsymbol{p}, t)$ then it is only the deviation from local equilibrium which makes a contribution. The result however is essentially the same as eqn [5]. This was shown by Boltzmann, who derived an accurate formula for $\kappa$ in gases by using the Boltzmann equation. If one takes $\kappa$ from experiment, the above analysis yields a value for $\sigma$, the effective size of an atom or molecule, which turns out to be close to other determinations of the characteristic size of an atom. This gave an evidence for the reality of atoms and the molecular theory of heat.

### Heat Conduction in Insulating Crystals

In (electrically) conducting solids, heat is mainly transported by the conduction electron. In this case, one can adapt the theory discussed in the previous section. In (electrically) insulating solids, on the other hand, heat is transmitted through the vibrations of the lattice. In order to use the concepts of kinetic theory, it is useful to picture a solid as a gas of phonons which can store and transmit heat. A perfectly harmonic crystal, due to the fact that phonons do not interact, has an infinite thermal conductivity: in the language of kinetic theory, the mean free path $\lambda$ is infinite. In a real crystal, the anharmonic forces produce interactions between the phonons and therefore a finite mean free path. Another source of finite thermal conductivity may be the lattice imperfections and impurities which scatter the phonons. Debye devised a kind of kinetic theory for phonons in order to describe thermal conductivity. One assumes that a small gradient of temperature is imposed and that the collisions between phonons maintain local equilibrium. An elementary argument gives a thermal conductivity analogous to eqn [5] obtained in the last subsection for gases (remembering, however, that the density of phonons is itself a function of $T$)

$$\kappa \sim c_v c^2 \tau \qquad [6]$$

where, with respect to eqn [5], $\rho$ has been replaced by $c_v$, the specific heat of phonons, $\sqrt{T}$ by $c$, the (mean) velocity of the phonons, and $\lambda$ by $c\tau$, where $\tau$ is the effective mean free time between phonon collisions. The thermal conductivity depends on the temperature via $\tau$, and a more refined theory is needed to account for this dependence. This was done by Peierls via a Boltzmann equation for the phonons. In collisions among phonons, the momentum of phonons is conserved only modulo a vector of the reciprocal lattice. One calls "normal processes" those where the phonon momentum is conserved and "Umklap processes" those where the initial and final momenta differ by a nonzero reciprocal lattice vector. Peierls' theory may be summarized (very roughly) as follows: in the absence of Umklap processes, the mean free path, and thus the thermal conductivity of an insulating solid, is infinite. A success of Peierls' theory is to describe correctly the temperature dependence of the thermal conductivity. Furthermore, on the basis of this theory, one does not expect a finite thermal conductivity in one-dimensional monoatomic lattices with pair interactions. This seems so far to be a correct prediction, at least in the numerous numerical results performed on various models.

## Statistical Mechanics Paradigm: Rigorous Analysis

In a rigorous approach to the above arguments, we have to first formulate precisely the problem on a

mathematical level. It is natural to adapt the standard formalism of statistical mechanics to our situation. To this end, we assume that our system is described by the positions $Q$ and momenta $P$ of a (very large) number of particles, $N$, with $Q = (\boldsymbol{q}_1, \ldots, \boldsymbol{q}_N) \in \Lambda^N, \Lambda \subset \mathbb{R}^d$, and $P = (\boldsymbol{p}_1, \ldots, \boldsymbol{p}_N) \in \mathbb{R}^{dN}$. The dynamics (in the bulk) is given by a Hamiltonian function $H(Q, P)$. A state of the system is a probability measure $\mu(P, Q)$ on phase space. As usual in statistical mechanics, the value of an observable $f(P, Q)$ will be given by the expected value of $f$ with respect to the measure $\mu$. In the case of a fluid contained in a region $\Lambda$, we can assume that the Hamiltonian has the form

$$H(P, Q) = \sum_{i=1}^{N} \left[ \frac{\boldsymbol{p}_i^2}{2m} + \sum_{j \neq i} \phi(\boldsymbol{q}_j - \boldsymbol{q}_i) + u(\boldsymbol{q}_i) \right] = \sum_{i=1}^{N} \frac{\boldsymbol{p}_i^2}{2m} + \mathcal{V}(Q) \qquad [7]$$

where $\phi(\boldsymbol{q})$ is some short-range interparticle potential and $u(\boldsymbol{q}_i)$ an external potential (*e.g.*, the interaction of the particle with fixed obstacles such as a conduction electron interacting with the fixed crystalline ions). If we want to describe the case in which the temperature at the boundary is kept different in different regions $\partial\Lambda_\alpha$, we have to properly define the dynamics at the boundary of the system. A possibility is to use "Maxwell boundary conditions": when a particle hits the wall in $\partial\Lambda_\alpha$, it gets reflected and re-emerges with a distribution of velocities

$$f_\alpha(\mathrm{d}\boldsymbol{v}) = \frac{m^2}{2\pi(kT_\alpha)^2} |v_x| \exp\left[ -\frac{m\boldsymbol{v}^2}{2kT_\alpha} \right] \mathrm{d}\boldsymbol{v} \qquad [8]$$

Several other ways to impose boundary conditions have been considered in the literature. The notion of LTE can be made precise here in the so-called hydrodynamic scaling limit (HSL), where the ratio of microscopic to macroscopic scales goes to zero. The macroscopic coordinates $\boldsymbol{r}$ and $t$ are related to the microscopic ones $\boldsymbol{q}$ and $\tau$, by $\boldsymbol{r} = \epsilon\boldsymbol{q}$ and $t = \epsilon^\alpha \tau$, that is, if $\Lambda$ is a cube of macroscopic sides $l$, then its sides, now measured in microscopic length units, are of length $L = \epsilon^{-1} l$. We then suppose that at $t = 0$ our system of $N = \rho L^d$ particles is described by an equilibrium Gibbs measure with a temperature $T(\boldsymbol{r}) = T(\epsilon\boldsymbol{q})$: roughly speaking, the phase-space ensemble density has the form

$$\mu_0(P, Q) \sim \exp\left\{ -\sum_{i=1}^{N} \beta_0(\epsilon\boldsymbol{q}_i) \times \left[ \frac{\boldsymbol{p}_i^2}{2m} + \sum_{j \neq i} \phi(\boldsymbol{q}_j - \boldsymbol{q}_i) + u(\boldsymbol{q}_i) \right] \right\} \qquad [9]$$

where $\beta_0^{-1}(\boldsymbol{r}) = T_0(\boldsymbol{r})$. In the limit $\epsilon \to 0, \rho$ fixed, the system at $t = 0$ will be macroscopically in LTE with a local temperature $T_0(\boldsymbol{r})$ (as already noted, here we suppress the variation in the particle density $n(\boldsymbol{r})$). We are interested in the behavior of a macroscopic system, for which $\epsilon \ll 1$, at macroscopic times $t \geq 0$, corresponding to microscopic times $\tau = \epsilon^{-\alpha} t, \alpha = 2$ for heat conduction or other diffusive behavior. The implicit assumption then made in the macroscopic description given earlier is that, since the variations in $T_0(\boldsymbol{r})$ are of order $\epsilon$ on a microscopic scale, then for $\epsilon \ll 1$, the system will, also at time $t$, be in a state very close to LTE, with a temperature $T(\boldsymbol{r}, t)$ that evolves in time according to Fourier's law, eqn [1]. From a mathematical point of view, the difficult problem is to prove that the system stays in LTE for $t > 0$ when the dynamics are given by a Hamiltonian time evolution. This requires proving that the macroscopic system has some very strong ergodic properties, for example, that the only time-invariant measures locally absolutely continuous with respect to the Lebesgue measure are, for infinitely extended spatially uniform systems, of the Gibbs type. This has only been proved so far for systems evolving via stochastic dynamics (e.g., interacting Brownian particles or lattice gases). For such stochastic systems, one can sometimes prove the hydrodynamical limit and derive macroscopic transport equations for the particle or energy density and thus verify the validity of Fourier law. Another possibility, as we already saw, is to use the Boltzmann equation. Using ideas of hydrodynamical space and time scaling described earlier, it is possible to derive a controlled expansion for the solution of the stationary Boltzmann equation describing the steady state of a gas coupled to temperature reservoirs at the top and bottom. One then shows that for $\epsilon \ll 1$, $\epsilon$ being now the ratio $\lambda/L$, the Boltzmann equation for $f$ in the slab has a time-independent solution which is close to a local Maxwellian, corresponding to LTE (apart from boundary layer terms) with a local temperature and density given by the solution of the Navier–Stokes equations which incorporates Fourier's law as expressed in eqn [2]. The main mathematical problem is in controlling the remainder in an asymptotic expansion of $f$ in power of $\epsilon$. This requires that the macroscopic temperature gradient, that is, $|T_1 - T_2|/h$, where $h = \epsilon L$ is the thickness of the slab on the macroscopic scale, be small. Even if this apparently technical problem could be overcome, we would still be left with the question of justifying the Boltzmann equation for such steady states and, of course, it would not tell us anything

about dense fluids or crystals. In fact, the Boltzmann equation itself is really closer to a macroscopic than to a microscopic description. It is obtained in a well-defined kinetic scaling limit in which, in addition to rescaling space and time, the particle density goes to zero, that is, $\lambda \gg \sigma$.

A simplified model of a crystal is characterized by the fact that all atoms oscillate around given equilibrium positions. The equilibrium positions can be thought of as the points of a regular lattice in $\mathbb{R}^d$, say $\mathbb{Z}^d$. Although $d = 3$ is the physical situation, one can also be interested in the case $d = 1, 2$. In this situation, $\Lambda \subset \mathbb{Z}^d$ with cardinality $N$, and each atom is identified by its position $\boldsymbol{x}_i = \boldsymbol{i} + \boldsymbol{q}_i$, where $\boldsymbol{i} \in \Lambda$ and $\boldsymbol{q}_i \in \boldsymbol{R}^d$ is the displacement of the particle at lattice site $\boldsymbol{i}$ from this equilibrium position. Since interatomic forces in real solids have short range, it is reasonable to assume that the atoms interact only with their nearest neighbors via a potential that depends only on the relative distance with respect to the equilibrium distance. Accordingly, the Hamiltonians that we consider have the general form

$$H(P, Q) = \sum_{i \in \Lambda} \frac{\boldsymbol{p}_i^2}{2m} + \sum_{|i-j|=1} V(\boldsymbol{q}_i - \boldsymbol{q}_j) + \sum_i U_i(\boldsymbol{q}_i) = \sum_{i \in \Lambda} \frac{\boldsymbol{p}_i^2}{2m} + \mathcal{V}(Q) \qquad [10]$$

where $P = (\boldsymbol{p}_i)_{i \in \Lambda}$ and analogously for $Q$. We shall further assume that as $|\boldsymbol{q}| \to \infty$ so do $U_i(\boldsymbol{q})$ and $V(\boldsymbol{q})$. The addition of $U_i(\boldsymbol{q})$ pins down the crystal and ensures that $\exp[-\beta H(P, Q)]$ is integrable with respect to $\mathrm{d}P\mathrm{d}Q$, and thus the corresponding Gibbs measure is well defined. In this case, in order to fix the temperature at the boundary, one can add a Langevin term to the equation of particles on the boundaries, that is, if $\boldsymbol{i} \in \partial\Lambda_\alpha$ the equation for the particle is

$$\dot{\boldsymbol{p}}_i = -\partial_{q_i} H(P, Q) - \lambda \boldsymbol{p}_i + \sqrt{\lambda T_\alpha}\, \dot{w}_i \qquad [11]$$

where $\dot{w}_i$ is a standard white noise. Other thermostatting mechanisms can be considered. In this case we can also define LTE using eqn [9] but we run into the same difficulties described above – although the problem is somehow simpler due to the presence of the lattice structure and the fact that the particles oscillate close to their equilibrium points. We can obtain Fourier's law only by adding stochastic terms, for example, terms like eqn [11], to the equation of motion of every particle and assuming that $U(\boldsymbol{q})$ and $V(\boldsymbol{q})$ are harmonic. These added noises can be thought of as an effective description of the chaotic motion generated by the anharmonic terms in $U(\boldsymbol{q})$ and $V(\boldsymbol{q})$.

Just how far we are from establishing rigorously the Fourier law is clear from our very limited mathematical understanding of the stationary nonequilibrium state (SNS) of mechanical systems whose ends are, as in the example of the Benard problem, kept at fixed temperatures $T_1$ and $T_2$. Various models have been considered, for example, models with Hamiltonian [10] coupled at the boundaries with heat reservoirs described by eqns [11]. The best mathematical results one can prove are: the existence and uniqueness of SNS; the existence of a stationary nontrivial heat flow; properties of the fluctuations of the heat flow in the SNS; the central-limit theorem type fluctuations (related to Kubo formula and Onsager relations; and large-deviation type fluctuations related to the Gallavotti–Cohen fluctuation theorem). What is missing is information on how the relevant quantities depend on the size of the system, $N$. In this context, the heat conductivity can be defined precisely without invoking LTE. To do this, we let $\tilde{J}$ be the expectation value in the SNS of the energy or heat current flowing from reservoir 1 to reservoir 2. We then define the conductivity $\kappa_L$ as $\tilde{J}/(A\delta T/L)$, where $\delta T/L = (T_1 - T_2)/L$ is the effective temperature gradient for a cylinder of microscopic length $L$ and uniform cross section $A$, and $\kappa(T)$ is the limit of $\kappa_L$ when $\delta T \to 0 (T_1 = T_2 = T)$ and $L \to \infty$. The existence of such a limit with $\kappa$ positive and finite is what one would like to prove.

# Fourier–Mukai Transform in String Theory

**B Andreas**, Humboldt-Universität zu Berlin, Berlin, Germany

## Introduction

The Fourier–Mukai transform has been introduced in the study of abelian varieties by Mukai and can be thought of as a nontrivial algebro-geometric analog of the Fourier transform. Since its original introduction, the Fourier–Mukai transform turned out to be a useful tool for studying various aspects of sheaves on varieties and their moduli spaces, and as a natural consequence, to learn about the varieties themselves. Various links between geometry and derived categories have been uncovered; for instance, Bondal and Orlov proved that Fano varieties, and certain varieties of general type, can be reconstructed from their derived categories. Moreover, Orlov proved a derived version of the Torelli theorem for K3 surfaces and also a structure theorem for derived categories of abelian varieties. Later, Kawamata gave evidence to the conjecture that two birational smooth projective varieties with trivial canonical sheaves have equivalent derived categories, which has been proved by Bridgeland in dimension 3.

The Fourier–Mukai transform also enters into string theory. The most prominent example is Kontsevich's homological mirror-symmetry conjecture. The conjecture predicts (for mirror dual pairs of Calabi–Yau manifolds) an equivalence between the bounded derived category of coherent sheaves and the Fukaya category. The conjecture implies a correspondence between certain self-equivalences (given by Fourier–Mukai transforms) of the derived category and symplectic self-equivalences of the mirror manifold.

Besides their importance for geometrical aspects of mirror symmetry, the Fourier–Mukai transforms have also been important for heterotic string compactifications. The motivation for this came from the conjectured correspondence between the heterotic string and F-theory, which both rely on elliptically fibered Calabi–Yau manifolds. To give evidence for this correspondence, an explicit description of stable holomorphic vector bundles was necessary and inspired a series of publications by Friedman, Morgan, and Witten. Their bundle construction relies on two geometrical objects: a hypersurface in the Calabi–Yau manifold together with a line bundle on it; more precisely, they construct vector bundles using a relative Fourier–Mukai transform.

Various aspects and refinements of this construction have been studied by now. For instance, a physical way to understand the bundle construction can be given using the fact that holomorphic vector bundles can be viewed as D-branes and that D-branes can be mapped under $T$-duality to new D-branes (of different dimensions).

We survey aspects of the Fourier–Mukai transform, its relative version and outline the bundle construction of Friedman, Morgan, and Witten. The construction has led to many new insights, for instance, the presence of 5-branes in heterotic string vacua has been understood. The construction also inspired a tremendous amount of work towards a heterotic string phenomenology on elliptic Calabi–Yau manifolds. For the many topics omitted the reader should consult the "Further reading" section.

## The Fourier–Mukai Transforms

Every object $E$ of the derived category on the product $X \times Y$ of two smooth algebraic varieties $X$ and $Y$ gives rise to a functor $\Phi^E$ from the bounded derived category $D(X)$ of coherent sheaves on $X$ to the similar category on $Y$:

$$\Phi^E : D(X) \to D(Y)$$
$$F \mapsto \Phi^E(F) = R\hat{\pi}_*(\pi^* F \otimes E)$$

where $\pi, \hat{\pi}$ are the projections from $X \times Y$ to $X$ and $Y$, respectively, and $\otimes$ denotes the derived tensor product. $\Phi^E(F)$ is called Fourier–Mukai transform with kernel $E \in D(X \times Y)$ (in analogy

with the definition of an integral transform with kernel). Note that given a Fourier–Mukai functor $\Phi^E$, $\Phi^E(F)$ is in general a complex having homology in several degrees even if $F$ is a sheaf. Furthermore, a result by Orlov states that if $X$ and $Y$ are smooth projective varieties then any fully faithful functor $D(X) \to D(Y)$ is a Fourier–Mukai functor.

In analogy with the Fourier transform, there is a kind of "convolution product" giving the composition of two such functors. More precisely, given smooth algebraic varieties $X$, $Y$, $Z$, and elements $E \in D(X \times Y)$ and $G \in D(Y \times Z)$, we can define $G \circ E \in D(X \times Z)$ by

$$G \circ E = R\pi_{XZ_*}(\pi^*_{XY}E \otimes \pi^*_{YZ}G)$$

where $\pi_{XY}, \pi_{YZ}, \pi_{XZ}$ are the projections from $X \times Y \times Z$ to the pairwise products giving a natural isomorphism of functors

$$\Phi^G \circ \Phi^E = \Phi^{G \circ E}$$

Another analogy with the Fourier transform can be drawn. For this, assume that we have sheaves $F$ and $G$ which only have one nonvanishing Fourier–Mukai transform, the $i$th one $\Phi^i(F)$ (where $\Phi^i$: $D(X) \to \mathrm{Coh}(Y), F \mapsto \mathcal{H}^i(\Phi^E(F))$; cf. remarks below) in the case of $F$, and the $j$th one $\Phi^j(G)$ in the case of $G$. Given such sheaves, there is the Parseval formula

$$\mathrm{Ext}^h_X(F, G) = \mathrm{Ext}^{h+i-j}_Y(\Phi^i(F), \Phi^j(G))$$

which gives a correspondence between the extensions of $F, G$ and the extensions of their Fourier–Mukai transforms. This formula can be considered as the analog of the Parseval formula for the ordinary Fourier transform for functions on a torus.

The Parseval formula can be proved using two facts. First, for arbitrary coherent sheaves $E, G$ the Ext groups can be computed in terms of the derived category, namely

$$\mathrm{Ext}^i(E, G) = \mathrm{Hom}_{D(X)}(E, G[i])$$

Second, the Fourier–Mukai transforms of $F$ and $G$ in the derived category $D(X)$ are given by $\Phi(F) = \Phi^i(F)[-i]$ and $\Phi(G) = \Phi^j(G)[-j]$. Since the Fourier–Mukai transform is an equivalence of categories, we have

$$\mathrm{Hom}_{D(X)}(F, G[i]) = \mathrm{Hom}_{D(X)}(\Phi^i(F), \Phi^j(G)[i - j + h])$$

implying the Parseval formula.

A first simple example of a Fourier–Mukai functor can be given: let $F$ be the complex in $D(X \times X)$ defined by the structure sheaf $\mathcal{O}_\Delta$ of the diagonal $\Delta \subset X \times X$. Then it is easy to check that $\Phi^F$: $D(X) \to D(X)$ is isomorphic to the identity functor on $D(X)$. Moreover, if we shift degrees by $n$ taking $F = \mathcal{O}_\Delta[n]$ (a complex with only the sheaf $\mathcal{O}_\Delta$ placed in degree $n$), then $\Phi^F: D(X) \to D(X)$ is the degree shifting functor $\mathcal{G} \mapsto \mathcal{G}[n]$.

As we will be interested in relative Fourier–Mukai transforms for elliptic fibrations, let us consider the case of a Fourier– Mukai transform on an elliptic curve: consider an elliptic curve $E$ with a fixed origin $p_0$ and identify $E$ with $\hat{E} = \mathrm{Pic}^0(E)$ via $f: E \to \hat{E}, x \mapsto \mathcal{O}_E(x - p_0)$. As kernel we take the normalized Poincaré line bundle $\mathcal{P} := \mathcal{O}_{E \times E}(\Delta - \{p_0\} \times E - E \times \{p_0\})$. The restriction of $\mathcal{P}$ to $p_0 \times E$ or $E \times p_0$ is isomorphic to the trivial line bundle $\mathcal{O}$. $\mathcal{P}$ has the universal property which can be expressed by $\Phi^{\mathcal{P}}(k(x)) = f(x)$, where $k(x)$ is the sheaf supported at a point $x \in E$; in particular, $\Phi^{\mathcal{P}}(k(p_0)) = \mathcal{O}_E$ and $\Phi^{\mathcal{P}}(\mathcal{O}_E) = k(p_0)[-1]$, where $\mathcal{O}_E$ is the structure sheaf of $E$.

### Relative Fourier–Mukai Transforms for Elliptic Fibrations

It is often convenient to study problems for families rather than for single varieties. The main advantage of the relative setting is that base-change properties (or parameter dependencies) are better encoded into the problem. We can do that for Fourier–Mukai functors as well. To this end, we consider two morphisms $p: X \to B, \hat{p}: \widehat{X} \to B$ of algebraic varieties. We will assume that the morphisms are flat and so give nice families of algebraic varieties. We shall define relative Fourier–Mukai functors in this setting by means of a "kernel" $E$ in the derived category $D(X \times_B \widehat{X})$.

Let us make the relative setting explicit for elliptic fibrations: an elliptic fibration is a proper flat morphism $p: X \to B$ of schemes whose fibers are Gorenstein curves of arithmetic genus 1. We also assume that $p$ has a section $\sigma: B \hookrightarrow X$ taking values in the smooth locus $X' \to B$ of $p$. The generic fibres are then smooth elliptic curves, whereas some singular fibers are allowed. If the base $B$ is a smooth curve, elliptic fibrations were studied and classified by Kodaira, who described all the types of singular fibers that may occur, the so-called Kodaira curves. When the base is a smooth surface, more complicated configuration of singular curves can occur and have indeed been studied by Miranda.

First let us fix notation and setup. We denote by $\sigma = \sigma(B)$ the image of the section, by $X_t$ the fiber of $p$ over $t \in B$ (we assume, in what follows, $B$ is either a smooth curve or surface) and by $i_t: X_t \hookrightarrow X$ the inclusion. Furthermore, $\omega_{X/B}$ is the relative dualizing

sheaf and $\omega = R^1 p_* \mathcal{O}_X \xrightarrow{\sim} (p_* \omega_{X/B})^*$, where the isomorphism is Grothendieck–Serre duality for $p$. The sheaf $\mathcal{L} = p_* \omega_{X/B}$ is a line bundle whose first Chern class we denote by $K = c_1(\mathcal{L})$. The adjunction formula for $\sigma \hookrightarrow X$ gives that $\sigma^2 = -\sigma \cdot p^* K$ as cycles on $X$. Moreover, we will consider elliptic fibrations with a section whose fibers are all geometrically integral. This means that the fibration is isomorphic with its Weierstrass model.

From Kodaira's classification of possible singular fibers one finds that the components of reducible fibers of $p$ which do not meet $\sigma$ form rational double point configurations disjoint from $\sigma$. Let $X \to \bar{X}$ be the result of contracting these configurations and let $\bar{p} : \bar{X} \to B$ be the induced map. Then all fibers of $\bar{p}$ are irreducible with at worst nodes or cusps as singularities. In this case, one refers to $\bar{X}$ as the Weierstrass model of $X$.

The Weierstrass model can be constructed as follows: the divisor $3\sigma$ is relatively ample and, if $\mathcal{E} = p_* \mathcal{O}_X(3\sigma) \xrightarrow{\sim} \mathcal{O}_B \oplus \omega^{\otimes 2} \oplus \omega^{\otimes 3}$ and $\bar{p} : P = \mathbb{P}(\mathcal{E}^*) \to B$ is the associated projective bundle, there is a projective morphism $j : X \to P$ such that $j(X) = \bar{X}$.

Now special fibers of $X \to B$ can have at most one singular point, either a cusp or a simple node. Thus, in this case $3\sigma$ is relatively very ample and gives rise to a closed immersion $j : X \hookrightarrow P$ such that $j^* \mathcal{O}_P(1) = \mathcal{O}_X(3\sigma)$, where $j$ is locally a complete intersection whose normal sheaf is $\mathcal{N}(X/P) \xrightarrow{\sim} \pi^* \omega^{-\otimes 6} \otimes \mathcal{O}_X(9\sigma)$. This follows by relative duality since $\omega_{P/B} = \bigwedge \Omega_{P/B} \xrightarrow{\sim} \bar{\pi}^* \omega^{\otimes 5}(-3)$, due to the Euler exact sequence

$$0 \to \Omega_{P/B} \to \bar{\pi}^* \mathcal{E}(-1) \to \mathcal{O}_P \to 0$$

The morphism $p : X \to B$ is then a local complete intersection morphism (cf. Fulton (1984)) and has a virtual relative tangent bundle $T_{X/B} = [j^* T_{P/B}] - [\mathcal{N}_{X/P}]$ in the $K$-group $K^\bullet(X)$. The Todd class of $T_{X/B}$ is given by

$$\begin{aligned}\mathrm{Td}(T_{X/B}) = 1 - \tfrac{1}{2} p^{-1} K + \tfrac{1}{12}(12\sigma \cdot p^{-1} K + 13 p^{-1} K^2) \\ - \tfrac{1}{2} \sigma \cdot p^{-1} K^2 + \text{terms of higher degree}\end{aligned}$$

Now if $\hat{p} : \hat{X} \to B$ denotes the dual elliptic fibration, defined as the relative moduli space of torsion-free rank-1 sheaves of relative degree 0, it is known that for $t \in B$ there is an isomorphism $\hat{X}_t \cong X_t$ between the fibers of both fibrations. Since we assume that the original fibration $p : X \to B$ has a section $\sigma$, then $p$ and $\hat{p}$ are globally isomorphic; hereafter we identify $X \cong \widehat{X}$, where $\hat{X}$ denotes the compactified relative Jacobian of $X$.

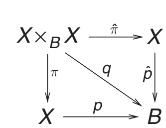
Note that $\hat{X}$ is the scheme representing the functor which, to any scheme morphism $\phi : S \to B$, associates the space of equivalence classes of $S$-flat sheaves on $p_s : X \times_B S \to S$, whose restrictions to the fibers of $\phi$ are torsion-free (the usual definition of "torsion free" is only for integral varieties, i.e., varieties whose local rings have no zero-divisors. In this case, a sheaf $M$ is torsion free if for any open subset $U$, any nonzero section $m$ of $M$ on $U$ and any nonzero section $a$ of the relevant functions sheaf, one has $a \cdot m \neq 0$. When the variety is not integral (it is reducible, or nonreduced) this definition has no real meaning, then what substitutes the notion of "torsion free" is the Simpson definition of "pure of maximal dimension": a sheaf $M$ is "torsion free" in this sense if the support of any of its subsheaves is the whole variety (cf. Huybrechts and Lehn (1997)), of rank 1 and degree 0; two such sheaves $\mathcal{F}, \mathcal{F}'$ are considered to be equivalent if $\mathcal{F}' \cong \mathcal{F} \otimes p_s^* \mathcal{L}$ for a line bundle $\mathcal{L}$ on $S$ (cf. Altman and Kleiman (1980); note the Altman–Kleiman compactification of the relative Jacobian applies to our situation since we consider elliptic fibrations with integral fibers). Moreover, the natural morphism $X \to \widehat{X}, x \mapsto \mathcal{I}_x \otimes \mathcal{O}_{X_t}(\sigma(t))$ is an isomorphism (of $B$-schemes); here $\mathcal{I}_x$ is the ideal sheaf of the point $x$ in $X_t$.

Note also that if $\pi : Y \to X_t$ is the normalization of one of our fibers $X_t$ and $z$ is the exceptional divisor (the pre-image of the singular point $x$) then $\pi_*(\mathcal{O}_Y(-z))$ is the maximal ideal of $x$.

The variety $\widehat{X}$ is a fine moduli space. This means that there exists a coherent sheaf $\mathcal{P}$ on $X \times_B \widehat{X}$ flat over $\widehat{X}$, whose restrictions to the fibers of $\hat{p}$ are torsion free, and of rank 1 and degree 0. The sheaf $\mathcal{P}$ is defined, up to tensor product, by the pullback of a line bundle on $\widehat{X}$, and is called the universal Poincaré sheaf, which we will normalize by letting $\mathcal{P}_{|\sigma \times_B \widehat{X}} \simeq \mathcal{O}_X$. We shall henceforth assume that $\mathcal{P}$ is normalized in this way, so that

$$\mathcal{P} = \mathcal{I}_\Delta \otimes \pi^* \mathcal{O}_X(\sigma) \otimes \hat{\pi}^* \mathcal{O}_X(\sigma) \otimes q^* \omega^{-1}$$

where $\pi, \hat{\pi}$ and $q = p \circ \pi = \hat{p} \circ \hat{\pi}$ refer to the diagram



and $\mathcal{I}_\Delta$ is the ideal sheaf of the diagonal immersion $X \hookrightarrow X \times_B X$.

Starting with the diagram and with the kernel given by the normalized relative universal Poincaré sheaf $\mathcal{P}$ on the fibered product $X \times_B X$, we define the relative Fourier–Mukai transform as

$$\begin{aligned}\Phi = \Phi^{\mathcal{P}} : D(X) \to D(X) \\ F \mapsto \Phi(F) = R\hat{\pi}_*(\pi^* F \otimes \mathcal{P})\end{aligned}$$

Note that $\Phi(F)$ can be generalized if we allow changes in the base space $B$, that is, we consider base-change morphisms $g: S \to B$.

We close this section with some remarks:

- An important feature of Fourier–Mukai functors is that they are exact as functors of triangulated categories. In more familiar terms, we can say that for any exact sequence $0 \to \mathcal{N} \to \mathcal{F} \to \mathcal{G} \to 0$ of coherent sheaves in $X$, we obtain an exact sequence

  $$\cdots \to \Phi^{i-1}(\mathcal{G}) \to \Phi^i(\mathcal{N}) \to \Phi^i(\mathcal{F}) \to \Phi^i(\mathcal{G}) \to \Phi^{i+1}(\mathcal{N}) \to \cdots$$

  where we have written $\Phi = \Phi^E$ and $\Phi^i(F) = \mathcal{H}^i(\Phi(F))$ denotes the $i$th cohomology sheaves of the complexes $\Phi(F)$.

  Given a Fourier–Mukai functor $\Phi^E$, a complex $F$ in $D(X)$ satisfies the $\mathrm{WIT}_i$ condition (or is $\mathrm{WIT}_i$) if there is a coherent sheaf $\mathcal{G}$ on $\widehat{X}$ such that $\Phi^E(F) \simeq \mathcal{G}[i]$ in $D(\widehat{X})$, where $\mathcal{G}[i]$ is the associated complex concentrated in degree $i$. Furthermore, we say that $F$ satisfies the $\mathrm{IT}_i$ condition if, in addition, $\mathcal{G}$ is locally free.

  When the kernel $E$ is simply a sheaf $\mathcal{Q}$ on $X \times \widehat{X}$ flat over $\widehat{X}$, the cohomology and base-change theorem (cf. Hartshorne (1977)) allows one to show that a coherent sheaf $\mathcal{F}$ on $X$ is $\mathrm{IT}_i$ if and only if $H^j(X, \mathcal{F} \otimes \mathcal{Q}_\xi) = 0$ for all $\xi \in \widehat{X}$ and for all $j \neq i$, where $\mathcal{Q}_\xi$ denotes the restriction of $\mathcal{Q}$ to $X \times \{\xi\}$ and $\mathcal{F}$ is $\mathrm{WIT}_0$ if and only if it is $\mathrm{IT}_0$.

  The acronym "IT" stands for "index theorem," while "W" stands for "weak." This terminology comes from Nahm transforms for connections on tori in complex differential geometry.
- The Parseval formula for the relative Fourier–Mukai transform has been proved by Mukai in his original Fourier–Mukai transform for abelian varieties and can be extended to any situation in which a Fourier–Mukai transform is fully faithful.
- For physical applications, it is often convenient to work in cohomology $H^*(X, \mathbb{Q})$. The passage from $D(X)$ to $H^*(X, \mathbb{Q})$ can be described as follows. We first send a complex $Z \in D(X)$ to its natural class in the $K$-group; we then make use of the fact that the Chern character ch maps $K(X) \to \mathrm{CH}^*(X) \otimes \mathbb{Q}$ and finally we apply the cycle map to $H^*(X, \mathbb{Q})$. This passage (by abuse of notation) is often denoted by $\mathrm{ch}: D(X) \to H^{\mathrm{even}}(X, \mathbb{Q})$, it commutes with pullbacks and transforms tensor products into dot products. Moreover, if we substitute the Mukai vector $v(Z) = \mathrm{ch}(Z)\sqrt{\mathrm{Td}(X)}$ for the Chern character $\mathrm{ch}(Z)$ then we find the commutative diagram

  $$\begin{array}{ccc} D(X) & \xrightarrow{\Phi^E} & D(Y) \\ \downarrow{\scriptstyle v} & & \downarrow{\scriptstyle v} \\ H^*(X, \mathbb{Q}) & \xrightarrow{\Phi^{v(E)}} & H^*(Y, \mathbb{Q}) \end{array}$$

  This can be shown using the Grothendieck–Riemann–Roch theorem and the fact that the power series defining the Todd class starts with constant term 1 and thus is invertible.

## Vector Bundles for Heterotic Strings

A compactification of the ten-dimensional heterotic string is given by a holomorphic, stable $G$-bundle $V$ (with $G$ some Lie group specified below) over a Calabi–Yau manifold $X$. The Calabi–Yau condition, the holomorphy and stability of $V$ are a direct consequence of the required supersymmetry in the uncompactified spacetime. We assume that the underlying ten-dimensional space $M_{10}$ is decomposed as $M_{10} = M_4 \times X$, where $M_4$ (the uncompactified spacetime) denotes the four-dimensional Minkowski space and $X$ a six-dimensional compact space given by a Calabi–Yau 3-fold. To be more precise: supersymmetry requires that the connection $A$ on $V$ satisfies

$$F_A^{2,0} = F_A^{0,2} = 0, \qquad F^{1,1} \wedge J^2 = 0$$

where $J$ denotes a Kähler form of $X$. It follows that the connection has to be a holomorphic connection on a holomorphic vector bundle and, in addition, satisfies the Donaldson–Uhlenbeck–Yau equation, which has a unique solution if and only if the vector bundle is polystable.

In addition to $X$ and $V$, we have to specify a $B$-field on $X$ of field strength $H$. In order to get an anomaly-free theory, the Lie group $G$ is fixed to be either $E_8 \times E_8$ or $\mathrm{Spin}(32)/\mathbb{Z}_2$ or one of their subgroups and $H$ must satisfy the identity

$$\mathrm{d}H = \mathrm{tr}\, R \wedge R - \mathrm{Tr}\, F \wedge F$$

where $R$ and $F$ are, respectively, the associated curvature forms of the spin connection on $X$ and the gauge connection on $V$. Also tr refers to the trace of the composite endomorphism of the tangent bundle to $X$ and Tr denotes the trace in the adjoint representation of $G$. For any closed four-dimensional submanifold $X_4$ of the ten-dimensional spacetime $M_{10}$, the 4-form $\mathrm{tr}\, R \wedge R - \mathrm{Tr}\, F \wedge F$ must have trivial cohomology. Thus, a necessary topological condition $V$ has to satisfy is $\mathrm{ch}_2(TX) = \mathrm{ch}_2(V)$, which simplifies to $c_2(TX) = c_2(V)$ for Calabi–Yau manifolds, $V$ being an $\mathrm{SU}(n)$ vector bundle.

A physical interpretation of the third Chern class can be given as a result of the decomposition of the ten-dimensional spacetime into a four-dimensional flat Minkowski space and $X$. The decomposition of the corresponding ten-dimensional Dirac operator with values in $V$ shows that massless four-dimensional fermions are in one-to-one correspondence with zero modes of the Dirac operator $D_V$ on $X$. The index of $D_V$ can be effectively computed using the Hirzebruch–Riemann–Roch theorem and is given by

$$\mathrm{index}(D) = \int_X \mathrm{Td}(X)\mathrm{ch}(V) = \frac{1}{2}\int_X c_3(V)$$

equivalently, we can write the index as $\mathrm{index}(D) = \sum_{i=0}^{3}(-1)^k \dim H^k(X, V)$. For stable vector bundles, we have $H^0(X, V) = H^3(X, V) = 0$ and so the index computes the net number of fermion generations $N_{\mathrm{gen}}$ in the respective model.

Now it has been observed that the inclusion of background 5-branes changes the anomaly constraint. Various 5-brane solutions of the heterotic string equations of motion have been discussed in the gauge 5-brane, the symmetric 5-brane, and the neutral 5-brane. It has been shown that the gauge and symmetric 5-brane solutions involve finite-size instantons of an unbroken nonabelian gauge group. In contrast, the neutral 5-branes can be interpreted as zero-size instantons of the SO(32) heterotic string. The magnetic 5-brane contributes a source term to the Bianchi identity for the 3-form $H$,

$$\mathrm{d}H = \mathrm{tr}\, R \wedge R - \mathrm{Tr}\, F \wedge F + n_5 \sum_{\text{five-branes}} \delta_5^{(4)}$$

and integration over a 4-cycle in $X$ gives the anomaly constraint

$$c_2(TX) = c_2(V) + [W]$$

The new term $\delta_5^{(4)}$ is a current that integrates to 1 in the direction transverse to a single 5-brane whose class is denoted by $[W]$. The class $[W]$ is the Poincaré dual of an integer sum of all these sources and thus $[W]$ should be an integral class, representing a class in $H_2(X, \mathbb{Z})$. $[W]$ can be further specified taking by into account that supersymmetry requires that 5-branes are wrapped on holomorphic curves and thus $[W]$ must correspond to the homology class of holomorphic curves. This fact constrains $[W]$ to be an algebraic class. Further, algebraic classes include negative classes; however, these lead to negative magnetic charges, which are unphysical, and so they have to be excluded. This constrains $[W]$ to be an effective class. Thus, for a given Calabi–Yau 3-fold $X$ the effectivity of $[W]$ constrains the choice of vector bundles $V$.

The study of the correspondence between the heterotic string (on an elliptic Calabi–Yau 3-fold) and $F$-theory (on an elliptic Calabi–Yau fourfold) has led Friedman, Morgan, and Witten to introduce a new class of vector bundles which satisfy the anomaly constraint with $[W]$ nonzero. As a result, they prove that the number obtained by integration of $[W]$ over the elliptic fibers of the Calabi–Yau 3–fold agrees with the number of 3-branes given by the Euler characteristic of the Calabi–Yau fourfold divided by 24.

### Fourier–Mukai Transforms and Spectral Covers

Let us now describe how the construction of vector bundles out of spectral data (first considered in Hitchin and Beauville, Narasimhan, and Ramanan) can be easily described in the case of elliptic fibrations by means of the relative Fourier–Mukai transform. This construction was widely exploited by Friedman, Morgan, and Witten to construct stable vector bundles on elliptic Calabi–Yau three-folds $X$, which we will summarize now.

If $V \to X$ is a vector bundle of rank $n$ which is semistable and of degree 0 on each fibre $\mathfrak{f}$ of $X \to B$, then its Fourier–Mukai transform $\Phi^1(V)$ is a torsion sheaf of pure dimension 2 on $X$. The support of $\Phi^1(V)$ is a surface $i : C \hookrightarrow X$, which is finite of degree $n$ over $B$. Moreover, $\Phi^1(V)$ is of rank 1 on $C$ and, if $C$ is smooth, then $\Phi^1(V) = i_* L$ is just the extension by zero of some line bundle $L \in \mathrm{Pic}(C)$. Conversely, given a sheaf $\mathcal{G} \to X$ of pure dimension 2 which is flat over $B$, then $\Phi(\mathcal{G})$ is a vector bundle on $X$ of rank equal to the degree of $\mathrm{supp}(\mathcal{G})$ over $B$.

This correspondence between vector bundles on $X$ and sheaves on $X$ supported on finite covers of $B$ is known as the spectral cover construction. The torsion sheaf $\mathcal{G}$ is called the spectral sheaf (or line bundle) and the surface $C = \mathrm{supp}(\mathcal{G})$ is called the spectral cover.

For the description of vector bundles on elliptic Calabi–Yau 3-folds $X$ it is appropriate to take $i_* L$ with Chern characters given by ($\eta_E, \eta \in H^2(B, \mathbb{Q})$ and $a_E, s_E \in \mathbb{Z}$)

$$\mathrm{ch}_0(i_* L) = 0, \qquad \mathrm{ch}_1(i_* L) = n\sigma + \pi^*\eta$$
$$\mathrm{ch}_2(i_* L) = \sigma\pi^*\eta_E + a_E \mathfrak{f}, \qquad \mathrm{ch}_3(i_* L) = s_E$$

The characteristic classes of the rank-$n$ vector bundle $V$ can be obtained if we apply the Grothendieck–Riemann–Roch theorem to the projection $\pi$:

$$\mathrm{ch}(V) = \pi_*[\hat{\pi}^*(\mathrm{ch}(i_* L))\, \mathrm{ch}(\mathcal{P})\mathrm{Td}(T_{X/B})]$$

where $\mathrm{Td}(T_{X/B})$ as given above.

To make sure that the construction leads to SU($n$) vector bundles we set $\eta_E = (1/2)nc_1$ giving $c_1(V) = 0$ and the remaining Chern classes are given by

$$c_2(V) = \pi^*(\eta)\sigma + \pi^*(\varpi), \qquad c_3(V) = -2\gamma_{|s}$$

where

$$\varpi = \tfrac{1}{24}c_1(B)^2(n^3 - n) + \tfrac{1}{2}(\lambda^2 - \tfrac{1}{4})n\eta(\eta - nc_1(B))$$

and $\gamma \in H^{1,1}(C, \mathbb{Z})$ is some cohomology class satisfying $\pi_{C*}\gamma = 0 \in H^{1,1}(B, \mathbb{Z})$. The general solution for $\gamma$ has been derived by Friedman, Morgan, and Witten and is given by $\gamma = \lambda(n\sigma_{|C} - \pi_C^*\eta + n\pi_C^* c_1(B))$ and $\gamma_{|s} = -\lambda\pi^*\eta(\pi^*\eta - n\pi^* c_1(B))\sigma$ with $S = C \cap \sigma$. The parameter $\lambda$ has to be determined such that $c_1(L)$ is an integer class. If $n$ is even, $\lambda = m (m \in \mathbb{Z})$ and in addition we must impose $\eta = c_1(B)$ modulo 2. If $n$ is odd, $\lambda = m + 1/2$.

It remains to discuss the stability of $V$. The stability depends on the properties of the defining data $C$ and $L$. If $C$ is irreducible and $L$ a line bundle over $C$ then $V$ will be a vector bundle stable with respect to the polarization

$$J = \epsilon J_0 + \pi^* H_B, \quad \epsilon > 0$$

if $\epsilon$ is sufficiently small. This has been proved by Friedman, Morgan, and Witten under the additional assumption that the restriction of $V$ to the generic fiber is regular and semistable. Here $J_0$ refers to some arbitrary Kähler class on $X$ and $H_B$ a Kähler class on the base $B$. It implies that the bundle $V$ can be taken to be stable with respect to $J$ while keeping the volume of the fiber $\mathfrak{f}$ of $X$ arbitrarily small compared to the volumes of effective curves associated with the base. That $J$ is actually a good polarization can be seen by assuming $\epsilon = 0$. Now we observe that $\pi^* H_B$ is not a Kähler class on $X$ since its integral is non-negative on each effective curve $C$ in $X$; however, there is one curve, the fiber $\mathfrak{f}$, where the integral vanishes. This means that $\pi^* H_B$ is on the boundary of the Kähler cone and, to make $V$ stable, we have to move slightly into the interior of the Kähler cone, that is, into the chamber which is closest to the boundary point $\pi^* H_B$. Also we note that although $\pi^* H_B$ is in the boundary of the Kähler cone, we can still define the slope $\mu_{\pi^* H_B}(V)$ with respect to it. Since $(\pi^* H_B)^2$ is some positive multiple of the class of the fiber $\mathfrak{f}$, semistability with respect to $\pi^* H_B$ is implied by the semistability of the restrictions $V|_{\mathfrak{f}}$ to the fibers. Assume that $V$ is not stable with respect to $J$, then there is a destabilizing sub-bundle $V' \subset V$ with $\mu_J(V') \geq \mu_J(V)$. But semistability along the fibers says that $\mu_{\pi^* H_B}(V') \leq \mu_{\pi^* H_B}(V)$. If we had equality, it would follow that $V'$ arises by the spectral construction from a proper subvariety of the spectral cover of $V$, contradicting the assumption that this cover is irreducible. So we must have a strict inequality $\mu_{\pi^* H_B}(V') < \mu_{\pi^* H_B}(V)$. Now taking $\epsilon$ small enough, we can ensure that $\mu_J(V') < \mu_J(V)$, thus $V'$ cannot destabilize $V$.

## D-Branes and Homological Mirror Symmetry

Kontsevich proposed a homological mirror symmetry for a pair $(X, Y)$ of mirror dual Calabi–Yau manifolds; it is conjectured that there exists a categorical equivalence between the bounded derived category $D(X)$ and Fukaya's $A_\infty$ category $\mathcal{F}(Y)$, which is defined by using the symplectic structure on $Y$. A Lagrangian submanifold with a flat bundle gives an object of $\mathcal{F}(Y)$. If we consider a locally trivial family of symplectic manifolds $Y$ (i.e., the symplectic form is locally constant as we vary $Y$ in the family) the object of $\mathcal{F}(Y)$ undergoes monodromy transformations going round a loop in the base. On the other hand, the object of $D(X)$ is a complex of coherent sheaves on $X$ and under the categorical equivalence between $D(X)$ and $\mathcal{F}(Y)$ the monodromy (of 3-cycles) is mapped to certain self-equivalences in $D(X)$.

Since all elements in $D(X)$ can be represented by suitable complexes of vector bundles on $X$, we can consider the topological $K$-group and the image $K_{\text{hol}}(X)$ of $D(X)$. The Fourier–Mukai transform $\Phi^{\mathcal{E}}: D(X) \to D(X)$ induces then a corresponding automorphism $K_{\text{hol}}(X) \to K_{\text{hol}}(X)$ and also an automorphism on $H^{\text{even}}(X, \mathbb{Q})$ if we use the Chern character ring homomorphism $\text{ch}: K(X) \to H^{\text{even}}(X, \mathbb{Q})$, as described above. With this in mind, we can introduce various kernels and their associated monodromy transformations.

For instance, let $D$ be the associated divisor defining the large-radius limit in the Kähler moduli space and consider the kernel $\mathcal{O}_\Delta(D)$, with $\Delta$ being the diagonal in $X \times X$. The corresponding Fourier–Mukai transform acts on an object $G \in D(X)$ as twisting by a line bundle, that is, $G \mapsto G \otimes \mathcal{O}(D)$. This automorphism is then identified with the monodromy about the large complex structure limit point (LCSL point) in the complex structure moduli space.

Furthermore, if we consider the kernel given by the ideal sheaf $\mathcal{I}_\Delta$ on $\Delta$, we find that the action of $\Phi^{\mathcal{I}_\Delta}$ on $H^{\text{even}}(X)$ can be expressed by taking the Chern character ring homomorphism:

$$\begin{aligned}\text{ch}(\Phi^{\mathcal{I}_\Delta}(G)) &= \text{ch}_0(\Phi^{\mathcal{O}_{X\times X}}(G)) - \text{ch}(G) \\ &= \left(\int \text{ch}(G) \cdot \text{Td}(X)\right) - \text{ch}(G)\end{aligned}$$

Kontsevich proposed that this automorphism should reproduce the monodromy about the principal component of the discriminant of the mirror family $Y$. At the principal component we have vanishing $S^3$ cycles (and the conifold singularity), thus the action of this monodromy on cohomology may be identified with the Picard–Lefschetz formula.

Now for a given pair of mirror dual Calabi–Yau 3-folds, it is generally assumed that $A$-type and $B$-type D-branes exchange under mirror symmetry. For such a pair, Kontsevich's correspondence between automorphisms of $D(X)$ and monodromies of 3-cycles can then be tested. More specifically, a comparison relies on the identification of two central charges associated to D-brane configurations on both sides of the mirror pair.

For this, we first have to specify a basis for the 3-cycles $\Sigma_i \in H^3(Y, \mathbb{Z})$ such that the intersection form takes the canonical form $\Sigma_i \cdot \Sigma_j = \delta_{j, i+b_{2,1}+1} = \eta_{i,j}$ for $i = 0, \ldots, b_{2,1}$. It follows that a 3-brane wrapped about the cycle $\Sigma = \sum_i n_i \Sigma^i$ has an (electric, magnetic) charge vector $\boldsymbol{n} = (n_i)$. The periods of the holomorphic 3-form $\Omega$ are then given by

$$\Pi_i = \int_{\Sigma_i} \Omega$$

and can be used to provide projective coordinates on the complex structure moduli space. If we choose a symplectic basis $(A_i, B_j)$ of $H_2(Y, \mathbb{Z})$ then the $A_i$ periods serve as projective coordinates and the $B_j$ periods satisfy the relations $\Pi^j = \eta_{i,j} \partial \mathcal{F} / \partial \Pi^i$, where $\mathcal{F}$ is the prepotential which has, near the large-radius limit, the asymptotic form (as analyzed by Candelas, Klemm, Theisen, Yau, and Hosono, cf. "Further reading"):

$$\mathcal{F} = \frac{1}{6} \sum_{abc} k_{abc} t_a t_b t_c + \frac{1}{2} \sum_{ab} c_{ab} t_a t_b - \sum_a \frac{c_2(X) J_a}{24} t_a + \frac{\zeta(3)}{2(2\pi i)^3} \chi(X) + \text{const.}$$

where $\chi(X)$ is the Euler characteristic of $X, c_{ab}$ are rational constants (with $c_{ab} = c_{ba}$) reflecting an $\mathrm{Sp}(2h^{11} + 2)$ ambiguity, and $k_{abc}$ is the classical triple intersection number given by

$$k_{abc} = \int_X J_a \wedge J_b \wedge J_c$$

The periods determine the central charge $Z(\boldsymbol{n})$ of a 3-brane wrapped about the cycle $\Sigma = \sum_i n_i [\Sigma_i]$:

$$Z(\boldsymbol{n}) = \int_\Sigma \Omega = \sum_i n_i \Pi_i$$

On the other hand, the central charge associated with an object $E$ of $D(X)$ is given by

$$Z(E) = -\int_X \mathrm{e}^{-t_a J_a} \operatorname{ch}(E) \left( 1 + \frac{c_2(X)}{24} \right)$$

Now, physically it is assumed that the two central charges are to be identified under mirror symmetry. If we compare the two central charges $Z(\boldsymbol{n})$ and $Z(E)$, then we obtain a map relating the Chern characters $\operatorname{ch}(E)$ of $E$ to the D-brane charges $\boldsymbol{n}$. If we insert the expressions for $\operatorname{ch}(E)$ in $\operatorname{ch}(\Phi^{\mathcal{I}_\Delta}(E))$, it yields a linear transformation acting on $\boldsymbol{n}$, such that $n_6 \to n_6 + n_3$, which agrees with the monodromy transformation about the conifold locus.

Similarly, the monodromy transformation about the LCSL point corresponding to automorphisms $[E] \to [E \otimes \mathcal{O}_X(D)]$ can be made explicit.

Using the central charge identification, the automorphism/monodromy correspondence has been made explicit for various dual pairs of mirror Calabi–Yau 3-folds (given as hypersurfaces in weighted projective spaces). This identification provides evidence for Kontsevich's proposal of homological mirror symmetry.

# Four-Manifold Invariants and Physics

**C Nash**, National University of Ireland, Maynooth, Ireland

## Introduction

Manifolds of dimension 4 play a distinguished role in physics and have done so ever since special and general relativity ushered in the celebrated four-dimensional spacetime. It is also the case that manifolds of dimension 4 play a distinguished role in mathematics: many generalities about manifolds of a general dimension do not apply in dimension 4; there are also phenomena in dimension 4 with no counterpart in other dimensions.

This article describes some of the more important physical and mathematical properties of dimension 4. We begin with an account of some topological and geometric properties for manifolds in general, but avoiding dimension 4, and then embark on the dimension 4 discussion. The references at the end will serve to take the reader further into the subject.

## Topological, Piecewise-Linear, and Differentiable Structures for Manifolds

In dealing with topological spaces which are manifolds, one distinguishes three types of manifolds $M$: topological, piecewise-linear, and differentiable (also called smooth). It is possible to describe the more important differences between these three types using topological techniques.

Consider then a manifold $M$ of dimension $n$; $M$ will always be assumed to be compact, connected and closed unless we indicate the contrary. The type of $M$ is determined by examining whether the transition functions $g_{\alpha\beta}$ are homeomorphisms, (invertible) piecewise-linear maps, or diffeomorphisms. Now, since the transition functions are maps from one subset of $\boldsymbol{R}^n$ to another, we introduce the groups $TOP_n$, $PL_n$, and $DIFF_n$ which are all the homeomorphisms, piecewise-linear maps, and diffeomorphisms of $\boldsymbol{R}^n$, respectively. We are naturally led to the three sets of inclusions:

$$\begin{array}{ccccccccc} TOP_1 & \subset & TOP_2 & \subset & \cdots & \subset & TOP_n & \subset & \cdots \\ PL_1 & \subset & PL_2 & \subset & \cdots & \subset & PL_n & \subset & \cdots \\ DIFF_1 & \subset & DIFF_2 & \subset & \cdots & \subset & DIFF_n & \subset & \cdots \end{array} \quad [1]$$

For each of the three sets of inclusions we pass to the direct limit and construct the three limiting groups

$$TOP, \quad PL, \quad DIFF \quad [2]$$

With these three groups are associated the classifying spaces $BTOP$, $BPL$ and $BDIFF$. The transition functions $g_{\alpha\beta}$ are those of the tangent bundle to $M$; and there are three possible tangent bundles depending on the type of $M$ and we denote these tangent bundles by $TM_{TOP}, TM_{PL}$, and $TM_{DIFF}$ in an obvious notation. Then to determine the tangent bundles $TM_{TOP}$, $TM_{PL}$, and $TM_{DIFF}$ one simply selects an element of the homotopy classes

$$[M, BTOP], \quad [M, BPL], \text{ and } [M, BDIFF] \quad [3]$$

respectively.

Given this threefold hierarchy of manifold structures one wishes to know when one can straighten out a topological manifold to make it piecewise linear; and also, when can one *smooth* a piecewise-linear manifold to make it differentiable?

If $\dim M \geq 5$ of $M$ these two questions can be formulated as lifting problems.

### TOP versus PL for $\dim M \neq 4$

Taking the first of them, so that we are comparing piecewise-linear and topological structures on $M$, one can check $BPL$ fibers over $BTOP$ with fiber $TOP/PL$ yielding

$$\begin{array}{ccc} TOP/PL & \rightarrow & BPL \\ & & \downarrow \pi \\ & & BTOP \end{array} \qquad [4]$$

A method for *straightening out* a PL manifold is now apparent: now a topological manifold is a choice of map $\alpha : M \rightarrow BTOP$, and a *factorization* of $\alpha$ through $BPL$ will give $M$ a PL structure. We show this below

$$\begin{array}{ccc} & BPL & \\ {\scriptstyle\beta}\nearrow & \downarrow \pi & \alpha = \pi \circ \beta \\ M \xrightarrow{\alpha} & BTOP & \end{array} \qquad [5]$$

The existence of the map $\beta : M \rightarrow BPL$ satisfying $\alpha = \pi \circ \beta$ provides $M$ with a PL structure and is a *lifting* of the map $\alpha$ from the base $BTOP$ to the total space $BPL$.

This lifting method, for passing from TOP structures to PL structures, does work, *provided* $\dim M \geq 5$, since we have the stability result that

$$\frac{TOP_n}{PL_n} \simeq \frac{TOP}{PL}, \quad n \geq 5 \qquad [6]$$

For the map $\beta$ to exist the obstructions to the lifting which are cohomology classes of the form

$$H^{k+1}(M; \pi_k(TOP/PL)) \qquad [7]$$

must vanish. However, Kirby and Siebenmann have shown that

$$TOP/PL \simeq K(\mathbf{Z}_2, 3) \qquad [8]$$

where $K(\mathbf{Z}_2, 3)$ is *Eilenberg–Mac Lane space* so that its sole nonvanishing homotopy group is in dimension 3 giving us

$$\pi_n(TOP/PL) = \begin{cases} \mathbf{Z}_2 & \text{if } n = 3 \\ 0 & \text{otherwise} \end{cases} \qquad [9]$$

Any obstruction to $\beta$'s existence is a class $e(M)$, say, in

$$H^4(M; \mathbf{Z}_2) \quad \dim M \geq 5 \qquad [10]$$

When $e(M)$ *vanishes*, the map $\beta$ exists and furnishes $M$ with a PL structure; if $e(M) = 0$ it is natural to go on to ask how many (homotopy classes of) such $\beta$'s exist? Standard obstruction theory says the relevant homotopy classes are just the whole cohomology group

$$H^k(M; \pi_k(TOP/PL)) \qquad [11]$$

which, since $k = 3$, is just

$$H^3(M; \mathbf{Z}_2) \qquad [12]$$

So, for $\dim M \geq 5$, we see that when a closed topological manifold $M$ acquires a PL structure by the lifting process just described, then the possible distinct PL structures are isomorphic to

$$H^3(M; \mathbf{Z}_2) \qquad [13]$$

which is not zero in general.

Finally, if $\dim M \leq 3$, then the notions PL and TOP coincide, so we are left with the case $\dim M = 4$ which we shall come to below. Now we wish to describe the next step in the sequence TOP, PL, DIFF which is the smoothing problem.

### PL versus DIFF for $\dim M \neq 4$

Similar ideas are used to address the question of smoothing a piecewise-linear manifold – however, the results are different. Let us assume that $M$ is a closed PL manifold with $\dim M \geq 5$. This time the fibration is

$$\begin{array}{ccc} PL/DIFF & \rightarrow & BDIFF \\ & & \downarrow \pi \\ & & BPL \end{array} \qquad [14]$$

The smoothing of a piecewise-linear $M$ can also be handled with obstruction theory and leads us immediately to the consideration of the homotopy groups $\pi_n(PL/DIFF)$. This time the nontrivial homotopy groups of the fiber are much more numerous than in the piecewise-linear case. In fact one has

$$\pi_n(PL/DIFF) = \begin{cases} 0 & \text{if } n \leq 6 \\ \mathbf{Z}_{28} & \text{if } n = 7 \\ \mathbf{Z}_2 & \text{if } n = 8 \\ \vdots & \vdots \\ \mathbf{Z}_{992} & \text{if } n = 11 \\ \vdots & \vdots \end{cases} \qquad [15]$$

The obstructions to passing from a PL to a DIFF structure on $M$ now lie in

$$H^{k+1}(M; \pi_k(PL/DIFF)) \qquad [16]$$

and the number of distinct liftings comprises the cohomology group

$$H^k(M; \pi_k(PL/DIFF)) \qquad [17]$$

As an illustration of all this, consider the case $M = S^7$; then the first nontriviality occurs when $n = 7$ and so the obstruction to smoothing $S^7$ lies in

$$H^8(S^7; \pi_7(PL/DIFF)) \qquad [18]$$

which is of course zero – this means that $S^7$ can be smoothed, a fact which we know from first principles. However, by the obstruction theory introduced above, the resulting smooth structures are isomorphic to

$$H^7(S^7; \pi_7(PL/DIFF)) = H^7(S^7; \mathbf{Z}_{28}) = \mathbf{Z}_{28} \qquad [19]$$

Hence, we have the celebrated result of Milnor and Kervaire and Milnor that $S^7$ has 28 distinct differentiable structures, 27 of which correspond to what are known as *exotic* spheres.

Lastly, if $\dim M \leq 3$, then PL and DIFF coincide – this leaves us with the case of greatest interest namely $\dim M = 4$.

## The Strange Case of Four Dimensions

In four dimensions there are phenomena which have no counterpart in any other dimension. First of all, there are topological 4-manifolds which have no smooth structure, though if they have a PL structure, then they possess a unique smooth structure. Second, the impediment to the existence of a smooth structure is of a completely different type to that met in the standard obstruction theory – it is not the pullback of an element in the cohomology of a classifying space, that is, it is not a characteristic class. Also the four-dimensional story is far from completely known. Nevertheless, there are some very striking results dating from the early 1980s onwards.

We begin by disposing of the difference between PL and DIFF structures: our earlier results together with the vanishing statement

$$\pi_n(PL/DIFF) = 0, \quad n \leq 6 \qquad [20]$$

mean that every PL 4-manifold possesses a unique DIFF structure. Thus, we can take the crucial difference to be between DIFF and TOP.

In Freedman (1982) all, simply connected, *topological* 4-manifolds were classified by their intersection form $q$.

We recall that $q$ is a quadratic form constructed from the cohomology of $M$ as follows: take two elements $\alpha$ and $\beta$ of $H^2(M; \mathbf{Z})$ and form their cup product $\alpha \cup \beta \in H^4(M; \mathbf{Z})$; then we define $q(\alpha, \beta)$ by

$$q(\alpha, \beta) = (\alpha \cup \beta)[M] \qquad [21]$$

where $(\alpha \cup \beta)[M]$ denotes the integer obtained by evaluating $\alpha \cup \beta$ on the generating cycle $[M]$ of the top homology group $H_4(M; \mathbf{Z})$ of $M$. Poincaré duality ensures that such a form is always nondegenerate over $\mathbf{Z}$ and so has $\det q = \mp 1$; $q$ is then called unimodular. Also we refer to $q$, as "even" if all its diagonal entries are even, and as "odd" otherwise.

Freedman's work yields the following:

**Theorem** (Freedman). *A simply connected 4-manifold M with even intersection form q belongs to a unique homeomorphism class, while if q is odd there are precisely two nonhomeomorphic manifolds M with q as their intersection form.*

This is a very powerful result – the intersection form $q$ very nearly determines the homeomorphism class of a simply connected $M$, and actually only fails to do so in the odd case where there are still just two possibilities. Further, *every* unimodular quadratic form occurs as the intersection form of some manifold.

As an illustration of the impressive nature of Freedman's work, choose $M$ to be the sphere $S^4$, since $H^2(S^4; \mathbf{Z})$ is trivial, then $q$ is the zero quadratic form and is of course even; we write this as $q = \emptyset$. Now recollect that the *Poincaré conjecture* in four dimensions is the statement that any homotopy 4-sphere, $S^4_h$ say, is actually *homeomorphic* to $S^4$. Well, since $H^2(S^4_h; \mathbf{Z})$ is also trivial then any $S^4_h$ also has intersection form $q = \emptyset$. Applying Freedman's theorem to $S^4_h$ immediately asserts that $S^4_h$ belongs to a unique homeomorphism class which must be that of $S^4$ thereby establishing the Poincaré conjecture.

Freedman's result combined with a much earlier result of Rohlin (1952) also gives us an example of a nonsmoothable 4-manifold: Rohlin's theorem asserts that given a smooth, simply connected, 4-manifold with even intersection form $q$, then the signature – the signature of $q$ being defined to be the difference between the number of positive and negative eigenvalues of $q$ – $\sigma(q)$ of $q$ is divisible by 16.

Now write

$$q = \begin{pmatrix} 2 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 2 & -1 & 0 & -1 \\ 0 & 0 & 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 2 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & 2 \end{pmatrix} = E_8 \qquad [22]$$

($E_8$ is actually the Cartan matrix for the exceptional Lie algebra $e_8$), then, by inspection, $q$ is even, and by calculation, it has signature 8. By Freedman's theorem there is a single, simply connected, 4-manifold with intersection form $q = E_8$. However, by

Rohlin's theorem, it cannot be smoothed since its signature is 8.

The next breakthrough was due to Donaldson (1983). Donaldson's theorem is applicable to definite forms $q$, which by appropriate choice of orientation on $M$ we can take to be *positive* definite. One has:

**Theorem** (Donaldson). *A simply connected, smooth 4-manifold, with positive-definite intersection form $q$ is always diagonalizable over the integers to* $q = \mathrm{diag}(1, \ldots, 1)$.

One can immediately deduce that no, simply connected, 4-manifold for which $q$ is even and positive definite can be smoothed!

For example, the manifold with $q = E_8 \oplus E_8$ has signature 16 (by Rohlin's theorem). But since $E_8$ is even, then so is $E_8 \oplus E_8$ and so Donaldson's theorem forbids such a manifold from existing smoothly.

In fact, in contrast to Freedman's theorem, which allows *all* unimodular quadratic forms to occur as the intersection form of some topological manifold, Donaldson's theorem says that in the positive-definite, smooth, case only *one* quadratic form is allowed, namely $I$.

Donaldson's work makes contact with physics because it uses the *Yang–Mills equations* as we now outline.

Let $A$ be a connection on a principal SU(2) bundle over a simply connected 4-manifold $M$ with positive-definite intersection form. If the curvature 2-form of $A$ is $F$, then $F$ has an $L^2$ norm which is the Euclidean Yang–Mills action $S$. One has

$$S = \|F\|^2 = -\int_M \mathrm{tr}(F \wedge *F) \qquad [23]$$

where $*F$ is the usual dual 2-form to $F$. The minima of the action $S$ are given by those $A$, called instantons, which satisfy the famous self-duality equations

$$F = *F \qquad [24]$$

Given one instanton $A$ which minimizes $S$ one can perturb about $A$ in an attempt to find more instantons. This process is successful and the space of all instantons can be fitted together to form a global moduli space of finite dimension. For the instanton which provides the absolute minimum of $S$, the moduli space $\mathcal{M}$ is a noncompact space of dimension 5.

We can now summarize the logic that is used to prove Donaldson's theorem: there are very strong relationships between $M$ and the moduli space $\mathcal{M}$; for example, let $q$ be regarded as an $n \times n$ matrix with precisely $p$ unit eigenvalues (clearly $p \le n$ and Donaldson's theorem is just the statement that $p = n$), then $\mathcal{M}$ has precisely $p$ singularities which look like cones on the space $CP^2$. These combine to produce the result that the 4-manifold $M$ has the same topological signature Sign($M$) as $p$ copies of $CP^2$; and so they have signature $a - b$, where $a$ of the $CP^2$'s are oriented as usual and $b$ have the opposite orientation. Thus,

$$\mathrm{Sign}\,(M) = a - b \qquad [25]$$

Now by definition, $\mathrm{Sign}\,(M)$ is the signature $\sigma(q)$ of the intersection form $q$ of $M$. But, by assumption, $q$ is positive definite $n \times n$ so $\sigma(q) = n = \mathrm{Sign}\,(M)$. Hence,

$$n = a - b \qquad [26]$$

However, $a + b = p$ and $p \le n$ so we can say that

$$n = a - b, \qquad p = a + b \le n \qquad [27]$$

but one always has $a + b \ge a - b$ so we have

$$n \le p \le n \Rightarrow p = n \qquad [28]$$

which is Donaldson's theorem.

## Donaldson's Polynomial Invariants

Donaldson extended his work by introducing polynomial invariants also derived from Yang–Mills theory and to discuss them we must introduce some notation.

Let $M$ be a smooth, simply connected, orientable Riemannian 4-manifold without boundary and $A$ be an SU(2) connection which is anti-self-dual so that

$$F = - * F \qquad [29]$$

Then the space of all gauge-inequivalent solutions to this anti-self-duality equation – the moduli space $\mathcal{M}_k$ – has a dimension given by the integer

$$\dim \mathcal{M}_k = 8k - 3(1 + b_2^+) \qquad [30]$$

Here *$k$ is the instanton number* which gives the topological type of the solution $A$. The instanton number is minus the second Chern class $c_2(F) \in H^2(M; \mathbf{Z})$ of the bundle on which the $A$ is defined. This means that we have

$$k = -c_2(F)[M] = \frac{1}{8\pi^2} \int_M \mathrm{tr}(F \wedge F) \in \mathbf{Z} \qquad [31]$$

The number $b_2^+$ is defined to be the rank of the positive part of the *intersection form $q$ of $M$*.

A Donaldson invariant $q^M_{d,r}$ is a symmetric integer polynomial of degree $d$ in the 2-homology $H_2(M;\mathbf{Z})$ of $M$

$$q^M_{d,r} : \underbrace{H_2(M) \times \cdots \times H_2(M)}_{d \text{ factors}} \longrightarrow \mathbf{Z} \qquad [32]$$

Given a certain map $m_i$,

$$m_i : H_i(M) \to H^{4-i}(\mathcal{M}_k) \qquad [33]$$

if $\alpha \in H_2(M)$ and $*$ represents a point in $M$, we define $q^M_{d,r}(\alpha)$ by writing

$$q^M_{d,r}(\alpha) = m_2^d(\alpha) m_0^r(*)[\mathcal{M}_k] \qquad [34]$$

The evaluation of $[\mathcal{M}_k]$ on the RHS of the above equation means that

$$2d + 4r = \dim \mathcal{M}_k \qquad [35]$$

so that $\mathcal{M}_k$ is even dimensional; this is achieved by requiring $b_2^+$ to be odd.

Now the Donaldson invariants $q^M_{d,r}$ are *differential* topological invariants rather than topological invariants but they are difficult to calculate as they require detailed knowledge of the instanton moduli space $\mathcal{M}_k$. However they are nontrivial and their values are known for a number of 4-manifolds $M$. For example, if $M$ is a complex algebraic surface, a positivity argument shows that they are nonzero when $d$ is large enough. Conversely, if $M$ can be written as the connected sum

$$M = M_1 \# M_2$$

where both $M_1$ and $M_2$ have $b_2^+ > 0$, then they all vanish.

## Topological Quantum Field Theories

Turning now to physics, it is time to point out that the $q^M_{d,r}$ can also be obtained, Witten (1988), as the correlation functions of twisted $N=2$ supersymmetric topological quantum field theory.

The action $S$ for this theory is given by

$$\begin{aligned} S = \int_M \mathrm{d}^4x \sqrt{g}\, \mathrm{tr} \Big\{ & \frac{1}{4} F_{\mu\nu}F^{\mu\nu} + \frac{1}{4} F^*_{\mu\nu}F^{\mu\nu} \\ & + \frac{1}{2}\phi D_\mu D^\mu \lambda + \mathrm{i} D_\mu \psi_\nu \chi^{\mu\nu} - \mathrm{i}\eta D_\mu \psi^\mu \\ & - \frac{\mathrm{i}}{8}\phi[\chi_{\mu\nu}, \chi^{\mu\nu}] - \frac{\mathrm{i}}{2}\lambda[\psi_\mu, \psi^\mu] \\ & - \frac{\mathrm{i}}{2}\phi[\eta, \eta] - \frac{1}{8}[\phi, \lambda]^2 \Big\} \end{aligned} \qquad [36]$$

where $F_{\mu\nu}$ is the curvature of a connection $A_\mu$ and $(\phi, \lambda, \eta, \psi_\mu, \chi_{\mu\nu})$ are a collection of fields introduced in order to construct the right supersymmetric theory; $\phi$ and $\lambda$ are both spinless while the multiplet $(\psi_\mu, \chi_{\mu\nu})$ contains the components of a 0-form, a 1-form, and a self-dual 2-form, respectively.

The significance of this choice of multiplet is that the instanton deformation complex used to calculate $\dim \mathcal{M}_k$ contains precisely these fields.

Even though $S$ contains a metric, its correlation functions are *independent* of the metric $g$ so that $S$ can still be regarded as a topological quantum field theory. This is because both $S$ and its associated energy momentum tensor $T \equiv (\delta S/\delta g)$ can be written as BRST commutators $S = \{Q, V\}, T = \{Q, V'\}$ for suitable $V$ and $V'$.

With this theory, it is possible to show that the correlation functions are *independent* of the gauge coupling and hence we can evaluate them in a small coupling limit. In this limit, the functional integrals are dominated by the classical minima of $S$, which for $A_\mu$ are just the instantons

$$F_{\mu\nu} = -F^*_{\mu\nu} \qquad [37]$$

We also need $\phi$ and $\lambda$ to vanish for irreducible connections. If we expand all the fields around the minima up to quadratic terms and do the resulting Gaussian integrals, the correlation functions may be formally evaluated.

A general correlation function of this theory is given by

$$< P >= \int \mathcal{DF} \exp[-S]\, P(\mathcal{F}) \qquad [38]$$

where $\mathcal{F}$ denotes the collection of fields present in $S$ and $P(\mathcal{F})$ is some polynomial in the fields.

$S$ has been constructed so that the zero modes in the expansion about the minima are the tangents to the moduli space $\mathcal{M}_k$. This suggests doing the $\mathcal{DF}$ integration as follows: express the integral as an integral over modes, then integrate out all the nonzero modes first leaving a *finite-dimensional* integration over the compactified moduli space $\overline{\mathcal{M}}_k$. The Gaussian integration over the nonzero modes is a boson–fermion ratio of determinants, which supersymmetry constrains to be $\mp 1$, bosonic and fermionic eigenvalues being equal in pairs.

This amounts to writing

$$< P >= \int_{\overline{\mathcal{M}}_k} P_n \qquad [39]$$

where $P_n$ denotes some $n$-form over $\overline{\mathcal{M}}_k$ and $n = \dim \overline{\mathcal{M}}_k$. If the original polynomial $P(\mathcal{F})$ is judiciously chosen, then calculation of $< P >$ reproduces evaluation of the Donaldson polynomials $q^M_{d,r}$.

## The Seiberg–Witten Equations

The Seiberg–Witten equations constitute another breakthrough in the work on the topology of 4-manifolds, since they greatly simplify the calculation of the data supplied by the Donaldson polynomial invariants. We shall discuss this later below but turn now to the equations themselves.

If we choose an oriented, compact, closed, Riemannian manifold $M$, then the data we need for the Seiberg–Witten equations are a connection $A$ on a line bundle $L$ over $M$ and a "local spinor" field $\psi$. The Seiberg–Witten equations are then

$$\partial\!\!\!/_A \psi = 0, \qquad F^+ = -\tfrac{1}{2}\bar{\psi}\Gamma\psi \qquad [40]$$

where $\partial\!\!\!/_A$ is the Dirac operator and $\Gamma$ is made from the gamma matrices $\Gamma_i$ according to $\Gamma = (1/2)[\Gamma_i, \Gamma_j]\mathrm{d}x^i \wedge \mathrm{d}x^j$.

We call $\psi$ a local spinor because global spinors may not exist on $M$; however, in dimension 4, orientability guarantees that a $\mathrm{spin}_c$ structure exists on $M$ (a choice of $\mathrm{spin}_c$ structure on $M$ is an extra piece of data in the Seiberg–Witten case); $\psi$ is then the appropriate section for the $\mathrm{spin}_c$ bundle and behaves locally like a spinor coupled to the U(1) connection $A$. Let $\mathrm{Spin}_c(M)$ denote the set of isomorphism classes of $\mathrm{spin}_c$ structures on $M$ then, for the case $b_2^+ > 1$ – the case $b_2^+ = 1$ has some technicalities – the Seiberg–Witten invariants determine a map SW of the form

$$\mathrm{SW} : \mathrm{Spin}_c(M) \longrightarrow \mathbf{Z} \qquad [41]$$

We emphasize that $A$ is just a U(1) abelian connection and so $F = \mathrm{d}A$, with $F^+$ denoting the self-dual part of $F$.

We shall now have a look at an example of a new result obtained directly from the Seiberg–Witten equations. The equations clearly provide the absolute minima for the action

$$S = \int_M \left\{ |\partial\!\!\!/_A\psi|^2 + \tfrac{1}{2}|F^+ + \tfrac{1}{2}\bar{\psi}\Gamma\psi|^2 \right\} \qquad [42]$$

If we use a Weitzenböck formula to relate the Laplacian $\nabla_A^*\nabla_A$ to $\partial\!\!\!/_A^*\partial\!\!\!/_A$ plus curvature terms, we find that $S$ satisfies

$$\int_M \left\{ |\partial\!\!\!/_A\psi|^2 + \tfrac{1}{2}|F^+ + \tfrac{1}{2}\bar{\psi}\Gamma\psi|^2 \right\} = \int_M \left\{ |\nabla_A\psi|^2 + \tfrac{1}{2}|F^+|^2 + \tfrac{1}{8}|\psi|^4 + \tfrac{1}{4}R|\psi|^2 \right\} \qquad [43]$$

$$= \int_M \left\{ |\nabla_A\psi|^2 + \tfrac{1}{4}|F|^2 + \tfrac{1}{8}|\psi|^4 + \tfrac{1}{4}R|\psi|^2 \right\} + \pi^2 c_1^2(L) \qquad [44]$$

where $R$ is the scalar curvature of $M$ and $c_1(L)$ is the Chern class of $L$.

We notice that the action now looks like one for monopoles. But now suppose that $R$ is positive and that the pair $(A, \psi)$ is a solution to the Seiberg–Witten equations, then the left-hand side (LHS) of this last expression is zero and all the integrands on the RHS are positive so the solution must obey $\psi = 0$ and $F^+ = 0$. A technical point is that if $M$ has $b_2^+ > 1$, then a perturbation of the metric can preserve the positivity of $R$ but perturb $F^+ = 0$ to be simply $F = 0$ rendering the connection $A$ flat. Hence, in these circumstances, the solution $(A, \psi)$ is the trivial one. This means that we have a new kind of vanishing theorem in four dimensions.

**Theorem** (Witten 1994). *No 4-manifold with $b_2^+ > 1$ and nontrivial solution to the Seiberg–Witten equations admits a metric of positive scalar curvature.*

Now, for technical reasons, we assume that the $q_{d,r}^M$ have the property that

$$q_{d,r+2}^M = 4q_{d,r}^M \qquad [45]$$

A simply connected $M$ with this property is called of *simple type*. We also define $\tilde{q}_d^M$ by writing

$$\tilde{q}_d^M = \begin{cases} q_{d,0}^M, & \text{if } d = (b_2^+ + 1) \bmod 2 \\ \tfrac{1}{2}q_{d,1}^M, & \text{if } d = b_2^+ \bmod 2 \end{cases} \qquad [46]$$

The generating function $G_M(\alpha)$ is now given by

$$G_M(\alpha) = \sum_{d=0}^{\infty} \frac{1}{d!}\tilde{q}_d^M(\alpha) \qquad [47]$$

According to Kronheimer and Mrowka (1994), $G_M(\alpha)$ can be expressed in terms of a *finite* number of classes (known as *basic classes*) $\kappa_i(\kappa_i \in H^2(M))$ with rational coefficients $a_i$ (the Seiberg–Witten invariants) resulting in the formula

$$G_M(\alpha) = \exp[\alpha \cdot \alpha/2] \sum_i a_i \exp[\kappa_i \cdot \alpha] \qquad [48]$$

Hence, for $M$ of simple type, the polynomial invariants are determined by a (finite) number of basic classes and the Seiberg–Witten invariants.

Returning now to the physics we find that the quantum field theory approach to the polynomial invariants relates them to properties of the moduli space for the Seiberg–Witten equations rather than to properties of the instanton moduli space $\mathcal{M}_k$.

The moduli space for the Seiberg–Witten equations, unlike the instanton case, is *compact* and generically has dimension

$$\frac{c_1^2(L) - 2\chi(M) - 3\sigma(M)}{4} \qquad [49]$$

$\chi(M)$ and $\sigma(M)$ being the Euler characteristic and signature of $M$, respectively. When

$$c_1^2(L) = 2\chi(M) + 3\sigma(M) \quad [50]$$

we get a zero-dimensional moduli space consisting of a finite collection of points

$$\{P_1, \ldots, P_N\} \quad [51]$$

Now each point $P_i$ has a sign $\epsilon_i = \mp 1$ associated with it coming from the sign of the determinant of elliptic operator whose index gave the dimension of the moduli space. The sum of these signs is an integer topological invariant denoted by $n_L$, that is,

$$n_L = \sum_{j=1}^{N} \epsilon_i \quad [52]$$

Returning now to our formula for $G_M(\alpha)$, one finds that

$$G_M(\alpha) = 2^{p(M)} \exp[\alpha \cdot \alpha/2] \sum_T n_L \exp[c_1(L) \cdot \alpha] \quad [53]$$

$$p(M) = 1 + \tfrac{1}{4}(7\chi(M) + 11\sigma(M)) \quad [54]$$

and the sum over $L$ on the RHS of the formula is over line bundles $L$ that satisfy

$$c_1^2(L) = 2\chi(M) + 3\sigma(M) \quad [55]$$

that is, it is a sum over $L$ with zero-dimensional Seiberg–Witten moduli spaces.

Comparison of the two formulas for $G_M(\alpha)$ – the first mathematical in origin and the second physical – allows one to identify the Seiberg–Witten invariants $a_i$ and the Kronheimer–Mrowka basic classes $\kappa_i$ as the $c_1(L)$'s.

The results described thus far are for *simply connected* 4-manifolds but this condition is not obligatory for and there is also a theory in the non-simply-connected case (Mariño and Moore 1999).

The physics underlying these topological results is of great importance since many of the ideas originate there. It is known that the computation of the Donaldson invariants there uses the fact that the $N = 2$ gauge theory is asymptotically free. This means that the ultraviolet limit being one of weak coupling is tractable. However, the less tractable infrared or strong-coupling limit would do just as well to calculate the Donaldson invariants since these latter are metric independent.

In Seiberg and Witten's work, this infrared behavior is actually determined and it is found that, in the strong-coupling infrared limit, the theory is equivalent to a *weakly coupled* theory of abelian fields and monopoles. There is also a duality between the original theory and the theory with monopoles which is expressed by the fact that the (abelian) gauge group of the monopole theory is the dual of the maximal torus of the group of the nonabelian theory.

We recall that the Yang–Mills gauge group in this discussion is SU(2). Seiberg and Witten's results mean the replacement of SU(2) instantons used to compute the Donaldson invariants by the counting of U(1) monopoles. This calculation of the non-abelian Donaldson data by abelian Seiberg–Witten data theory is much like the representation theory of a nonabelian Lie group $G$ where everything is determined by an abelian object: the maximal torus.

The theory considered by Seiberg and Witten possesses a collection of quantum vacua labeled by a complex parameter $u$ which turns out to parametrize a family of elliptic curves. A central part is played by a function $\tau(u)$ on which there is a modular action of $SL(2, \mathbf{Z})$. The successful determination of the infrared limit involves an electric–magnetic duality and the whole matter is of very considerable independent interest for quantum field theory, quark confinement, and string theory in general.

## Seiberg–Witten Theory and Exotic Structures on 4-Manifolds

We saw earlier that, when $\dim M \neq 4$, a manifold may possess a finite number of differentiable structures, $S^7$ having 28 distinct smooth structures. However, in dimension 4, Seiberg–Witten theory has been used to show that there are many 4-manifolds with a countable infinity of smooth structures. We just mention two: the $K3$ surface has infinitely many smooth structures as does the manifold $\mathbf{CP}^2 \# 5\overline{\mathbf{CP}}^2$. This is another instance of how dimension 4 differs from all other dimensions. This infinite variety of exotic smooth structures in four dimensions is also of great interest to physics.

An outstanding four-dimensional matter still is the *smooth Poincaré conjecture* which asks whether a smooth 4-manifold $M$ homotopic to $S^4$ is *diffeomorphic* to $S^4$? Such an $M$ is certainly *homeomorphic* to $S^4$ because this is the standard Poincaré conjecture proved by Freedman and, if the answer to this question is yes then $S^4$ would be an example of a 4-manifold with no exotic smooth structures. There is at present no consensus on the answer to this question.

## Exotic Structures on Open 4-Manifolds

If $M$ is an open manifold, that is, a noncompact manifold without boundary, and $M = \mathbf{R}^n$ then, for

$n \neq 4$, there is only one smooth structure; but for $n = 4$, there are exotic differentiable structures on $\boldsymbol{R}^4$. In fact, Gompf showed that there is a *continuum* of exotic differentiable structures that can be placed on $\boldsymbol{R}^4$.

### Symplectic and Kähler 4-Manifolds

Many 4-manifolds are symplectic, and symplectic manifolds are central in physics; there are many results obtained using Seiberg–Witten theory concerning the topology and geometry of symplectic manifolds. The exotic $K3$ structures referred to above are all symplectic and so there is no shortage of symplectic structures even within one homeomorphism class. Taubes obtained far-reaching new results for symplectic 4-manifolds including establishing an equivalence between the Seiberg–Witten invariants in the symplectic case and the Gromov invariants.

Kähler manifolds possess, simultaneously, compatible, Riemannian, symplectic and complex structures and, beginning with Witten's work, there are many results to be found for Kähler 4-manifolds using Seiberg–Witten techniques.

## 4-Manifolds with Boundary

There is a very important extension of the Donaldson–Seiberg–Witten theory to 4-manifolds $M$ with boundary $\partial M = N$. When $\partial M \neq \phi$, the Donaldson invariants are not numerical invariants but take values in HF($N$) where HF($N$) denotes what is called the Floer homology of the 3-manifold $N$. Topological quantum field theory is the ideal setting for this theory since it naturally treats manifolds with boundaries. The Floer homology groups HF($N$) act as Hilbert spaces for the quantum fields defined on the boundary. There is now a full interplay of 4-manifold theory and 3-manifold theory as well as Yang–Mills theory in three and four dimensions. This interplay is often realized by taking two 4-manifolds $M_1$ and $M_2$ with the same boundary $N$ and joining them along $N$ to obtain a *closed 4-manifold* $M$ so that

$$M = M_1 \cup_N M_2 \qquad [56]$$

Given a 3-manifold $N$, and an SU(2) connection $A$, Floer studied the critical points of the Chern–Simons function $f(A)$ defined by

$$f(A) = \frac{1}{8\pi^2}\int_N \operatorname{tr}\left(A \wedge \mathrm{d}A + \tfrac{2}{3}A \wedge A \wedge A\right) \qquad [57]$$

where $f(A)$ is regarded as a function on the infinite-dimensional space $A$ of connections. The function $f(A)$ changes by an integer under a gauge transformation and so descends to a single-valued gauge-invariant function on the space of gauge orbits $\mathcal{A}/\mathcal{G}$ if one considers $\exp(2\pi k i f(A))$ where $k \in \boldsymbol{Z}$ ($\mathcal{G}$ being the group of gauge transformations). Morse theory applied to this infinite-dimensional setting gives an infinite Morse index to each critical point, a pathology which is avoided by only defining the difference of the index between two critical points using spectral flow. The critical points correspond, via gradient flow and a consideration of the instanton equations

$$F = \pm * F \qquad [58]$$

on the 4-manifold $N \times \boldsymbol{R}$, to the flat connections on the 3-manifold $N$. The latter are identifiable as the set of (equivalence classes) of representations of the fundamental group $\pi_1(M)$ in the gauge group SU(2), that is, with

$$\operatorname{Hom}(\pi_1(N), \mathrm{SU}(2))/\mathrm{Ad}\ \mathrm{SU}(2) \qquad [59]$$

For the Seiberg–Witten formulation, let $\hat{A}$ denote a connection on the 3-manifold $N$ with curvature $F(\hat{A})$. Then the Chern–Simons function $f(A)$ is replaced by the abelian Chern–Simons function together with a quadratic fermion term resulting in the function $f^{\mathrm{SW}}(\hat{A})$, defined by

$$f^{\mathrm{SW}}(\hat{A}) = \int_N \left\{\phi \not{D}_{\hat{A}}\phi + \hat{A} \wedge F(\hat{A})\right\} \qquad [60]$$

where $\not{D}_{\hat{A}}$ denotes the self-adjoint Dirac operator in three dimensions acting on a spinor $\phi$ on $N$; because of the presence of the Chern–Simons function $f^{\mathrm{SW}}(\hat{A})$ is only defined up to a multiple of $8\pi^2$ in a manner similar to the case for $f(A)$. Gradient flow together with the Seiberg–Witten equations on the 4-manifold $N \times \boldsymbol{R}$ result in critical points corresponding to the solutions to

$$\not{D}_{\hat{A}}\phi = 0, \qquad F(\hat{A}) = -\tfrac{1}{2}\phi\Gamma\phi \qquad [61]$$

which is a three-dimensional version of the Seiberg–Witten equations.

The critical point theory of these two functions $f(A)$ and $f^{\mathrm{SW}}(\hat{A})$ permit the construction of the instanton Floer homology groups $\mathrm{HF}^{\mathrm{inst}}(N)$ and $\mathrm{HF}^{\mathrm{SW}}(N)$, respectively. In fact, there are several kinds of Floer homology: Lagrangian Floer homology, instanton Floer homology, Heegard–Floer homology, Seiberg–Witten–Floer homology and conjectures concerning their relations to one another.

There are still many unanswered questions of joint interest to mathematicians and physicists in the entire area of 4-manifold theory.

# Fractal Dimensions in Dynamics

**V Županović and D Žubrinić**, University of Zagreb, Zagreb, Croatia

## Introduction

Since the 1970s, dimension theory for dynamics has evolved into an independent field of mathematics. Its main goal is to measure complexity of invariant sets and measures using fractal dimensions. The history of fractal dimensions is closely related to the names of H Minkowski (Minkowski content, 1903), H Hausdorff (Hausdorff dimension, 1919), G Bouligand (Bouligand dimension, 1928), L S Pontryagin and L G Schnirelmann (metric order, 1932), P Moran (Moran geometric constructions, 1946), A S Besicovitch and S J Taylor (Besicovitch–Taylor index, 1954), A Rényi (Rényi spectrum for dimensions, 1957), A N Kolmogorov and V M Tihomirov (metric dimension, Kolmogorov complexity, 1959), Ya G Sinai, D Ruelle, R Bowen (thermodynamic formalism, Bowen's equation, 1972, 1973, 1979), B Mandelbrot (fractals and multifractals, 1974), J L Kaplan and J A Yorke (Lyapunov dimension, 1979), J E Hutchinson (fractals and self-similarity, 1981), C Tricot, D Sullivan (packing dimension, 1982, 1984), H G E Hentschel and I Procaccia (Hentschel–Procaccia spectrum for dimensions, 1983), Ya Pesin (Carathéodory–Pesin dimension, 1988), M Lapidus and M van Frankenhuysen (complex dimensions for fractal strings, 2000), etc. Fractal dimensions enable us to have a better insight into the dynamics appearing in various problems in physics, engineering, chemistry, medicine, geology, meteorology, ecology, economics, computer science, image processing, and, of course, in many branches of mathematics. Concentrating on box and Hausdorff dimensions only, we describe basic methods of fractal analysis in dynamics, sketch their applications, and indicate some trends in this rapidly growing field.

## Fractal Dimensions

### Box Dimensions

Let $A$ be a bounded set in $\mathbb{R}^N$, and let $d(x,A)$ be Euclidean distance from $x$ to $A$. The Minkowski sausage of radius $\varepsilon$ around $A$ (a term coined by B Mandelbrot) is defined as $\varepsilon$-neighborhood of $A$, that is, $A_\varepsilon := \{y \in \mathbb{R}^N\colon d(y,A) < \varepsilon\}$. By the upper s-dimensional Minkowski content of $A$, $s \geq 0$, we mean

$$\mathcal{M}^{*s}(A) := \overline{\lim_{\varepsilon\to 0}} \frac{|A_\varepsilon|}{\varepsilon^{N-s}} \in [0,\infty]$$

Here $|\cdot|$ denotes $N$-dimensional Lebesgue measure. The corresponding upper box dimension is defined by

$$\overline{\dim}_B A := \inf\{s \geq 0\colon\ \mathcal{M}^{*s}(A) = 0\}$$

The lower s-dimensional Minkowski content $\mathcal{M}_*^s(A)$ and the corresponding lower box dimension $\underline{\dim}_B A$ are defined analogously. The name of box dimension stems from the following: if we have an $\varepsilon$-grid in $\mathbb{R}^N$ composed of closed $N$-dimensional boxes with side $\varepsilon$, and if $N(A,\varepsilon)$ is the number of boxes of the grid intersecting $A$, then

$$\overline{\dim}_B A = \overline{\lim_{\varepsilon\to 0}} \frac{\log N(A,\varepsilon)}{\log(1/\varepsilon)}$$

and analogously for $\underline{\dim}_B A$. It suffices to take any geometric subsequence $\varepsilon_k = b^{-k}$ in the limit, where $b > 1$ (H Furstenberg, 1970). There are many other names for the upper box dimension appearing in the literature, like the Cantor–Minkowski order, Minkowski dimension, Bouligand dimension, Borel logarithmic rarefaction, Besicovitch–Taylor index, entropy dimension, Kolmogorov dimension, fractal dimension, capacity dimension, and limit capacity. If $A$ is such that $\underline{\dim}_B A = \overline{\dim}_B A$, the common value is denoted by $d := \dim_B A$, and we call it the box dimension of $A$. If, in addition to this, both $\mathcal{M}_*^d(A)$ and $\mathcal{M}^{*d}(A)$ are in $(0,\infty)$, we say that $A$ is Minkowski nondegenerate. If, moreover, $\mathcal{M}_*^d(A) = \mathcal{M}^{*d}(A) =: \mathcal{M}^d(A) \in (0,\infty)$, then $A$ is said to be Minkowski measurable.

Assume that $A$ is such that $d := \dim_B A$ and $\mathcal{M}^d(A)$ exist. Then the value of $\mathcal{M}^d(A)^{-1}$ is called the lacunarity of $A$ (B Mandelbrot, 1982). A bounded set $A \subset \mathbb{R}^N$ is said to be porous (A Denjoy, 1920) if there exist $\alpha > 0$ and $\delta > 0$ such that for every $x \in A$ and $r \in (0,\delta)$ there is $y \in \mathbb{R}^N$ such that the open ball $B_{\alpha r}(y)$ is contained in $B_r(x) \setminus A$. If $A$ is porous then it is easy to see that $\overline{\dim}_B A < N$ (O Martio and M Vuorinen, 1987, A Salli, 1991).

We proceed with two examples. Let $A := C^{(a)}$, $a \in (0,1/2)$, be the Cantor set obtained from $[0,1]$ by consecutive deletion of $2^k$ middle open intervals of length $a^k(1-2a)$ in step $k \in \mathbb{N} \cup \{0\}$. Then $\dim_B A = (\log 2)/(\log(1/a))$ (G Bouligand, 1928), and $A$ is nondegenerate, but not Minkowski measurable (Lapidus and Pomerance, 1993). For the spiral $\Gamma$ of focus type defined by $r = m\varphi^{-\alpha}$ in polar coordinates, where $\alpha \in (0,1)$ and $m > 0$ are fixed, $\varphi \geq \varphi_1 > 0$, we have $\dim_B \Gamma = 2/(1+\alpha)$ (Y Dupain, M Mendés-France, C Tricot, 1983). It is Minkowski measurable (Žubrinić and Županović, 2005), and the larger $m$, the smaller the lacunarity; see Figure 1.

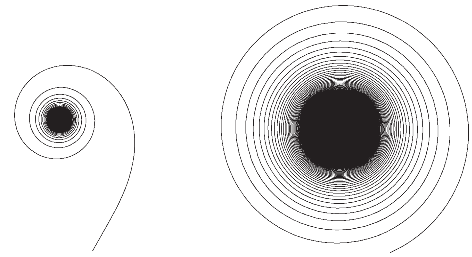

**Figure 1** Spirals of equal box dimensions (4/3) and different lacunarities (0.43 and 0.05).

### Hausdorff Dimension

For a given subset $A$ of $\mathbb{R}^N$ (not necessarily bounded) and $s \geq 0$ we define $\mathcal{H}^s(A) := \lim_{\varepsilon\to 0} \inf\{\sum_{i=1}^{\infty} r_i^s\} \in [0,\infty]$, where the infimum is taken over all finite or countable coverings of $A$ by open balls of radii $r_i \leq \varepsilon$. The value of $\mathcal{H}^s(A)$ is called $s$-dimensional Hausdorff outer measure of $A$. The Hausdorff dimension of $A$, sometimes called the Hausdorff–Besicovitch dimension, is defined by

$$\dim_H A := \inf\{s \geq 0\colon\ \mathcal{H}^s(A) = 0\}$$

If $A$ is bounded then $\dim_H A \leq \underline{\dim}_B A \leq \overline{\dim}_B A \leq N$.

We say that $A$ is Hausdorff nondegenerate (or $d$-set) if $\mathcal{H}^d(A) \in (0,\infty)$ for some $d \geq 0$. Cantor sets share this property, and $\dim_H C^{(a)} = (\log 2)/(\log(1/a))$, where $a \in (0,1/2)$ (Hausdorff, 1919).

### Gauge Functions

The notions of Minkowski contents and Hausdorff measure can be generalized using gauge functions $h : [0,\varepsilon_0) \to \mathbb{R}$ that are assumed to be continuous, increasing, and $h(0) = 0$. For example,

$$\mathcal{M}^{*h}(A) := \overline{\lim_{\varepsilon\to 0}} \frac{|A_\varepsilon|}{\varepsilon^N} h(\varepsilon)$$

and similarly for $\mathcal{M}_*^h(A)$ (M Lapidus and C He, 1997), while for $\mathcal{H}^h(A)$ it suffices to change $r_i^s$ with $h(r_i)$ in the above definition of the Hausdorff outer measure (Besicovitch, 1934). Gauge functions are used for sets that are Minkowski or Hausdorff

degenerate. The aim, if possible, is to find an explicit gauge function so that the corresponding generalized Minkowski contents or Hausdorff measure of $A$ be nondegenerate.

## Methods of Fractal Analysis in Dynamics

### Thermodynamic Formalism

Thermodynamic formalism has been developed by Sinai (1972), Ruelle (1973), and Bowen (1975), using methods of statistical mechanics in order to study dynamics and to find dimensions of various fractal sets. We first describe a "dictionary" for explicit geometric constructions of Cantor-like sets. Let $X_p$ be the set of all sequences $\boldsymbol{i}=(i_1,i_2,\ldots)$ of elements $i_k$ from a given set of $p$ symbols, say $\{1,2,\ldots,p\}$. We endow $X_p$ with the metric $d(\boldsymbol{i},\boldsymbol{j}):=\sum_k 2^{-k}|i_k-j_k|$ and introduce the one-sided shift operator (or left shift) $\sigma: X_p\to X_p$ defined by $(\sigma(\boldsymbol{i}))_n=i_{n+1}$, that is, $\sigma(i_1,i_2,i_3,\ldots)=(i_2,i_3,i_4,\ldots)$. A set $Q\subseteq X_p$ is called the symbolic dynamics if it is compact and $\sigma$-invariant, that is, $\sigma(Q)\subseteq Q$. Hence, $(Q,\sigma)$ is a symbolic dynamical system. Denote $\boldsymbol{i}[n]:=(i_1,\ldots,i_n)$. Given a continuous function $\varphi: Q\to\mathbb{R}$, let us define the topological pressure of $\varphi$ with respect to $\sigma$ by

$$P(\varphi):=\lim_{n\to\infty}\frac{1}{n}\log\sum_{\{\boldsymbol{i}[n]:\boldsymbol{i}\in Q\}}E(\boldsymbol{i}[n])$$

$$E(\boldsymbol{i}[n]):=\exp\left(\sup_{\{\boldsymbol{j}\in Q:\ \boldsymbol{j}[n]=\boldsymbol{i}[n]\}}\sum_{k=0}^{n-1}\varphi(\sigma^k(\boldsymbol{j}))\right)$$

The topological entropy of $\sigma|Q$ is defined by $h(\sigma|Q):=P(0)$, that is,

$$h(\sigma|Q)=\lim_{n\to\infty}\frac{1}{n}\log\#\{\boldsymbol{i}[n]:\ \boldsymbol{i}\in Q\}$$

where # denotes the cardinal number of a set. The above function $\varphi_n:=\sum_{k=0}^{n-1}\varphi\circ\sigma^k$ has the property $\varphi_{n+m}=\varphi_n+\varphi_m\circ\sigma^n$, and therefore we speak about additive thermodynamic formalism. Topological pressure was introduced by D Ruelle (1973) and extended by P Walters (1976). Bowen's equation (1979) has a very important role in the computation of the Hausdorff dimension of various sets. For the unknown $s\in\mathbb{R}$, and with a suitably chosen function $\varphi$, this equation reads

$$P(s\varphi)=0$$

### Geometric Constructions

A geometric construction $(Q,\Delta)$ in $\mathbb{R}^m$ indexed by symbolic dynamics $Q$ is a family $\Delta$ of compact sets $\Delta_{\boldsymbol{i}[n]}\subset\mathbb{R}^m, \boldsymbol{i}\in Q, n\in\mathbb{N}$, such that $\operatorname{diam}\Delta_{\boldsymbol{i}[n]}\to 0$ as $n\to\infty$, $\Delta_{\boldsymbol{i}[n+1]}\subseteq\Delta_{\boldsymbol{i}[n]}$, $\Delta_{\boldsymbol{i}[n]}=\overline{\operatorname{int}\Delta_{\boldsymbol{i}[n]}}$ for every $\boldsymbol{i}\in Q$ and all $n$, and $\operatorname{int}\Delta_{\boldsymbol{i}[n]}\cap\operatorname{int}\Delta_{\boldsymbol{j}[n]}=\emptyset$ whenever $\boldsymbol{i}[n]\neq\boldsymbol{j}[n]$ (Moran's open set condition). This family induces the Cantor-like set

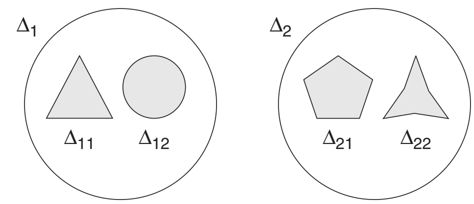

**Figure 2** Cantor-like set.

$$F:=\bigcap_{n=1}^{\infty}\left(\bigcup_{\boldsymbol{i}\in Q}\Delta_{\boldsymbol{i}[n]}\right)$$

(see Figure 2). The mapping $h: Q\to F$ defined by $h(\boldsymbol{i}):=\cap_{n=1}^{\infty}\Delta_{\boldsymbol{i}[n]}$ is called the coding map of $F$. The above geometric construction includes well-known iterated function systems of similarities as a special case. If $\lambda_1,\ldots,\lambda_p$ are given numbers in (0, 1), and $\Delta_{\boldsymbol{i}[n]}$ are balls of radii $r_{\boldsymbol{i}[n]}:=\lambda_{i_1}\ldots\lambda_{i_n}$, then $s:=\dim_H F$ is the unique solution of Bowen's equation $P(s\varphi)=0$, where $\varphi$ is defined by $\varphi(\boldsymbol{i}):=\log\lambda_{i_1}$ (Ya Pesin and H Weiss, 1996). In this case Bowen's equation is equivalent to Moran's equation (1946),

$$\sum_{k=1}^{p}{\lambda_k}^s=1$$

This result has been generalized by L Barreira (1996) using the Carathéodory–Pesin construction (1988). Let us illustrate Barreira's theory of nonadditive thermodynamic formalism with a special case. Assume that $(Q,\Delta)$ is a geometric construction for which the sets $\Delta_{\boldsymbol{i}[n]}$ are balls, and let there exist $\delta>0$ such that $r_{\boldsymbol{i}[n+1]}\geq\delta\cdot r_{\boldsymbol{i}[n]}$ and $r_{\boldsymbol{i}[n+m]}\leq r_{\boldsymbol{i}[n]}r_{\sigma^n(\boldsymbol{i})[m]}$ for all $\boldsymbol{i}\in Q, n, m\in\mathbb{N}$. Then $\dim_H F=\dim_B F=s$, where $s$ is the unique real number such that

$$\lim_{n\to\infty}\frac{1}{n}\log\sum_{\{\boldsymbol{i}[n]:\boldsymbol{i}\in Q\}}{r_{\boldsymbol{i}[n]}}^s=0 \qquad [1]$$

This is a special case of Barreira's extension of Bowen's equation to nonadditive thermodynamic formalism. Moran's equation can be deduced from [1] by defining $r_{\boldsymbol{i}[n]}:=\lambda_{i_1}\ldots\lambda_{i_n}$, where $\boldsymbol{i}=(i_1,i_2,\ldots)$, and $\lambda_1,\ldots,\lambda_p\in(0,1)$ are given numbers. Pesin and Weiss (1996) showed that Moran's open set condition can be weakened so that partial intersections of interiors of pairs of basic sets in the family $\Delta$ are allowed. Thermodynamic formalism has been used to study the Hausdorff dimension of Julia sets

(Ruelle, 1982), horseshoes (H McCluskey and A Manning, 1983), etc.

An important example of symbolic dynamics is the topological Markov chain $X_A$ generated by a $p \times p$ matrix $A$ with entries $a_{ij} \in \{0, 1\}$:

$$X_A := \{\boldsymbol{i} = (i_1, i_2, \ldots) \in X_p\colon\ a_{i_k i_{k+1}} = 1 \text{ for all } k \in \mathbb{N}\}$$

It is a compact, $\sigma$-invariant subset of $X_p$. The map $\sigma | X_A$ is called the subshift of finite type (Bowen, 1975). A construction of Cantor-like set $F$ using dynamics $Q = X_p$ is called a simple geometric construction, while a geometric construction is said to be a Markov geometric construction if $Q = X_A$. If $F$ is obtained by a Markov geometric construction such that all $\Delta_{\boldsymbol{i}[n]}$ are balls of radii $r_{\boldsymbol{i}[n]} := \lambda_{i_1} \ldots \lambda_{i_n}$, where $\lambda_{i_j} \in (0,1), i_j \in \{1, \ldots, p\}$, then $\dim_{\mathrm{B}} F = \dim_{\mathrm{H}} F = s$, where $s$ is the unique solution of equation $\rho(AM_s) = 1$. Here $M_s := \mathrm{diag}({\lambda_1}^s, \ldots, {\lambda_p}^s)$ and $\rho(AM_s)$ is the spectral radius of the matrix $AM_s$. This and more general results have been obtained by Pesin and Weiss (1996).

Any Cantor-like set $F$ obtained via iterated function system of similarities satisfying Moran's open set condition is Hausdorff nondegenerate (Moran, 1946). If $F$ is of nonlattice type, that is, the set $\{\log \lambda_1, \ldots, \log \lambda_p\}$ is not contained in $r \cdot \mathbb{Z}$ for any $r > 0$, then $F$ is Minkowski measurable (D Gatzouras, 1999).

### Hyperbolic Measures

Let $X$ be a complete metric space and assume that $f : X \to X$ is continuous. Let $\mu$ be an $f$-invariant Borel probability measure on $X$ (i.e., $\mu(f^{-1}(A)) = \mu(A)$ for measurable sets $A$) with a compact support. The Hausdorff dimension of $\mu$, and the lower and upper box dimensions of $\mu$ (L-S Young, 1982) are defined by

$$\dim_{\mathrm{H}} \mu := \inf\{\dim_{\mathrm{H}} Z : Z \subseteq X, \mu(Z) = 1\}$$
$$\underline{\dim}_{\mathrm{B}} \mu := \lim_{\delta \to 0} \inf\{\underline{\dim}_{\mathrm{B}} Z : Z \subseteq X, \mu(Z) \geq 1 - \delta\}$$
$$\overline{\dim}_{\mathrm{B}} \mu := \lim_{\delta \to 0} \inf\{\overline{\dim}_{\mathrm{B}} Z : Z \subseteq X, \mu(Z) \geq 1 - \delta\}$$

It is natural to introduce the lower and upper pointwise dimensions of $\mu$ at $x \in X$ by

$$\underline{d}_\mu(x) := \varliminf_{r \to 0} \frac{\log \mu(B_r(x))}{\log r}$$

and similarly $\overline{d}_\mu(x)$. It has been shown by Young (1982) that if $X$ has finite topological dimension and if $\mu$ is exact dimensional, that is, $\underline{d}_\mu(x) = \overline{d}_\mu(x) =: d$ for $\mu$-a.e. $x \in X$, then

$$\dim_{\mathrm{H}} \mu = \dim_{\mathrm{B}} \mu = d$$

She also proved that hyperbolic measures (ergodic measures with nonzero Lyapunov exponents), invariant under a $C^{1+\alpha}$-diffeomorphism, $\alpha > 0$, are exact dimensional. F Ledrappier (1986) derived exact dimensionality for hyperbolic Bowen–Ruelle–Sinai measures. This result was extended by Ya Pesin and Ch Yue (1996) to hyperbolic measures with semilocal product structure. J-P Eckmann and D Ruelle (1985) conjectured that the exact dimensionality holds for general hyperbolic measures, and this was proved by Barreira, Pesin, and Schmeling (1996). More precisely, if $f$ is a $C^{1+\alpha}$-diffeomorphism on a smooth Riemann manifold $X$ without boundary, and if $\mu$ is $f$-invariant, compactly supported Borel probability measure, then its hyperbolicity implies that

$$\underline{d}_\mu(x) = \overline{d}_\mu(x) = d^s_\mu(x) + d^u_\mu(x)$$

for $\mu$-a.e. $x \in X$, where $d^s_\mu(x)$ and $d^u_\mu(x)$ are stable and unstable pointwise dimensions of $\mu$ at $x$ introduced by Ledrappier and Young (1985).

### Multifractal Analysis of Functions and Measures

Invariant sets of many dynamical systems are not self-similar. Roughly speaking, the aim of multifractal analysis is to make a decomposition of the invariant set with respect to desired fractal properties and then to study a fractal dimension of each set of the decomposition. Some dynamical systems have invariant sets equal to graphs of Hölderian functions $f : \mathbb{R}^N \to \mathbb{R}$, so that wavelet methods can be used. One of the goals of multifractal analysis of functions is to study the spectrum of singularities of $f$ defined by

$$d_f(\alpha) := \dim_{\mathrm{H}} H_\alpha(f)$$

introduced by U Frisch and G Parisi (1985) in the context of fully developed turbulence. Here $H_\alpha(f)$ is the set of points at which the corresponding pointwise Hölder exponent of $f$ is equal to $\alpha \geq 0$. If the function $f$ is self-similar then $d_f(\alpha)$ is real analytic and strictly concave (first increasing and then decreasing) on an explicit interval $(\underline{a}, \overline{a})$ (S Jaffard, 1997). It is natural to consider the set $C_{\alpha,\beta}(f)$ of points $x_0$ called chirps of order $(\alpha, \beta)$ (Y Meyer 1996), at which $f$ behaves roughly like $|x - x_0|^\alpha \sin(1/|x - x_0|^\beta), \beta > 0$. The function $D_f(\alpha, \beta) := \dim_H C_{\alpha,\beta}(f)$ is called the chirp spectrum of $f$ (S Jaffard 2000). Wavelet methods have found applications in the study of evolution equations and in modeling and detection of chirps in turbulent flows (S Jaffard, Y Meyer, R D Robert, 2001).

Basic ideas of multifractal analysis have been introduced by physicists T Halsey, M H Jensen,

L P Kadanoff, I Procaccia, and B I Shraiman (1988). In applications it often deals with an invariant ergodic probability measure associated with the dynamical system considered. Multifractal analysis of a Borel finite measure $\mu$ defined on $\mathbb{R}^N$ consists in the study of the function

$$d_\mu(\alpha) := \dim_{\mathrm{H}} K_\alpha(\mu), \quad \alpha \geq 0$$

called the spectrum of pointwise dimensions of $\mu$. Here $K_\alpha(\mu)$ is the set of points where the pointwise dimension of $\mu$ is equal to $\alpha$:

$$K_\alpha(\mu) := \{x \in \mathbb{R}^N \colon \; \underline{d}_\mu(x) = \overline{d}_\mu(x) = \alpha\}$$

It is also of interest to study the Hausdorff dimension of irregular set $K(\mu) := \{x \in \mathbb{R}^N \colon \underline{d}_\mu(x) < \overline{d}_\mu(x)\}$. These sets are pairwise disjoint and constitute a multifractal decomposition of $\mathbb{R}^N$, that is,

$$\mathbb{R}^N = K(\mu) \cup (\cup_{\alpha \in \mathbb{R}} K_\alpha(\mu))$$

The function $d_\mu(\alpha)$ provides an important information about the complexity of multifractal decomposition. In many situations, there is an open interval $(\underline{\alpha}, \overline{\alpha})$ on which the function $d_\mu(\alpha)$ is analytic and strictly concave (first increasing and then decreasing), and equal to the Legendre transform of an explicit convex function. We thus obtain an uncountable family of sets $K_\alpha(\mu)$ with positive Hausdorff dimension, which shows enormous complexity of the multifractal decomposition of $\mathbb{R}^N$. These and related questions have been studied by L Olsen (1995), K Falconer (1996), Pesin and Weiss (1996), Barreira and Schmeling (2000), and many other authors.

### Local Lyapunov Dimension

Let $\Omega$ be an open set in $\mathbb{R}^N$ and let $f : \Omega \to \mathbb{R}^N$ be a $C^1$-map. To any fixed $x \in \Omega$ we assign $N$ singular values $a_1 \geq a_2 \geq \cdots \geq a_N \geq 0$ of $f$, defined as square roots of eigenvalues of the matrix $f'(x)^\top \cdot f'(x)$, where $f'(x)$ is the Jacobian of $f$ at $x$, and $f'(x)^\top$ its transpose. The local Lyapunov dimension of $f$ at $x$ is defined by

$$\dim_{\mathrm{L}}(f, x) := j + s$$

where $j$ is the largest integer in $[0, N]$ such that $a_1 \cdots a_j \geq 1$ (if there is no such $j$ we let $j = 0$), and $s \in [0, 1)$ is the unique solution of $a_1 \cdots a_j a_{j+1}^s = 1$ (except for $j = N$, when we define $s = 0$). This definition, due to B R Hunt (1996), is close to that of Kaplan and Yorke (1979). The Jacobian $f'(x)$ contracts $k$-dimensional volumes (that is, $a_1 \cdots a_k < 1$) if and only if $\dim_{\mathrm{L}}(f, x) < k$. In this case, we say that $f$ is $k$-contracting at $x$. Furthermore, the function $x \mapsto \dim_{\mathrm{L}}(f, x)$ is upper-semicontinuous, so that for any compact subset $A$ of $\Omega$ the Lyapunov dimension of $f$ on A,

$$\dim_{\mathrm{L}}(f, A) := \max_{x \in A} \dim_{\mathrm{L}}(f, x)$$

is well defined. Yu S Ilyashenko conjectured that if $f$ locally contracts $k$-dimensional volumes then the upper box dimension of any compact invariant set is $< k$. Hunt (1996) proved that if $A$ is a compact, strictly invariant set of $f$ (i.e., $f(A) = A$) then

$$\overline{\dim}_{\mathrm{B}} A \leq \dim_{\mathrm{L}}(f, A) \qquad [2]$$

This is an improvement of $\dim_H A \leq \dim_{\mathrm{L}}(f, A)$ obtained by A Douady and J Oesterlé (1980), and independently by Ilyashenko (1982). M A Blinchevskaya and Yu S Ilyashenko (1999) proved that if $A$ is any attractor of a smooth map in a Hilbert space that contracts $k$-dimensional volumes then $\overline{\dim}_{\mathrm{B}} A \leq k$. See [3] below.

A continuous variant of this method is used in order to obtain estimates of fractal dimensions of global attractors of dynamical systems $(X, S)$ on a Hilbert space $X$. Here $S(t), t \geq 0$, is a semigroup of continuous operators on $X$, that is, $S(t+s) = S(t)S(s)$ and $S(0) = I$. A set $A$ in $X$ is called a global attractor of dynamical system if it is compact, attracting (i.e., for any bounded set $B$ and $\varepsilon > 0$ there exists $t_0$ such that for $t \geq t_0$ we have $S(t)B \subseteq A_\varepsilon$), and $A$ is strictly invariant (i.e., $S(t)A = A$ for all $t \geq 0$).

## Applications in Dynamics

### Logistic Map

M Feigenbaum, a mathematical physicist, introduced and studied the dynamics of the logistic map $f_\lambda : [0,1] \to [0,1], f_\lambda(x) := \lambda x(1-x), \lambda \in (0, 4]$. Taking $\lambda = \lambda_\infty \approx 3.570$ the corresponding invariant set $A \subset [0, 1]$ (i.e., $S_1(A) \cup S_2(A) = A$, where $S_i$ are two branches of $f_\lambda^{-1}$) has both Hausdorff and box dimensions equal to $\approx 0.538$ (P Grassberger 1981, P Grassberger and I Procaccia, 1983). The set $A$ has Cantor-like structure, but is not self-similar. Its multifractal properties have been studied by U Frisch, K Khanin, and T Matsumoto (2004).

### Smale Horseshoe

In the early 1960s S Smale defined his famous horseshoe map and showed that it has a strange invariant set resulting in chaotic dynamics. The notion of strange attractor was introduced in 1971 by Ruelle and Takens in their study of turbulence. Let $S$ be a square in the plane and let $f : \mathbb{R}^2 \to \mathbb{R}^2$ be a map transforming $S$ as indicated in Figure 3, such that on both components of $S \cap f^{-1}(S)$ the map $f$ is

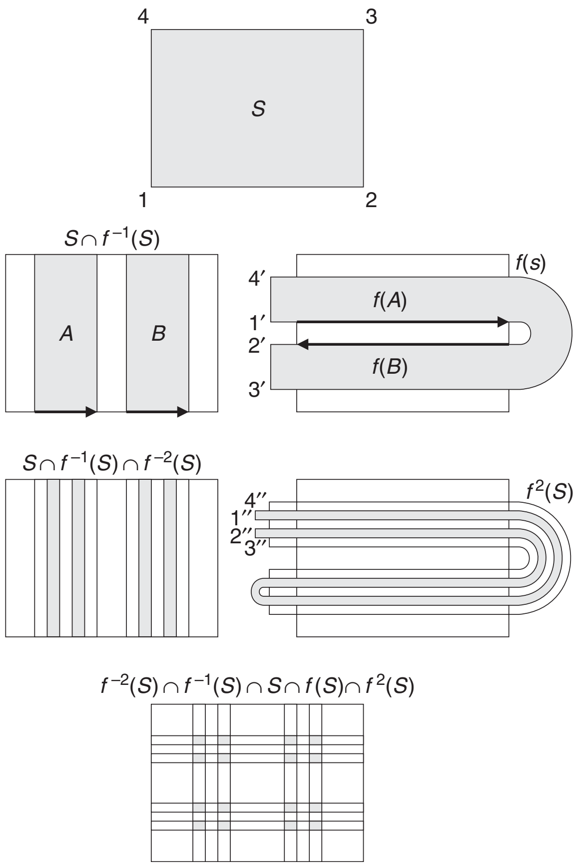

**Figure 3** The Smale horseshoe.

affine and preserves both horizontal and vertical directions, and such that points 1, 2, 3, and 4 are mapped to $1', 2', 3'$, and $4'$. Iterating $f$ we get backward invariant set $\Lambda_- := \cap_{j=0}^{\infty} f^{-j}(S)$, forward invariant set $\Lambda_+ := \cap_{j=0}^{\infty} f^{j}(S)$, and invariant set (horseshoe) $\Lambda_f := \Lambda_+ \cap \Lambda_-$. These sets have the Cantor set structure. More precisely, assuming that the contraction parameter of $f$ in vertical direction is $a \in (0, 1/2)$, and the expansion parameter in horizontal direction is $b > 2$, then $\Lambda_+ = [0,1] \times C^{(a)}$, where $C^{(a)}$ is the Cantor set, $\Lambda_- = C^{(1/b)} \times [0,1]$, and $\Lambda_f = C^{(1/b)} \times C^{(a)}$, so that $\dim_B \Lambda_+ = \dim_H \Lambda_+ = 1 + (\log 2)/(\log(1/a))$ and

$$\dim_B \Lambda_f = \dim_H \Lambda_f = \frac{\log 2}{\log b} + \frac{\log 2}{\log(1/a)}$$

This is a special case of a general result about horseshoes in $\mathbb{R}^2$ (not necessarily affine), due to McCluskey and Manning (1983), stated in terms of the pressure function. Analogous result as above can be obtained for Smale solenoids. In $\mathbb{R}^3$ it is possible to construct affine horseshoes $\Lambda_f$ such that $\dim_H \Lambda_f < \dim_B \Lambda_f$ (M Pollicott and H Weiss, 1994).

Smale discovered a connection between homoclinic orbits and the horseshoe map. It has been noticed that fractal dimensions have important role in the study of homoclinic bifurcations of nonconservative dynamical systems. Since the 1970s the relationship between invariants of hyperbolic sets and the typical dynamics appearing in the unfolding of a homoclinic tangency by a parametrized family of surface diffeomorphisms has been studied by J Newhouse, J Palis, F Takens, J-C Yoccoz, C G Moreira and M Viana. The main result is that if the Hausdorff dimension of the hyperbolic set involved in the tangency is $<1$ then the parameter set where the hyperbolicity prevails has full Lebesgue density. If the Hausdorff dimension is $>1$, then hyperbolicity is not prevalent. This result and its proof were inspired by previous work of J M Marstrand (1954) about arithmetic differences of Cantor sets on the real line. According to the result by Moreira, Palis, and Viana (2001) the paradigm "hyperbolicity prevails if and only if the Hausdorff dimension is $<1$" extends to homoclinic bifurcations in any dimension.

Using methods of thermodynamic formalism McCluskey and Manning (1983) proved that if $f$ is the above horseshoe map, then there exists a $C^1$-neighborhood $U$ of $f$ such that the mapping $f \mapsto \dim_H \Lambda_f$ is continuous. Continuity of box and Hausdorff dimensions for horseshoes has been studied also by Takens, Palis, and Viana (1988).

## Lorenz Attractor

E N Lorenz (1963), a meteorologist and student of G Birkhoff, showed by numerical experiments that for certain values of positive parameters $\sigma, r, b$, the quadratic system

$$\dot{x} = \sigma(y - x), \qquad \dot{y} = rx - y - xz, \qquad \dot{z} = xy - bz$$

has the global attractor $A$, for example, for $\sigma = 10$, $r = 28, b = 8/3$. In this case $\dim_B A \approx 2.06$, which is a numerical result (Grassberger and Procaccia, 1983). Using the analysis of local Lyapunov dimension along the flow in $A$, G A Leonov (2001) showed that if $\sigma + 1 \geq b \geq 2$ and $r\sigma^2(4 - b) + 2\sigma(b - 1) \times (2\sigma - 3b) > b(b - 1)^2$ then

$$\overline{\dim}_B A \leq 3 - \frac{2(\sigma + b + 1)}{\sigma + 1 + \sqrt{(\sigma - 1)^2 + 4r\sigma}}$$

## Hénon Attractor

M Hénon (1976), a theoretical astronomer, discovered the map $f : \mathbb{R}^2 \to \mathbb{R}^2, f(x, y) := (a + by - x^2, x)$, capturing several essential properties of the Lorenz system. In the case of $a = 1.4$ and $b = 0.3$, Hunt (1996) derived from [2] that for any compact, strictly $f$-invariant set $A$ in the trapping region $[-1.8, 1.8]^2$

there holds $\overline{\dim}_B A < 1.5$. Numerical experiments show that $\dim_B A \approx 1.28$ (Grassberger, 1983). Assuming $a > 0, b \in (0, 1)$, and $P_\pm(x_\pm, x_\pm) \in A$, where $P_\pm$ are fixed points of $f$, Leonov (2001) obtained that

$$\overline{\dim}_B A \le 1 + \frac{1}{1 - \ln b / \ln(\sqrt{x_-^2 + b} - x_-)}$$

Here

$$x_\pm := \frac{1}{2}\left[b - 1 \pm \sqrt{(b-1)^2 + 4a}\right]$$

The proof is based on the study of local Lyapunov dimension of $f$ and its iterates on $A$.

### Embedology

The physical relevance of box dimensions in the study of attractors is related to the problem of finding the smallest possible dimension $n$ sufficient to "embed" an attractor into $\mathbb{R}^n$. If $A \subset \mathbb{R}^k$ is a compact set and if $n > 2\underline{\dim}_B A$, then almost every map from $\mathbb{R}^k$ into $\mathbb{R}^n$, in the sense of prevalence, is one-to-one on $A$ and, moreover, it is an embedding on smooth manifolds contained in $A$ (T Sauer, J A Yorke, and M Casdagli, 1991). If $A$ is a strange attractor then the same is true for almost every delay-coordinate map from $\mathbb{R}^k$ to $\mathbb{R}^n$. This improves an earlier result by H Whitney (1936) and F Takens (Takens' embedology, 1981). The above notion of prevalence means the following: a property holds almost everywhere in the sense of prevalence if it holds on a subset $S$ of the space $V := C^1(\mathbb{R}^k, \mathbb{R}^n)$ for which there exists a finite-dimensional subspace $E \subset V$ (probe space) such that for each $v \in V$ we have that $v + e \in S$ for Lebesgue a.e. $e \in E$.

### Julia and Mandelbrot Sets

M Shishikura (1998) proved that the boundary of the Mandelbrot set $M$ generated by $f_c(z) := z^2 + c$ has the Hausdorff dimension equal to 2, thus answering positively to the conjecture by B Mandelbrot, J Milnor, and other mathematicians. Also for Julia sets there holds $\dim_H J(f_c) = 2$ for generic $c$ in $M$ (i.e., on the set of second Baire category). The proof is based on the study of the bifurcation of parabolic periodic points. Also, each baby Mandelbrot set sitting inside of $M$ has the boundary of Hausdorff dimension 2 (L Tan, 1998). Shishikura's results hold for more general functions $f(z) := z^d + c$, where $d \ge 2$.

For Julia sets $J(f_c)$ generated by $f_c(z) := z^2 + c$ there holds $d(c) := \dim_H J(f_c) = 1 + |c|^2/(4 \log 2) + o(|c|^2)$ for $c \to 0$. This and more general results have been obtained by Ruelle (1982). He also proved that the function $d(c)$ when restricted to the interval $[0, \infty)$ is real analytic in $[0, 1/4) \cup (1/4, \infty)$. Furthermore, it is left continuous at 1/4 (O Bodart and M Zinsmeister, 1996), but not continuous (A Douady, P Sentenac, and M Zinsmeister, 1997). Discontinuity of this map is related to the phenomenon of parabolic implosion at $c = 1/4$. The derivative $d'(c)$ tends to $+\infty$ from the left at $c = 1/4$ like $(1/4 - c)^{d(1/4) - 3/2}$ (G Havard and M Zinsmeister, 2000). Here $d(1/4) \approx 1.07$, which is a numerical result. Analysis of dimensions is based on methods of thermodynamic formalism.

C McMullen (1998) showed that if $\theta$ is an irrational number of bounded type (i.e., its continued fractional expansion $[a_1, a_2, \ldots]$ is such that the sequence $(a_i)$ is bounded from above) and $f(z) := z^2 + e^{2\pi\theta i} z$, then the Julia set $J(f)$ is porous. In particular, $\overline{\dim}_B J(f) < 2$. Y C Yin (2000) showed that if all critical points in $J(f)$ of a rational map $f : \overline{\mathbb{C}} \to \overline{\mathbb{C}}$ are nonrecurrent (a point is nonrecurrent if it is not contained in its $\omega$-limit set) then $J(f)$ is porous, hence $\overline{\dim}_B J(f) < 2$. Urbański and Przytycki (2001) described more general rational maps such that $\overline{\dim}_B J(f) < 2$.

### Spiral Trajectories

A standard planar model where the Hopf–Takens bifurcation occurs is $\dot{r} = r(r^{2l} + \sum_{i=0}^{l-1} a_i r^{2i}), \dot{\varphi} = 1$, where $l \in \mathbb{N}$. If $\Gamma$ is a spiral tending to the limit cycle $r = a$ of multiplicity $m$ (i.e., $r = a$ is a zero of order $m$ of the right-hand side of the first equation in the system) then $\dim_B \Gamma = 2 - 1/m$. Furthermore, for $m > 1$ the spiral is Minkowski measurable (Žubrinić and Županović, 2005). For $m = 1$ the spiral is Minkowski nondegenerate with respect to the gauge function $h(\varepsilon) := \varepsilon(\log(1/\varepsilon))^{-1}$.

### Infinite-Dimensional Dynamical Systems

In many situations the dynamics of the global attractor $A$ of the flow corresponding to an autonomous Navier–Stokes system is finite-dimensional (Ladyzhenskaya, 1972). This means that there exists a positive integer $N$ such that any trajectory in $A$ is completely determined by its orthogonal projection onto an $N$-dimensional subspace of a Hilbert space $X$. The aim is to find estimates of box and Hausdorff dimensions of the global attractor, in order to understand some of the basic and challenging problems of turbulence theory. If $A$ is a subset of a Hilbert space $X$, its Hausdorff dimension is defined analogously as for $A \subset \mathbb{R}^N$. The definition of the upper box dimension can be extended from $A \subset \mathbb{R}^N$ to

$$\overline{\dim}_B A := \overline{\lim}_{\varepsilon \to 0} \frac{\log m(A, \varepsilon)}{\log(1/\varepsilon)} \qquad [3]$$

where $m(A, \varepsilon)$ is the minimal number of balls sufficient to cover a given compact set $A \subset X$. The value of $\log m(A, \varepsilon)$ is called $\varepsilon$-entropy of $A$.

Foiaş and Temam (1979), Ladyzhenskaya (1982), A V Babin and M I Vishik (1982), Ruelle (1983), and E Lieb (1984) were among the first who obtained explicit upper bounds of Hausdorff and box dimensions of attractors of infinite-dimensional systems. For global attractors $A$ associated with some classes of two-dimensional Navier–Stokes equations with nonhomogeneous boundary conditions it can be shown that $\overline{\dim}_B A \le c_1 G + c_2 Re^{3/2}$, where $G$ is the Grashof number, $Re$ is the Reynolds number, and $c_i$ are positive constants (R M Brown, P A Perry, and Z Shen, 2000). V V Chepyzhov and A A Ilyin (2004) obtained that $\overline{\dim}_B A \le (1/\sqrt{2}\pi)(\lambda_1 |\Omega|)^{1/2} G$ for equations with homogeneous boundary conditions, where $\Omega \subset \mathbb{R}^2$ is a bounded domain, and $\lambda_1$ is the first eigenvalue of $-\Delta$. In the case of periodic boundary conditions Constantin, Foiaş, and Temam (1988) proved that $\overline{\dim}_B A \le c_1 G^{2/3}(1 + \log G)^{1/3}$, while for a special class of external forces there holds $\dim_H A \ge c_2 G^{2/3}$ (V X Liu, 1993). Let us mention an open problem by V I Arnol'd: is it true that the Hausdorff dimension of any attracting set of the Navier–Stokes equation on two-dimensional torus is growing with the Reynolds number?

In their study of partial regularity of solutions of three-dimensional Navier–Stokes equations, L Caffarelli, R Kohn, and L Nirenberg (1982) proved that the one-dimensional Hausdorff measure in space and time (defined by parabolic cylinders) of the singular set of any "suitable" weak solution is equal to zero. A weak solution is said to be singular at a point $(x_0, t_0)$ if it is essentially unbounded in any of its neighborhoods. Dimensions of attractors of many other classes of partial differential equations (PDEs) have been studied, like for reaction–diffusion systems, wave equations with dissipation, complex Ginzburg–Landau equations, etc. Related questions for nonautonomous PDEs have been considered by V V Chepyzhov and M I Vishik since 1992.

### Probability

Important examples of trajectories appearing in physics are provided by Brownian motions. Brownian motions $\omega$ in $\mathbb{R}^N, N \ge 2$, have paths $\omega([0,1])$ of Hausdorff dimension 2 with probability 1, and they are almost surely Hausdorff degenerate, since $\mathcal{H}^2(\omega([0,1])) = 0$ for a.e. $\omega$ (S J Taylor, 1953). Defining gauge functions $h(\varepsilon) := \varepsilon^2 \log(1/\varepsilon) \times \log\log\log(1/\varepsilon)$ when $N = 2$, and $h(\varepsilon) := \varepsilon^2 \log(1/\varepsilon)$ when $N \ge 3$, there holds $\mathcal{H}^h(\omega([0,1])) \in (0, \infty)$ for a.e. $\omega$ (D Ray, 1963, S J Taylor, 1964). If $N = 1$ then a.e. $\omega$ has the box and Hausdorff dimensions of the graph of $\omega|_{[0,1]}$ equal to 3/2 (Taylor, 1953), and for the gauge function $h(\varepsilon) := \varepsilon^{3/2} \log\log(1/\varepsilon)$ the corresponding generalized Hausdorff measure is nondegenerate. In the case of $N \ge 2$ we have the uniform dimension doubling property (R Kaufman, 1969). This means that for a.e. Brownian motion $\omega$ there holds $\dim_H \omega(A) = 2 \dim_H A$ for all subsets $A \subset [0, \infty)$. There are also results concerning almost sure Hausdorff dimension of double, triple, and multiple points of a Brownian motion and of more general Lévy stable processes.

Fractal dimensions also appear in the study of stochastic differential equations, like

$$dx_t = X_0(x_t)\,dt + \sum_{k=1}^{d} X_k(x_t)\,d\theta_k(t), \quad x_0 = x \in \mathbb{R}^N$$

The stochastic flow $(x_t)_{t \ge 0}$ in $\mathbb{R}^N$ is driven by a Brownian motion $(\theta(t))_{t \ge 0}$ in $\mathbb{R}^d$. Let us assume that $X_k, k = 0, \dots, d$, are $C^\infty$-smooth $T$-periodic divergence-free vector fields on $\mathbb{R}^N$. Then for almost every realization of the Brownian motion $(\theta(t))_{t \ge 0}$, the set of initial points $x$ generating the flow $(x_t)_{t \ge 0}$ with linear escape to infinity (i.e., $\underline{\lim}_{t \to \infty}(|x_t|/t) > 0$) is dense and of full Hausdorff dimension $N$ (D Dolgopyat, V Kaloshin, and L Koralov, 2002).

### Other Directions

There are many other fractal dimensions important for dynamics, like the Rényi spectrum for dimensions, correlation dimension, information dimension, Hentschel–Procaccia spectrum for dimensions, packing dimension, and effective fractal dimension. Relations between dimension, entropy, Lyapunov exponents, Gibbs measures, and multifractal rigidity have been investigated by Pesin, Weiss, Barreira, Schmeling, etc. Fractal dimensions are used to study dynamics appearing in Kleinian groups (D Sullivan, C J Bishop, P W Jones, C McMullen, B O Stratmann, etc.), quasiconformal mappings and quasiconformal groups (F W Gehring, J Väisäla, K Astala, C J Bishop, P Tukia, J W Anderson, P Bonfert-Taylor, E C Taylor, etc.), graph directed Markov systems (R D Mauldin, M Urbański, etc.), random walks on fractal graphs (J Kigami, A Telcs, etc.), billiards (H Masur, Y Cheung, P Bálint, S Tabachnikov, N Chernov, D Szász, I P Tóth, etc.), quantum dynamics (J-M Barbaroux, J-M Combes, H Schulz-Baldes, I Guarneri, etc.), quantum gravity (M Aizenman, A Aharony, M E Cates, T A Witten, G F Lawler, B Duplantier, etc.), harmonic analysis (R S Strichartz, Z M Balogh, J T Tyson, etc.),

number theory (L Barreira, M Pollicott, H Weiss, B Stratmann, B Saussol, etc.), Markov processes (R M Blumenthal, R Getoor, S J Taylor, S Jaffard, C Tricot, Y Peres, Y Xiao, etc.), and theoretical computer science (B Ya Ryabko, L Staiger, J H Lutz, E Mayordomo, etc.), and so on.

# Fractional Quantum Hall Effect

**J K Jain**, The Pennsylvania State University, University Park, PA, USA

## Introduction

Interacting particles sometimes collectively behave in ways that take us by complete surprise. In a superfluid $^4$He atoms flow without viscosity, and in a superconductor electrons flow without resistance. Such behaviors announce emergent structures and principles which have often found applications in other areas. This article concerns the surprising collective effects that occur when electrons are confined in two dimensions and subjected to a strong transverse magnetic field. At low temperatures, the Hall resistance (defined below) exhibits plateaus on which it is precisely quantized at

$$R_H = \frac{h}{fe^2} \qquad [1]$$

where $h$ and $e$ are fundamental constants and $f$ is a plateau-specific rational fraction. This phenomenon is known as the "fractional quantum Hall effect" (FQHE), or, after its discoverers, the "Tsui–Stormer–Gossard" (TSG) effect. The underlying state provides a new paradigm for collective behavior in nature, and is understood in terms of a new class of quasiparticles known as "composite fermions," which are topological bound states of electrons and quantized vortices. This article will outline the basics of the experimental phenomenology and our theoretical understanding of this effect.

## The Hall Effect

The Ohm's law, $I = V/R$, tells us that the current through a resistor is proportional to the applied voltage. The local form of the law is

$$\boldsymbol{J} = \sigma \boldsymbol{E} \qquad [2]$$

where $\sigma$ is the conductivity, and $\boldsymbol{J} = q\rho \boldsymbol{v}$ is the current density for particles of charge $q$ and density $\rho$ moving with a velocity $\boldsymbol{v}$.

In 1879, E H Hall discovered that in the presence of a crossed electric and magnetic fields ($\boldsymbol{E}$ and $\boldsymbol{B}$), the current flows in a direction "perpendicular" to the plane containing the two fields. Alternatively, the passage of current induces a voltage perpendicular to the direction of the current flow. This is known as the Hall effect (see **Figure 1**). The phenomenon has a classical origin. A consequence of the Lorentz force law of electrodynamics,

$$\boldsymbol{F} = q\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{v} \times \boldsymbol{B}\right) \qquad [3]$$

which gives the force on a particle of charge $q$ moving with a velocity $\boldsymbol{v}$, is that for crossed electric and magnetic fields the particle drifts in the direction $\boldsymbol{E} \times \boldsymbol{B}$ with a velocity $v = cE/B$. The current density is therefore given by $\boldsymbol{J} = q\rho\boldsymbol{v}$, where $\rho$ is the (three-dimensional) density of particles. That produces the Hall resistivity

$$\rho_{\mathrm{H}} = \frac{E_y}{J_x} = \frac{B}{\rho q c} \qquad [4]$$

## The von Klitzing Effect

Molecular beam epitaxy allows controllable layer by layer growth in which one type of semiconductor, say GaAs, can be grown on top of another, say $\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$, to produce an atomically sharp interface. By appropriately doping such structures, electrons can be captured at the interface, thus producing a two-dimensional electron system (2DES). We note that these are three-dimensional electrons confined to move in two dimensions. The interaction has the standard Coulomb form $V(r) = e^2/\epsilon r$, where $\epsilon$ is the dielectric constant of the host material. (In a hypothetical world which has only two space dimensions, the interaction would be logarithmic.)

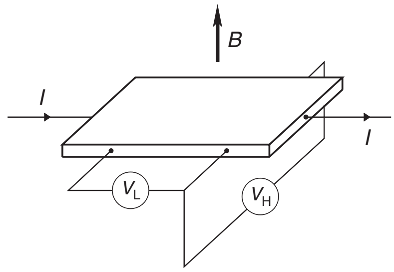

**Figure 1** Schematics of magnetotransport measurement. $I$, $V_{\mathrm{L}}$, and $V_{\mathrm{H}}$ are the current, longitudinal voltage, and the Hall voltage, respectively. The longitudinal and Hall resistances are defined as $R_{\mathrm{L}} \equiv V_{\mathrm{L}}/I$ and $R_{\mathrm{H}} \equiv V_{\mathrm{H}}/I$.

The "integral quantum Hall effect" (IQHE) or the "von Klitzing effect" was discovered unexpectedly by von Klitzing and collaborators in 1980, in their study of Hall effect in a 2DES. In two dimensions, one defines the Hall resistance as

$$R_{\mathrm{H}} = \frac{V_{\mathrm{H}}}{I} \qquad [5]$$

which, from classical electrodynamics, is expected to be proportional to the magnetic field $B$. That is indeed the case at small magnetic fields. At sufficiently high $B$, however, quantum mechanical effects appear in a dramatic manner. The essential observations are as follows.

1. When plotted as a function of the magnetic field $B$, the Hall resistance exhibits numerous plateaus. On any given plateau, $R_{\mathrm{H}}$ is precisely quantized with values given by

$$R_{\mathrm{H}} = \frac{h}{ne^2} \qquad [6]$$

where $n$ is an integer (hence the name "integral quantum Hall effect"). The plateau occurs in the vicinity of $\nu \equiv Be/\rho hc = n$, where $\nu$ is the "filling factor" (defined below).

2. In the plateau region, the longitudinal resistance exhibits an Arrhenius behavior:

$$R_{\mathrm{L}} \sim \exp\left(-\frac{\Delta}{2k_{\mathrm{B}}T}\right) \qquad [7]$$

This gives a filling-factor dependent energy scale $\Delta$, which indicates the presence of a gap in the excitation spectrum. $R_{\mathrm{L}}$ vanishes in the limit $T \to 0$.

The absolute accuracy of the quantization has been established to a few parts in $10^8$ for $1\sigma$ uncertainty, and the relative accuracy to a few parts in $10^{10}$. There is presently no known "intrinsic" correction to the quantization. Perhaps, the most remarkable aspect of the effect is its universality. It is independent of the sample type, geometry, various material parameters (the band mass of the electron or the dielectric constant of the semiconductor), and disorder. The combination $h/e^2$ also occurs in the definition of the fine

structure constant $\alpha = e^2/\hbar c$, the value of which is approximately 1/137. The Hall effect measurements in dirty, solid state systems thus provide one of the most accurate values for $\alpha$. Finally, the lack of resistance at $T = 0$ is to be contrasted with ordinary metals, for which the resistance at $T \to 0$, called the residual resistance, is finite and proportional to disorder.

## The TSG Effect

The next revolution occurred in 1982 with the discovery of the TSG effect, that is, plateaus on which the Hall resistance is quantized at values given by eqn [1] (see Figure 2). The observation of the $R_H = h/fe^2$ plateau is often referred to as the observation of the fraction $f$. Improvement of experimental conditions has led to the observation of a large number of fractions over the years, revealing the richness of the TSG effect. At the time of the writing of this article, the number of observed fractions is more than 50 if one counts only fractions below unity. As in the von Klitzing effect, the longitudinal resistance exhibits an Arrhenius behavior, vanishing in the limit $T \to 0$.

## Landau Levels

The Hamiltonian for a nonrelativistic electron moving in two space dimensions in a perpendicular magnetic field is given by

$$H = \frac{1}{2m_b}\left(p + \frac{eA}{c}\right)^2 \quad [8]$$

Here, $m_b$ is the electron's band mass and $-e$ its charge. For a uniform magnetic field, the vector potential $A$ satisfies

$$\nabla \times A = B\hat{z} \quad [9]$$

Because $A$ is a linear function of the spatial coordinates, it follows that $H$ is a generalized two-dimensional harmonic oscillator Hamiltonian which is quadratic in both the spatial coordinates and in the canonical momentum $p = -i\hbar\nabla$, and therefore can be diagonalized exactly.

A convenient gauge choice is the symmetric gauge:

$$A = \frac{B \times r}{2} = \frac{B}{2}(-y, x, 0) \quad [10]$$

With the magnetic length $\ell = \sqrt{\hbar c/eB}$ and the cyclotron energy $\hbar\omega_c = \hbar eB/m_b c$ chosen as the

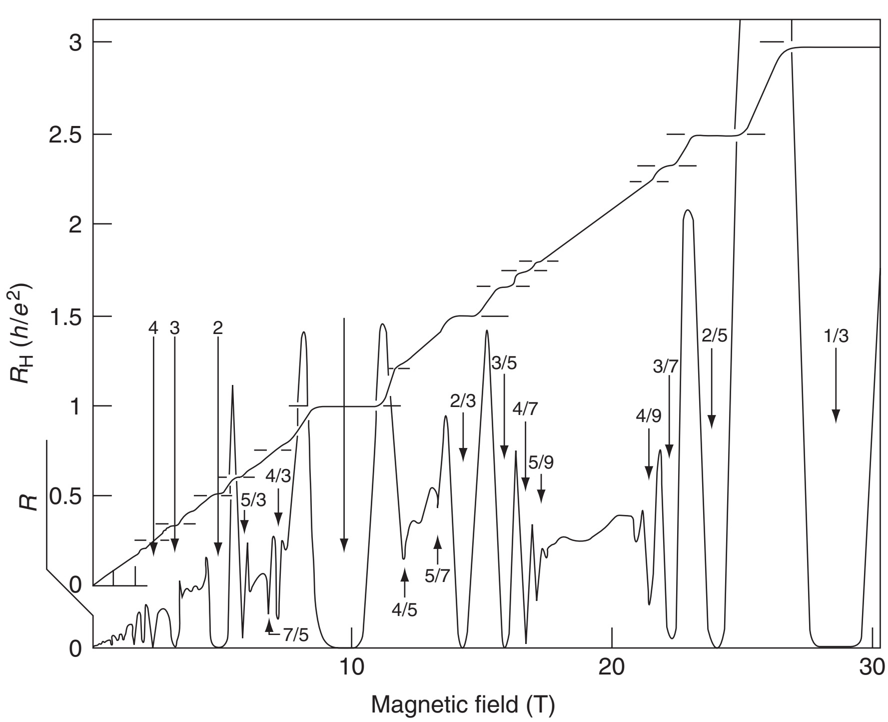

**Figure 2** The TSG effect. The Hall resistance ($R_H$) exhibits many precisely quantized plateaus, concurrent with minima in the longitudinal resistance ($R$). Reprinted with permission of John Wiley & Sons, Inc.

units for length and energy, the Hamiltonian can be expressed as

$$H = \frac{1}{2}\left[\left(-\mathrm{i}\frac{\partial}{\partial x} - \frac{y}{2}\right)^2 + \left(-\mathrm{i}\frac{\partial}{\partial y} + \frac{x}{2}\right)^2\right] \qquad [11]$$

Choosing as independent variables

$$z \equiv x - \mathrm{i}y, \qquad \bar{z} \equiv x + \mathrm{i}y \qquad [12]$$

we get

$$H = \frac{1}{2}\left(-4\frac{\partial^2}{\partial z \partial \bar{z}} + \frac{1}{4}z\bar{z} - z\frac{\partial}{\partial z} + \bar{z}\frac{\partial}{\partial \bar{z}}\right) \qquad [13]$$

Now define the following sets of ladder operators:

$$b = \frac{1}{\sqrt{2}}\left(\frac{\bar{z}}{2} + 2\frac{\partial}{\partial z}\right) \qquad [14]$$

$$b^\dagger = \frac{1}{\sqrt{2}}\left(\frac{z}{2} - 2\frac{\partial}{\partial \bar{z}}\right) \qquad [15]$$

$$a^\dagger = \frac{1}{\sqrt{2}}\left(\frac{\bar{z}}{2} - 2\frac{\partial}{\partial z}\right) \qquad [16]$$

$$a = \frac{1}{\sqrt{2}}\left(\frac{z}{2} + 2\frac{\partial}{\partial \bar{z}}\right) \qquad [17]$$

which have the property that

$$[a, a^\dagger] = 1, \qquad [b, b^\dagger] = 1 \qquad [18]$$

and all the other commutators are zero. In terms of these operators, the Hamiltonian can be written as

$$H = a^\dagger a + \tfrac{1}{2} \qquad [19]$$

The eigenvalue of $a^\dagger a$ is an integer, $n$, called the Landau level (LL) index. The $z$-component of the canonical angular momentum operator, the only relevant component for the two-dimensional problem, is defined as

$$L_z = -\mathrm{i}\frac{\partial}{\partial \theta} = \bar{z}\frac{\partial}{\partial \bar{z}} - z\frac{\partial}{\partial z} = a^\dagger a - b^\dagger b \qquad [20]$$

Exploiting the property $[H, L_z] = 0$, the eigenfunctions will be chosen to diagonalize $H$ and $L_z$ simultaneously. The eigenvalue of $L_z$ will be denoted by $-m$. The analogy to the Harmonic oscillator problem immediately gives the solution

$$H|m, n\rangle = E_n|m, n\rangle \qquad [21]$$

where

$$E_n = \left(n + \frac{1}{2}\right) \qquad [22]$$

and

$$|m, n\rangle = \frac{(b^\dagger)^{m+n}}{\sqrt{(m+n)!}}\frac{(a^\dagger)^n}{\sqrt{n!}}|0, 0\rangle \qquad [23]$$

where $m = -n, -n+1, \ldots$. The single-particle orbital at the bottom of the two ladders defined by the two sets of raising and lowering operators is

$$\langle \boldsymbol{r}|0, 0\rangle \equiv \eta_{0,0}(\boldsymbol{r}) = \frac{1}{\sqrt{2\pi}}\,\mathrm{e}^{-z\bar{z}/4} \qquad [24]$$

which satisfies

$$a|0, 0\rangle = b|0, 0\rangle = 0 \qquad [25]$$

The single-particle states are particularly simple in the lowest Landau level ($n = 0$):

$$\eta_{0,m}(\boldsymbol{r}) = \langle \boldsymbol{r}|0, m\rangle = \frac{z^m\,\mathrm{e}^{-z\bar{z}/4\ell^2}}{\sqrt{2\pi\ell^2 2^m m!}} \qquad [26]$$

Aside from the ubiquitous Gaussian factor, a general state in the lowest Landau level is given by a polynomial of $z$; it does not involve any $\bar{z}$. In other words, apart from the Gaussian factor, the lowest Landau level wave functions are analytic functions of $z$.

### Landau Level Degeneracy

The state $\eta_{0,m}(\boldsymbol{r})$ is peaked strongly at $r = \sqrt{2m}\,\ell$. Neglecting order-1 effects, there are $m$ states in the lowest Landau level in a disk of radius $r = \sqrt{2m}\,\ell$, giving a degeneracy of $(2\pi\ell^2)^{-1}$ per unit area per Landau level. (The same degeneracy is obtained for higher Landau levels as well.) It is equal to $B/\phi_0$, where $\phi_0 = hc/e$ is called the flux quantum, that is, there is one state per flux quantum in each Landau level.

### Filling Factor

The number of filled Landau levels, called the filling factor, is given by

$$\nu = \rho 2\pi\ell^2 = \frac{\rho\phi_0}{B} \qquad [27]$$

## The Origin of Plateaus

The von Klitzing effect can be explained in terms of a model which neglects the interactions between electrons. It occurs because the ground state at an integral filling is unique and nondegenerate, separated from excitations by a gap. Laughlin (1981) showed that the disorder-induced Anderson localization also plays a crucial role in the establishment of the Hall plateaus. To see this, imagine changing the filling away from an integer by adding some

electrons or holes. In a perfect system, the additional particles would also be free to carry current, but in the actual, disordered sample, they are immobilized by impurities (which create localized states in the energy gap), and do not contribute to transport. The transport properties therefore remain unaffected as the filling factor is varied slightly away from an integer, and the system continues to behave as though it had filled shells.

## The Lowest Landau Level Problem

The TSG effect arises due to interelectron interaction. We wish to obtain solutions for the Schrödinger equation

$$H\Psi = E\Psi \qquad [28]$$

at an arbitrary filling $\nu$, where

$$H = \sum_j \frac{1}{2m_{\rm b}}\left[\frac{\hbar}{\rm i}\nabla_j + \frac{e}{c}\boldsymbol{A}(\boldsymbol{r}_j)\right]^2 + \frac{e^2}{\epsilon}\sum_{j<k}\frac{1}{|\boldsymbol{r}_j - \boldsymbol{r}_k|} \qquad [29]$$

The first term on the right-hand side is the kinetic energy in the presence of a constant external magnetic field $\boldsymbol{B} = \nabla \times \boldsymbol{A}$, and the second term is the Coulomb interaction energy. (The Zeeman energy is not included explicitly because we consider, for now, magnetic fields that are sufficiently high that only fully spin-polarized states are relevant.) It is convenient to consider the limit $(e^2/\epsilon\ell)/(\hbar\omega_{\rm c}) \to 0$, when the Coulomb interaction is so weak that it is not able to cause Landau level mixing, so electrons can be taken to be within the lowest Landau level. The kinetic energy then is an irrelevant constant which can be thrown away, and the Hamiltonian reduces to

$$H = \mathcal{P}_{\rm LLL}\frac{e^2}{\epsilon}\sum_{j<k}\frac{1}{|\boldsymbol{r}_j - \boldsymbol{r}_k|}\mathcal{P}_{\rm LLL} \qquad [30]$$

"which must be solved with the lowest LL restriction," as explicitly indicated by the lowest LL projection operator $\mathcal{P}_{\rm LLL}$. The problem is thus mathematically well defined, but requires degenerate perturbation theory in an enormously large Hilbert space, with $\binom{N/\nu}{N}$ many particle basis vectors. The usual perturbative techniques are not useful due to the absence of a small parameter in the problem; $e^2/\epsilon\ell$ merely sets the energy scale in the lowest Landau level.

## Composite-Fermion Theory

Inspired by the qualitative similarity between the integral and the fractional Hall effects, the composite-fermion (CF) theory (Jain 1989) postulates that the eigenfunctions of interacting electrons at filling factor $\nu$, $\Psi_\nu$, are related to the (known) eigenfunctions of *non*interacting electrons at filling factor $\nu^*$, $\Phi_{\nu^*}$, according to

$$\Psi_\nu = \mathcal{P}_{\rm LLL}\Phi_{\nu^*}\prod_{j<k}(z_j - z_k)^{2p} \qquad [31]$$

where $\mathcal{P}_{\rm LLL}$ denotes projection of the wave function on its right into the lowest Landau level. The filling factors are related by

$$\nu = \frac{\nu^*}{2p\nu^* + 1} \qquad [32]$$

which can be seen as follows: the largest power of $z_1$ in $\Phi_{\nu^*}$ (neglecting order-one corrections) is $N/\nu^*$, as follows from the definition of the filling factor. The largest power of $z_1$ on the right-hand side is therefore $pN(N-1) + N/\nu^*$. This is the number of flux quanta penetrating the "sample." Dividing it by $N$ and taking the limit $N \to \infty$ gives the inverse of the filling factor $\nu^{-1}$. These wave functions are now known to capture the correct nonperturbative physics of the TSG effect (see below), and also to provide extremely accurate representations for the actual correlated ground states and their excitations. They recover Laughlin's 1983 wave function for the ground state at $\nu = 1/(2p+1)$, while clarifying that it is a part of a much bigger conceptual structure.

### Physical Interpretation

The crucial property of the wave function in eqn [31] is that the complex Jastrow factor $\prod_{j<k}(z_j - z_k)^{2p}$ binds $2p$ vortices on each electron. More precisely, each electron sees $2p$ vortices on every other electron, in that a complete loop of an electron around any other electron produces a phase of $2\pi \times 2p$. The bound state is interpreted as a particle, called the "composite fermion." Because the vortex is a topological object, so is the composite fermion. The vorticity $2p$ is quantized to be an even integer, as required by the single-valuedness and antisymmetry requirements of quantum mechanics, which will be seen to lie at the root of the exact quantization of the Hall resistance.

When composite fermions move about, they experience, in addition to the Aharonov–Bohm (AB) phase, also the Berry phases coming from vortices on other composite fermions. Imagine taking a composite fermion in a closed loop enclosing an area $A$. The phase associated with that loop is given by

$$\Phi^* = -2\pi\frac{BA}{\phi_0} + 2\pi 2pN_{\rm enc} \qquad [33]$$

where $N_{\rm enc}$ is the number of composite fermions inside the loop. The first term is the familiar AB phase due to a charge going around in a loop. The second is the Berry phase due to $2p$ vortices going around $N_{\rm enc}$ particles, with each particle producing a phase of $2\pi$. Replacing $N_{\rm enc}$ by its average value $\rho A$ shows that, on average, $\Phi^*$ is equal to the AB phase from an "effective" magnetic field

$$B^* = B - 2p\rho\phi_0 \qquad [34]$$

The composite fermions thus experience an effective magnetic field $B^*$ which is much smaller than the external, applied field $B$. That lies at the heart of the phenomenology of this lowest Landau level liquid. One treats composite fermions as noninteracting in the simplest approximation. They form their own Landau-like levels in $B^*$. Their filling factor is defined as $\nu^* = \rho\phi_0/B^*$, with which eqn [34] becomes equivalent to eqn [32]. The effective field $B^*$ can be antiparallel to $B$, in which case $\nu^* = \rho\phi_0/B^*$ is formally negative. For negative values of $\nu^*$,$\Phi_{\nu^*}$ in eqn [31] is defined as $\Phi_{-|\nu^*|} = [\Phi_{|\nu^*|}]^*$, because complex conjugation is equivalent to switching the direction of the magnetic field.

## Fermion Chern–Simons Theory

Lopez and Fradkin (1991) developed a field-theoretic formulation of composite fermions through a singular gauge transformation defined by

$$\Psi = \prod_{j<k}\left(\frac{z_j - z_k}{|z_j - z_k|}\right)^{2p}\Psi' \qquad [35]$$

under which the eigenvalue problem of eqn [29] transforms into

$$H'\Psi' = E\Psi' \qquad [36]$$

$$H' = \frac{1}{2m_{\rm b}}\sum_i\left(\boldsymbol{p}_i + \frac{e}{c}\boldsymbol{A}(\boldsymbol{r}_i) - \frac{e}{c}\boldsymbol{a}(\boldsymbol{r}_i)\right)^2 + V \qquad [37]$$

$$\boldsymbol{a}(\boldsymbol{r}_i) = \frac{2p}{2\pi}\phi_0\sum_j{}' \nabla_i\phi_{ij} \qquad [38]$$

where

$$\phi_{jk} = \mathrm{i}\ln\frac{z_j - z_k}{|z_j - z_k|}$$

is the relative angle between the particles $j$ and $k$. The magnetic field corresponding to $\boldsymbol{a}(\boldsymbol{r}_i)$ is given by

$$\boldsymbol{b}_i = \nabla_i \times \boldsymbol{a}(\boldsymbol{r}_i) = 2p\phi_0\sum_l{}' \delta^2(\boldsymbol{r}_i - \boldsymbol{r}_l) \qquad [39]$$

The above transformation thus amounts to attaching a point flux of strength $-2p\phi_0$ to each electron, which is how the composite fermion is modeled in this approach. (A flux quantum is topologically equivalent to a vortex.) This definition is reminiscent of the treatments of particles obeying fractional statistics ("anyons") introduced by Leinaas and Myrheim (1977) and Wilczek (1982); an anyon is modeled as an electron bound to a point flux of magnitude $\alpha\phi_0$, where $\alpha$ determines the winding statistics.

It is not possible to proceed further without making approximations. The usual approach is to make a "mean-field" approximation, which amounts to spreading the point flux on each electron into a uniform magnetic field. Formally, one writes

$$\boldsymbol{A} - \boldsymbol{a} \equiv \boldsymbol{A}^* + \delta\boldsymbol{A} \qquad [40]$$

$$\nabla \times \boldsymbol{A}^* = B^*\hat{z} \qquad [41]$$

The transformed Hamiltonian is written as

$$H' = \frac{1}{2m_{\rm b}}\sum_i\left(\boldsymbol{p}_i + \frac{e}{c}\boldsymbol{A}^*(\boldsymbol{r}_i)\right)^2 + V + V' = H_0' + V + V' \qquad [42]$$

$V$ is the Coulomb interaction and $V'$ denotes the terms containing $\delta\boldsymbol{A}$. The solution to $H_0'$ is trivial, describing free fermions in an effective magnetic field $B^*$. We have thus decomposed the Hamiltonian into a part $H_0'$, which can be solved exactly, and the rest, $V + V'$, which is to be treated perturbatively.

Lopez and Fradkin recast the problem in the language of functional integrals, which is suitable for studying corrections to the mean-field theory. One writes the zero-temperature quantum partition function

$$\mathcal{Z} = \int \mathcal{D}\psi\mathcal{D}\psi^*\mathcal{D}\boldsymbol{a}\exp\left(\frac{\mathrm{i}}{\hbar}\mathcal{S}\right) \qquad [43]$$

$$\mathcal{S} = \int \mathrm{d}^2\boldsymbol{r}\int \mathrm{d}t\mathcal{L} \qquad [44]$$

$$\mathcal{L} = \psi^*(\mathrm{i}\partial_t - a_0)\psi + \frac{1}{2m_{\rm b}}\left|\left(-\mathrm{i}\hbar\nabla + \frac{e}{c}\boldsymbol{A} - \frac{e}{c}\boldsymbol{a}\right)\psi\right|^2 + \frac{1}{2p\phi_0}a_0\nabla\times\boldsymbol{a} + \int \mathrm{d}^2\boldsymbol{r}'\rho(\boldsymbol{r})V(\boldsymbol{r} - \boldsymbol{r}')\rho(\boldsymbol{r}') \qquad [45]$$

where $\psi$ and $\psi^*$ are anticommuting Grassmann variables. The flux attachment is introduced through a Lagrange multiplier $a_0$; because $a_0$ enters linearly in the action, it can be integrated out to produce a delta function that imposes the constraint

$$\nabla \times \boldsymbol{a}(\boldsymbol{r}) = 2p\phi_0\rho(\boldsymbol{r}) = 2p\phi_0\psi^*(\boldsymbol{r})\psi(\boldsymbol{r}) \qquad [46]$$

This formalism is closely related to the topological Chern–Simons (CS) field theory. Recall that the CS Lagrangian has the form

$$\mathcal{L}_{\mathrm{CS}} \sim \epsilon^{\mu\nu\lambda} A_\mu F_{\nu\lambda} = 2\epsilon^{\mu\nu\lambda} A_\mu \partial_\nu A_\lambda \qquad [47]$$

where $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, and $\epsilon^{\mu\nu\lambda}$ is the antisymmetric Levy-Civita tensor, with $\epsilon^{012} = 1$. The index takes values $\mu = 0, 1, 2$, the first being the time component and the remaining space components. The CS action is invariant, up to surface terms, under a gauge transformation, because the change in $\mathcal{L}_{\mathrm{CS}}$ under a functional variation $\delta A_\mu = \partial_\mu \Lambda$ is a total derivative.

Zhang *et al.* (1989) noted that the term proportional to $a_0 \nabla \times \boldsymbol{a}$ in eqn [45], which enforces flux attachment, is precisely equal to the CS Langrangian in the Coulomb gauge. Write

$$\begin{aligned}\mathcal{L}_{\mathrm{CS}} &= \frac{1}{4p\phi_0} \epsilon^{\mu\nu\lambda} a_\mu \partial_\nu a_\lambda \\ &= \frac{1}{2p\phi_0} \epsilon^{ij} a_0 \partial_i a_j - \frac{1}{4p\phi_0} \epsilon^{ij} a_i \partial_0 a_j\end{aligned} \qquad [48]$$

where $i, j$ represent the spatial components $(i, j = 1, 2)$, and the time components have been displayed explicitly in the second step ($\partial_0 = \partial_t$). The first term on the right-hand side of eqn [48] is identical to the third term on the right-hand side of eqn [45]. In the Fourier space the last term is proportional to

$$\epsilon^{ij} a_i(\boldsymbol{q}, \omega)(-\mathrm{i}\omega) a_j(-\boldsymbol{q}, -\omega) \qquad [49]$$

By choosing the $x$-axis along $\boldsymbol{q}$, the Coulomb gauge condition $\boldsymbol{q}.\boldsymbol{a} = 0$ implies $a_2(\boldsymbol{q}, \omega) = 0$, guaranteeing that the last term in eqn [48] is identically zero.

The constraint of eqn [46] is used to eliminate the two factors of density in the last term of eqn [45]. The action is then quadratic in the fermion field, which can be integrated out. Various response functions can be expressed as correlation functions of the vector potential field and their averages over the CS field configurations are evaluated perturbatively by standard diagrammatic methods.

The fermion CS theory is believed to capture the topological properties of composite fermions, but has not lent itself, because of the lack of a small parameter, to quantitative calculations. It is not known what classes of Feynman diagrams will need to be summed to eliminate the electron mass $m_b$ (which is not a parameter of the lowest Landau problem – see eqn [30]) in the fermion CS approach). Halperin *et al.* (1993) proceeded by replacing $m_b$ by an adjustable parameter $m^*$, interpreted as the composite-fermion mass. Murthy and Shankar (1997) proposed to separate out the inter- and intra-Landau level degrees of freedom by making a sequence of further transformations.

## Consequences

### Fractional Quantum Hall Effect

The CF theory provides a simple understanding of why gaps open up at "fractional" fillings, which happens at those fillings $\nu = f$ for which composite fermions fill integral numbers of CF Landau levels. That results in Hall plateaus at $R_{\mathrm{H}} = h/fe^2$ in the presence of disorder. The fractional QHE is thus understood as the integral QHE for composite fermions.

### Sequences of Fractions

The integral fillings of composite fermions correspond to fractional fillings of electrons given by

$$\nu = \frac{|n|}{2p|n| \pm 1} \qquad [50]$$

which are precisely the observed fractions. Some of these are:

$$f = \frac{|n|}{2|n| + 1} = \frac{1}{3}, \frac{2}{5}, \ldots, \frac{10}{21} \qquad [51]$$

$$f = \frac{|n|}{2|n| - 1} = \frac{2}{3}, \frac{3}{5}, \ldots, \frac{10}{19} \qquad [52]$$

$$f = \frac{|n|}{4|n| + 1} = \frac{1}{5}, \frac{2}{9}, \ldots, \frac{6}{25} \qquad [53]$$

$$f = \frac{|n|}{4|n| - 1} = \frac{2}{7}, \frac{2}{5}, \ldots, \frac{6}{23} \qquad [54]$$

Particle–hole symmetry in the lowest Landau level also implies fractions $1 - f$. The fractions appear in the form of sequences because they are all derived from the sequence of integers. The Hall quantization is exact because the right-hand side of eqn [50] is made up of whole numbers and therefore is not susceptible to small perturbations in the Hamiltonian. The CF theory unifies the FQHEs and IQHEs.

### Fermi Sea at Half Filling

Equation [50] is consistent with the fact that only odd-denominator fractions have been observed in the lowest Landau level (i.e., with $f < 1$). Halperin *et al.* (1993) and Kalmeyer and Zhang (1992) proposed that at the simplest even-denominator fraction, namely $\nu = 1/2$, composite fermions form a Fermi sea. This was motivated by the fact that the effective magnetic field is $B^* = 0$ at $\nu = 1/2$. A number of experiments have directly measured the Fermi sea of composite fermions. The TSG effect with $f = 1/2$ is absent because the Fermi sea has gapless excitations.

### Effective Magnetic Field

For small values of $B^*$ (i.e., in the vicinity of $\nu = 1/2$), the cyclotron radius of composite fermions can be very large compared to the radius of the cyclotron orbit of a classical electron in $B$. Direct measurements of the cyclotron orbit in several geometric experiments have confirmed that the charge carriers experience a magnetic field $B^*$ rather than $B$.

### Fractional Charge

Laughlin (1983) showed that the presence of a gap at a fractional filling implies the existence of fractionally charged excitations. He obtained an excitation through the adiabatic insertion of a point flux quantum at, say the origin, which can be gauged away at the end leaving behind an exact excited state. The Faraday's law implies that the azimuthal component of the induced electric field is $E_\phi = -(2\pi r)^{-1}\, d\phi/dt$. The current density then is $j_r = \sigma_H E_\phi$, where $\sigma_H = fe^2/h$ is the Hall conductivity. The charge leaving the area defined by a circle of radius $r$ per unit time is $2\pi r j_r$. The total charge leaving this area in the adiabatic process then is

$$Q = \int 2\pi r j_r \, dt = -\sigma_H \phi_0 = -fe \qquad [55]$$

The charge excess associated with the excitation is therefore $fe$. It is in general not an elementary excitation. For $f = n/(2pn \pm 1)$, it can be shown to be a collection of $n$ elementary excitations, giving a charge of $e^* = e/(2pn \pm 1)$ for a single elementary excitation.

### Microscopic Tests

Exact solutions of the Schrödinger equation can be obtained, for a finite number of particles, by a brute-force diagonalization of the Hamiltonian in the lowest LL subspace, which enables a rigorous and nontrivial testing of the CF theory. **Figure 3** shows some typical comparisons, which help test both the qualitative and the quantitative aspects of the CF theory in a model-independent manner. The low-energy spectrum of interacting electrons at $B$ is explicitly seen to have a one-to-one correspondence to that of weakly interacting electrons at $B^*$. Furthermore, there is a remarkably good quantitative agreement. The predicted energies agree with the exact energies to better than 0.05%, and the overlaps between the wave functions of eqn [31] with the exact eigenfunctions are close to 100%. Such comparisons are even more convincing in light of the fact that the wave functions of eqn [31] do not contain any adjustable parameters for the states at $\nu$ in eqn [50], because the ground state wave function and its low-energy excitations at $\nu^* = n$ are unique and fully known: the former is the Slater determinant corresponding to $n$ filled

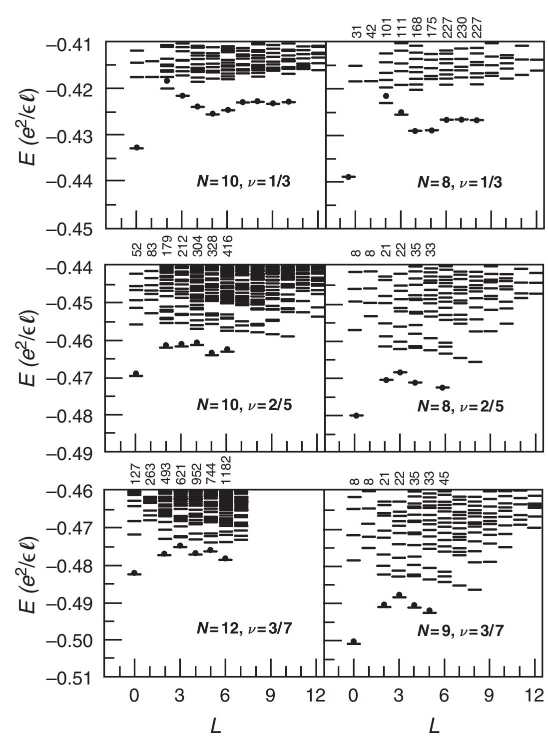

**Figure 3** Exact spectra (dashes) for several particle numbers at $\nu = 1/3$, 2/5, and 3/7. Dots show the CF prediction for the energy, obtained with no adjustable parameters. The electrons are taken to be confined on the surface of a sphere in the presence of a radial magnetic field; $L$ is the total orbital angular momentum, and each dash represents a multiplet of $2L + 1$ degenerate states. The number on top is the dimension of the Fock space in the corresponding $L$ sector. Reproduced from Jain JK (2000) The composite fermion: a quantum particle and its quantum fluids. *Physics Today* 39(4): 39–42, with permission from American Institute of Physics.

Landau levels, and the latter are the excitons. The predicted energies are calculated by determining the expectation values of the full Hamiltonian of eqn [30] with respect to the wave functions in eqn [31].

## More Physics

### Spin

At small Zeeman energies, partially spin-polarized or spin-unpolarized FQHE states become possible. The TSG effect with spin is well described by a generalization of the CF theory. The observed fractions are still given by eqn [50], but with

$$n = n_{\uparrow} + n_{\downarrow} \qquad [56]$$

where $n_{\uparrow}$ is the number of occupied spin-up Landau-like CF bands and $n_{\downarrow}$ is the number of occupied spin-down Landau-like CF bands. There are in general several states with different spin polarizations possible at any given fraction. The observed quantum phase transitions as a function of the Zeeman energy, which can be changed by increasing the parallel component of the magnetic field, are consistent with this picture. Direct measurements of the spin polarization further confirm this, but also see evidence for certain additional fragile states, which are presumably caused by the residual interaction between composite fermions.

### Bilayers

It has been proposed that for two parallel 2DES planes at small separations and at total filling $\nu = 1$, neutral interlayer excitons (each exciton made up of an electron in one layer and a hole in the other) undergo Bose–Einstein condensation, producing a true off-diagonal long-range order. Tunneling and transport experiments by Eisenstein and collaborators provide evidence for nontrivial behavior under such conditions. The resistivity in the antisymmetric channel is very small but does not vanish.

### Pairing

An even-denominator fraction $f = 5/2$ has been observed. Writing $5/2 = 2 + 1/2$ and noting that the lowest LL contributes 2 (counting the spin degree of freedom), $\nu = 5/2$ corresponds to a filling of 1/2 in the second Landau level. The most promising scenario for the explanation of the 5/2 effect is that composite fermions form a $p$-wave paired state, which opens up a gap to excitations. This state is believed to be well described by a Pfaffian wave function proposed by Moore and Read (1991)

$$\Psi^{\mathrm{Pf}}_{1/2} = \mathrm{Pf}\left(\frac{1}{z_i - z_j}\right) \times \prod_{i<j} (z_i - z_j)^2 \exp\left(-\frac{1}{4}\sum_k |z_k|^2\right) \qquad [57]$$

The Pfaffian of an antisymmetric matrix $M$ is defined, apart from an overall factor, as

$$\mathrm{Pf}(M_{ij}) = A(M_{12}M_{34}\ldots M_{N-1,N}) \qquad [58]$$

where $A$ is the antisymmetrization operator. The Bardeen–Cooper–Schrieffer wave function

$$\Psi_{\mathrm{BCS}} = A[\phi_0(\boldsymbol{r}_1, \boldsymbol{r}_2)\phi_0(\boldsymbol{r}_3, \boldsymbol{r}_4)\ldots\phi_0(\boldsymbol{r}_{N-1}, \boldsymbol{r}_N)] \qquad [59]$$

has the same form as the Pfaffian in eqn [58]. Hence, Pf $1/(z_i - z_j)$ describes a $p$-wave pairing of electrons, and $\Psi^{\mathrm{Pf}}_{1/2}$ is interpreted as a paired state of composite fermions carrying two vortices.

### FQHE of Composite Fermions

Recently, some fractions other than those in eqn [50] have been observed, for example, $f = 4/11$ and $f = 5/13$. These are understood as the delicate "fractional" QHE of composite fermions at $\nu^* = 1 + 1/3$ and $\nu^* = 1 + 2/3$.

### TSG Effect in Higher Landau Levels

The short-range part of the Coulomb interaction is less effective in higher Landau levels because of the greater spread of the electron wave function. As a result, composite fermions are less stable, often losing to charge density wave states. A few fractions have been observed in the second Landau level (1/3, 2/3, 2/5, 1/2) and one (1/3) in the third.

### Edge states

There is a gap to excitations in the bulk at the magic fillings of eqn [50], but there is no gap at the edge of the sample. The dynamics of the low-energy edge excitations is formally equivalent to that of a chiral one-dimensional Tomonaga–Luttinger liquid. Wen (1991) argued that the exponent characterizing the long-distance behavior of this liquid is quantized, fully determined by the filling factor of the bulk state. Experimental studies of the tunneling of an external electron into the edge of an FQHE system provide evidence for a nontrivial

Tomonaga–Luttinger liquid but do not find the predicted universal value for the edge exponent.

# Free Interfaces and Free Discontinuities: Variational Problems

**G Buttazzo**, Università di Pisa, Pisa, Italy

## Introduction

In several models coming from very different applications, one needs to describe physical phenomena where the state function may present some regions of discontinuity. We may think, for instance, of problems arising in fracture mechanics, where the function which describes the displacement of the body has a jump along the fracture, phase transitions, or also of problems of image reconstruction, where the function that describes a picture (the intensity of black, e.g., in black-and-white pictures) has naturally some discontinuities along the profiles of the objects.

The Sobolev space analysis is then no longer appropriate for this kind of problem, since Sobolev functions cannot have jump discontinuities along hypersurfaces, as, on the contrary, is required by the models above. For a rigorous presentation of variational problems involving functions with discontinuities, the essential tool is the space, BV, of functions with bounded variation. The first ideas about this space were developed by De Giorgi in the 1950s, in order to provide a variational framework to

study the problems of minimal surfaces, and several monographs are now available on the subject. We quote, for instance, the classical volumes of Evans and Gariepy (1992), Federer (1969), Giusti (1984), Massari and Miranda (1984), Ziemer (1989), and the recent book by Ambrosio *et al.* (2000), where a systematic presentation is given, also in view of the applications mentioned above.

## The Space BV

Consider a generic open subset $\Omega$ of $\mathbb{R}^N$, which, for simplicity, we take bounded and with a Lipschitz boundary. In the following, we denote by $\mathcal{L}^N(E)$, or simply $|E|$, the Lebesgue measure of $E$ in $\mathbb{R}^N$, while $\mathcal{H}^k$ denotes the $k$-dimensional Hausdorff measure.

**Definition 1** We say that a function $u \in L^1(\Omega)$ is a function of bounded variation in $\Omega$ if its distributional gradient Du is an $\mathbb{R}^N$-valued finite Borel measure on $\Omega$. In other words, we have

$$\int_\Omega u D_i \phi \, dx = -\int_\Omega \phi \, dD_i u \qquad \forall \phi \in C_c^\infty(\Omega), \quad \forall i = 1, \ldots, N \tag{1}$$

where $D_i u$ are finite Borel measures. The space of all functions of bounded variation in $\Omega$ is denoted by $BV(\Omega)$.

The space $BV(\Omega)$ is clearly a vector space and, with the norm

$$\|u\|_{BV(\Omega)} = \|u\|_{L^1(\Omega)} + |Du|(\Omega) \tag{2}$$

it becomes a Banach space. The total variation $|Du|(\Omega)$ appearing above is intended as

$$|Du|(\Omega) = \sup\left\{\sum_{i=1}^N \int_\Omega \phi_i \, dD_i u : \phi \in C_c^\infty(\Omega; \mathbb{R}^N), \ |\phi| \le 1\right\} = \sup\left\{-\int_\Omega u \, \mathrm{div}\phi \, dx : \phi \in C_c^\infty(\Omega; \mathbb{R}^N), \ |\phi| \le 1\right\}$$

and is sometimes indicated by $\int_\Omega |Du|$. The space $BV_{loc}(\Omega)$ is defined in a similar way, requiring that $u \in BV(\Omega')$ for every $\Omega' \subset\subset \Omega$.

From the point of view of functional analysis, the space $BV(\Omega)$ does not verify the nice properties of Sobolev spaces. In particular,

- the Banach space $BV(\Omega)$ is not separable;
- the Banach space $BV(\Omega)$ is not reflexive; and
- the class of smooth functions is not dense in $BV(\Omega)$ for the norm [2].

The above issues motivate why the norm [2] is not very helpful in the study of variational problems involving the space $BV(\Omega)$. On the contrary, the weak* convergence defined below is much more suitable to treat minimization problems for integral functionals.

**Definition 2** We say that a sequence $(u_n)$ weakly* converges in $BV(\Omega)$ to a function $u \in BV(\Omega)$ if $u_n \to u$ strongly in $L^1(\Omega)$ and $Du_n \to Du$ in the weak* convergence of measures.

The weak* convergence on $BV(\Omega)$ satisfies the following properties:

- *Compactness* Every bounded sequence in $BV(\Omega)$ for the norm [2] admits a weakly* convergent subsequence.
- *Lower-semicontinuity* The norm [2] is sequentially lower-semicontinuous with respect to the weak* convergence.
- *Density* Every function $u \in BV(\Omega)$ can be approximated, in the weak* convergence, by a sequence $(u_n)$ of smooth functions.

The density property above can be actually made stronger: in fact, the approximation of $(u_n)$ to $u$ holds in the sense that

$$\begin{cases} u_n \to u \text{ strongly in } L^1(\Omega) \\ Du_n \to Du \text{ weakly}^* \text{ as measures} \\ |Du_n|(\Omega) \to |Du|(\Omega) \end{cases}$$

Further properties of the space $BV(\Omega)$ concern the embeddings into Lebesgue spaces, traces, and Poincaré-type inequalities. More precisely, we have:

- *Embeddings* The space $BV(\Omega)$ is embedded continuously into $L^{N/(N-1)}(\Omega)$ and compactly into $L^p(\Omega)$ for every $p < N/(N-1)$.
- *Traces* Every function $u \in BV(\Omega)$ has a boundary trace which belongs to $L^1(\partial\Omega)$, and the trace operator from $BV(\Omega)$ into $L^1(\partial\Omega)$ is continuous.
- *Poincaré inequalities* There exist suitable constants $c_1$ and $c_2$ such that for every $u \in BV(\Omega)$

$$\int_\Omega |u| \, dx \le c_1 \left[|Du|(\Omega) + \int_{\partial\Omega} |u| \, d\mathcal{H}^{N-1}\right]$$

$$\int_\Omega |u - u_\Omega| \, dx \le c_2 |Du|(\Omega)$$

$$\left(\text{where } u_\Omega = \frac{1}{|\Omega|}\int_\Omega u \, dx\right)$$

## Sets of Finite Perimeter

An important class of functions with bounded variation are those that can be written as $1_E$, the characteristic function of a set $E$, taking the value 1 on $E$ and 0 elsewhere. This is the natural class where many phase-transition problems with sharp interfaces may be framed.

**Definition 3** For a measurable set $E \subset \mathbb{R}^N$ the perimeter of $E$ in $\Omega$ is defined as

$$\mathrm{Per}(E, \Omega) = |D1_E|(\Omega)$$

The equality above is intended as $\mathrm{Per}(E, \Omega) = +\infty$ whenever $1_E \notin \mathrm{BV}(\Omega)$. If $\mathrm{Per}(E, \Omega) < +\infty$ then the set $E$ is called a set of finite perimeter in $\Omega$.

Note that by the compactness property above for BV functions, a family of characteristic functions of sets with finite perimeter in a bounded open set $\Omega$ with equibounded perimeter is weakly$^*$-precompact, and its limit is of the same form.

For a set $E$ of finite perimeter in $\Omega$, we may define the inner normal versor and the reduced boundary as follows.

**Definition 4** Let $E$ be a set of finite perimeter in $\Omega$. We call reduced boundary $\partial^* E$ the set of all points $x \in \Omega \cap \mathrm{spt}|D1_E|$ such that the limit

$$\nu_E(x) = \lim_{r \to 0} \frac{D1_E(B_r(x))}{|D1_E|(B_r(x))}$$

exists and satisfies $|\nu_E(x)| = 1$. The vector $\nu_E(x)$ is called the generalized inner normal versor to $E$.

In order to link the measure-theoretical objects introduced above with some structure property of sets of finite perimeter, we introduce, for every $t \in [0, 1]$ and every measurable set $E \subset \mathbb{R}^N$, the set $E^t$ defined by

$$E^t = \left\{ x \in \mathbb{R}^N \colon \lim_{r \to 0} \frac{|E \cap B_r(x)|}{|B_r(x)|} = t \right\} \qquad [3]$$

For instance, if $E$ is a smooth domain of $\mathbb{R}^N$, $E^1$ is the interior part of $E$, $E^0$ is its exterior part, while $E^{1/2}$ is the boundary $\partial E$.

The main properties of the reduced boundary and of the generalized inner normal versor are stated in the following result.

**Theorem 5** *Let E be a set of finite perimeter in* $\Omega$. *Then its reduced boundary* $\partial^* E$ *coincides* $\mathcal{H}^{N-1}$*-a.e. with the set* $E^{1/2}$ *introduced in Definition 3, and we have the equality*

$$\mathrm{Per}(E, \Omega) = \mathcal{H}^{N-1}(\Omega \cap \partial^* E) = \mathcal{H}^{N-1}(\Omega \cap E^{1/2})$$

*Moreover, the generalized inner normal versor* $\nu_E(x)$ *exists for* $\mathcal{H}^{N-1}$*-a.e.* $x \in \partial^* E$, *and we have*

$$D1_E = \nu_E(x) \mathcal{H}^{N-1} \llcorner \partial^* E$$

Note that the lower-semicontinuity of $|D1_E|(\Omega)$ entails the lower-semicontinuity of $E \mapsto \mathcal{H}^{N-1}(\Omega \cap \partial^* E)$ with respect to the weak$^*$-convergence of $1_E$. As a consequence, we may apply the direct methods of the calculus of variations to obtain, for example, existence of minimizers of

$$\min \left\{ \mathrm{Per}(E, \mathbb{R}^N) - \int_E g \, \mathrm{d}x \right\}$$

that are sets with prescribed mean curvature $g$. This lower-semicontinuity property can be further generalized, for example, as in the following result for anisotropic perimeters.

**Theorem 6** *Let* $\varphi : S^{N-1} \to \mathbb{R}$ *be a Borel function. The energy*

$$\int_{\Omega \cap \partial^* E} \varphi(\nu_E) \, \mathrm{d}\mathcal{H}^{N-1}$$

*is lower-semicontinuous with respect to the weak*$^*$*-convergence of* $1_E$ *in* $\mathrm{BV}(\Omega)$ *if and only if the positively one-homogeneous extension of* $\varphi$ *from* $S^{N-1}$ *to* $\mathbb{R}^N$ *is convex.*

This result immediately implies the existence of solutions of isovolumetric problems of the form

$$\min \left\{ \int_{\partial^* E} \varphi(\nu_E) \, \mathrm{d}\mathcal{H}^{N-1} \colon \ |E| = c \right\}$$

whose solutions are obtained by suitably scaling the Wulff shape of $\varphi$.

## The Structure of BV Functions

The simplest situation occurs when $N = 1$ and so $\Omega$ is an interval of the real line. In this case, decomposing the derivative $u'$ into positive and negative parts, and taking their primitives, we obtain that $u \in \mathrm{BV}(\Omega)$ if and only if $u$ is the sum of two bounded monotone functions (one increasing and one decreasing). Therefore, in the one-dimensional case, the BV functions share all the properties of monotone functions.

The situation is more delicate when $N > 1$, for which we need the notion of approximate limit.

**Definition 7** Let $u \in \mathrm{BV}(\Omega)$. We say that $u$ has the approximate limit $z$ at $x$ if

$$\lim_{r \to 0} \frac{1}{|B_r(x)|} \int_{B_r(x)} |u(y) - z| \, \mathrm{d}y = 0$$

The set where no approximate limit exists is called the approximate discontinuity set, and is denoted by $S_u$. In a similar way, when $x \in S_u$ we may define the approximate values $z^+$ and $z^-$, by requiring that

$$\lim_{r\to 0} \frac{1}{|B_r^+(x,\nu)|} \int_{B_r^+(x,\nu)} |u(y) - z^+|\,\mathrm{d}y = 0$$
$$\lim_{r\to 0} \frac{1}{|B_r^-(x,\nu)|} \int_{B_r^-(x,\nu)} |u(y) - z^-|\,\mathrm{d}y = 0$$

where

$$B_r^+(x,\nu) = \{y \in B_r(x):\ (y-x)\cdot\nu > 0\}$$
$$B_r^-(x,\nu) = \{y \in B_r(x):\ (y-x)\cdot\nu < 0\}$$

Analogous definitions can be given in the vector-valued case, when $u \in \mathrm{BV}(\Omega;\mathbb{R}^m)$.

The triplet $(z^+, z^-, \nu)$ in Definition 7 is unique up to interchanging $z^+$ with $z^-$ and changing sign to $\nu$, and is denoted by $(u^+(x), u^-(x), \nu_u(x))$.

We are now in a position to describe the structure of the measure $Du$ when $u \in \mathrm{BV}(\Omega)$, or more generally $u \in \mathrm{BV}(\Omega;\mathbb{R}^m)$. We first apply the Radon–Nikodym theorem to $Du$ and we decompose it into absolutely continuous and singular parts: $Du = (Du)^{\mathrm{a}} + (Du)^{\mathrm{s}}$. We denote by $\nabla u$ the density of the absolutely continuous part, so that we have

$$Du = \nabla u \cdot \mathcal{L}^N + (Du)^{\mathrm{s}}$$

The singular part $(Du)^{\mathrm{s}}$ can be further decomposed into an $(N-1)$-dimensional part, concentrated on the approximate discontinuity set $S_u$, and the remaining part, which vanishes on all sets with finite $\mathcal{H}^{N-1}$ measure. More precisely, if $u \in \mathrm{BV}(\Omega;\mathbb{R}^m)$, we have

$$Du = \nabla u \cdot \mathcal{L}^N + (u^+(x) - u^-(x)) \otimes \nu_u(x) \cdot \mathcal{H}^{N-1} \llcorner S_u + (Du)^{\mathrm{c}} \qquad [4]$$

the three terms on the right-hand side are mutually singular and are, respectively, called the absolutely continuous part, the jump part, and the Cantor part of the gradient measure $Du$.

In the vector-valued case, $Du$ is an $m \times N$ matrix of finite Borel measures, $\nabla u$ is an $m \times N$ matrix of functions in $L^1(\Omega)$, and the jump term in [4] is an $(N-1)$-dimensional measure of rank 1. The structure of the Cantor part $(Du)^{\mathrm{c}}$ is described by the Alberti's rank-1 theorem (see Alberti (1993)).

**Theorem 8** *For every $u \in \mathrm{BV}(\Omega;\mathbb{R}^m)$ the Cantor part $(Du)^{\mathrm{c}}$ is a measure with values in the $m \times N$ matrices of rank 1.*

## Convex Functionals on BV

Many problems of the calculus of variations deal with the minimization of energies of the form

$$F(u) = \int_\Omega f(x, u, Du)\,\mathrm{d}x \qquad [5]$$

The direct methods to obtain the existence of at least a minimizer require some coercivity hypotheses on $F$, as well as its lower-semicontinuity. This last issue, already rather delicate when working in Sobolev spaces (see, e.g., Buttazzo (1989) and Dacorogna (1989)), presents additional difficulties when the unknown function $u$ varies in the space $\mathrm{BV}(\Omega)$, due to the fact that $Du$ is a measure, and the precise meaning of the integral in [5] has to be clarified.

In this section, we limit ourselves to consider the simpler situation of convex functionals, and we also assume that the integrand $f(x, u, Du)$ depends only on $x$ and $Du$. It is then convenient to study the problem in the framework of functionals defined on the space of finite Borel vector measures $\mathcal{M}(\Omega;\mathbb{R}^k)$. Let $f: \mathbb{R}^N \times \mathbb{R}^k \to [0, +\infty]$ be a Borel function such that

- $f$ is lower-semicontinuous, and
- $f(x,\cdot)$ is convex for every $x \in \mathbb{R}^N$.

We denote by $f^\infty(x,z)$ the recession function associated with $f$, given by

$$f^\infty(x,z) = \lim_{t\to+\infty} \frac{f(x, z_0 + tz)}{t}$$

where $z_0$ is any point in $\mathbb{R}^k$ such that $f(x,z_0) < +\infty$ (in fact, the definition above is independent of the choice of $z_0$). Then we may consider the functional

$$F(\lambda) = \int_\Omega f(x, \lambda^{\mathrm{a}}(x))\,\mathrm{d}x + \int_\Omega f^\infty\left(x, \frac{\mathrm{d}\lambda^{\mathrm{s}}}{\mathrm{d}|\lambda^{\mathrm{s}}|}\right)\mathrm{d}|\lambda^{\mathrm{s}}| \quad [6]$$

where $\lambda = \lambda^{\mathrm{a}} \cdot \mathrm{d}x + \lambda^{\mathrm{s}}$ is the Lebesgue–Nikodym decomposition of $\lambda$ into absolutely continuous and singular parts, and the notation $\mathrm{d}\lambda^{\mathrm{s}}/\mathrm{d}|\lambda^{\mathrm{s}}|$ stands for the density of $\lambda^{\mathrm{s}}$ with respect to its total variation $|\lambda^{\mathrm{s}}|$. For simplicity, the last term on the right-hand side of [6] is often denoted by $\int_\Omega f^\infty(x,\lambda^{\mathrm{s}})$.

For the functional $F$, the following lower-semicontinuity result holds (see, e.g., Buttazzo (1989)).

**Theorem 9** *Under the assumptions above the functional [6] is sequentially lower-semicontinuous for the weak* convergence on $\mathcal{M}(\Omega;\mathbb{R}^k)$. Moreover, if*

$$f(x,z) \geq c_0|z| - a(x) \quad \text{with } c_0 > 0 \text{ and } a \in L^1(\Omega) \qquad [7]$$

*then the functional F turns out to be coercive for the same topology.*

From Theorem 9 we deduce immediately a lower-semicontinuity result for functionals defined on $BV(\Omega; \mathbb{R}^m)$.

**Corollary 10** *Under the assumptions above on the integrand f(with k = mN) the functional defined on* $BV(\Omega; \mathbb{R}^m)$ *by*

$$F(u) = \int_\Omega f(x, (Du)^a)\,dx + \int_\Omega f^\infty\left(x, \frac{d(Du)^s}{d|Du|^s}\right) d|Du|^s \qquad [8]$$

*is sequentially lower-semicontinuous for the weak* convergence. Moreover, under the assumption [7] the functional F is coercive with respect to the same topology.*

For some extensions of the result above to the case when $f(x, \cdot)$ is quasiconvex (in the vector-valued situation $m > 1$), we refer the interested reader to Fonseca and Müller (1992) and references therein.

Fixing boundary data is another difference between variational problems on Sobolev spaces and on BV spaces. Due to the fact that the class $\{u \in BV(\Omega): u = u_0 \text{ on } \partial\Omega\}$ is not weakly* closed, to set in a correct way a minimum problem of Dirichlet type on $BV(\Omega)$ with datum $u_0 \in BV(\mathbb{R}^N)$ it is convenient to consider a larger domain $\Omega' \supset\supset \Omega$ and for every $u \in BV(\Omega)$ the extended function

$$\tilde{u} = \begin{cases} u & \text{on } \Omega \\ u_0 & \text{on } \Omega' \setminus \Omega \end{cases}$$

whose distributional gradient is

$$D\tilde{u} = Du \llcorner \Omega + Du_0 \llcorner \Omega' \setminus \bar{\Omega} + (u_0 - u)\nu_\Omega \mathcal{H}^{N-1} \llcorner \partial\Omega$$

$\nu_\Omega$ being the exterior normal versor to $\Omega$. We have then the following functional on $BV(\Omega')$:

$$\begin{aligned}\tilde{F}(\tilde{u}) &= \int_{\Omega'} f(x, (D\tilde{u})^a)\,dx + \int_{\Omega'} f^\infty(x, (D\tilde{u})^s) \\ &= \int_\Omega f(x, (Du)^a)\,dx + \int_{\Omega'\setminus\Omega} f(x, (Du_0)^a)\,dx \\ &\quad + \int_\Omega f^\infty(x, (Du)^s) + \int_{\Omega'\setminus\bar{\Omega}} f^\infty(x, (Du_0)^s) \\ &\quad + \int_{\partial\Omega} f^\infty(x, (u_0 - u)\nu_\Omega)\,d\mathcal{H}^{N-1}\end{aligned}$$

If we drop the constant term

$$\int_{\Omega'\setminus\Omega} f(x, (Du_0)^a)\,dx + \int_{\Omega'\setminus\bar{\Omega}} f^\infty(x, (Du_0)^s)$$

irrelevant for the minimization, we end up with the functional

$$F_{u_0}(u) = F(u) + \int_{\partial\Omega} f^\infty(x, (u_0 - u)\nu_\Omega)\,d\mathcal{H}^{N-1}$$

where $F$ is as in [8]. The Dirichlet problem we consider is then

$$\min\left\{F(u) + \int_{\partial\Omega} f^\infty(x, (u_0 - u)\nu_\Omega) d\mathcal{H}^{N-1}: u \in BV(\Omega)\right\} \qquad [9]$$

For instance, if $f(z) = |z|$, problem [9] becomes

$$\min\left\{\int_\Omega |Du| + \int_{\partial\Omega} |u - u_0|\,d\mathcal{H}^{N-1}: u \in BV(\Omega)\right\}$$

Under the assumptions considered, the problem above admits a solution $u \in BV(\Omega)$, but in general we do not have $u = u_0$ on $\partial\Omega$ in the sense of BV traces.

## Nonconvex Functionals on BV

In order to introduce the class of nonconvex functionals on $BV(\Omega)$, let us denote $v = Du$ so that every functional $\Phi(v)$ provides an energy $F(u)$. If we work in the setting of Sobolev spaces, we have $u \in W^{1,p}(\Omega)$ $(p \geq 1)$, which implies $v \in L^p(\Omega; \mathbb{R}^N)$; now, it happens that in this case all "interesting" functionals $\Phi$ are convex. More precisely, it can be proved that a functional $\Phi : L^p(\Omega; \mathbb{R}^N) \to [0, +\infty]$, which is

- sequentially lower-semicontinuous for the weak convergence of $L^p(\Omega; \mathbb{R}^N)$, and
- local on $L^p(\Omega; \mathbb{R}^N)$ in the sense that $\Phi(v + w) = \Phi(v) + \Phi(w)$ whenever $v \cdot w \equiv 0$ in $\Omega$,

has to be necessarily convex, and of the form

$$\Phi(v) = \int_\Omega \phi(x, v(x))\,dx$$

for a suitable integrand $\phi$ such that $\phi(x, \cdot)$ is convex. Then the energies $F(u)$ defined on Sobolev spaces and obtained by a functional $\Phi(v)$ through the identification $v = Du$ are necessarily convex. This is no longer true if $\Phi$ is defined on the space $\mathcal{M}(\Omega; \mathbb{R}^N)$ of measures, and hence $F$ is defined on $BV(\Omega)$. The first example of a nonconvex functional $\Phi$ on $\mathcal{M}(\Omega; \mathbb{R}^N)$ in the literature comes from the so-called Mumford–Shah model for computer vision (see below) and is given by

$$\Phi(\lambda) = \int_\Omega |\lambda^a(x)|^2 dx + \#(A_\lambda)$$

where $\lambda^a$ is the absolutely continuous part of $\lambda, A_\lambda$ is the set of atoms of $\lambda$, and $\#$ is the counting measure. The functional $\Phi$ is set equal to $+\infty$ on all measures $\lambda$ whose singular part $\lambda^s$ is nonatomic. A general representation result (see Bouchitte and Buttazzo (1992) and references therein) establishes that a functional $\Phi : \mathcal{M}(\Omega; \mathbb{R}^N) \to [0, +\infty]$, which is

- sequentially lower-semicontinuous for the weak$^*$ convergence of $\mathcal{M}(\Omega; \mathbb{R}^N)$, and
- local on $\mathcal{M}(\Omega; \mathbb{R}^N)$ in the sense that $\Phi(\lambda + \nu) = \Phi(\lambda) + \Phi(\nu)$ whenever $\lambda$ and $\nu$ are mutually singular in $\Omega$,

has to be of the form

$$\Phi(\lambda) = \int_\Omega \phi(x, \lambda^a)\, d\mu + \int_\Omega \phi^\infty(x, \lambda^c) + \int_\Omega \psi(x, \lambda^\#(x))\, d\#$$

where $\mu$ is a non-negative measure, $\lambda = \lambda^a \cdot dx + \lambda^c + \lambda^\#$ is the decomposition of $\lambda$ into absolutely continuous, Cantor, and atomic parts, $\phi(x, v)$ is an integrand convex in $v$, and $\phi^\infty$ is its recession function. The novelty is now represented by the integrand $\psi(x, v)$ which has to be subadditive in $v$ and satisfying the compatibility condition

$$\lim_{t \to +\infty} \frac{\phi(x, tv)}{t} = \lim_{t \to 0^+} \frac{\psi(x, tv)}{t}$$

When $\phi$ has a superlinear growth the condition above gives that the slope of $\psi(x, \cdot)$ at the origin has to be infinite. For instance, in the Mumford–Shah case we have

$$\phi(x, v) = |v|^2, \quad \psi(x, v) = \begin{cases} 1 & \text{if } v \neq 0 \\ 0 & \text{if } v = 0 \end{cases} \qquad [10]$$

Coming back to the case $u \in \mathrm{BV}(\Omega)$, we have the decomposition (see [4]):

$$Du = \nabla u \cdot \mathcal{L}^N + (Du)^c + [u]\nu_u(x) \cdot \mathcal{H}^{N-1} \llcorner S_u$$

where we considered, for simplicity, only the scalar case $m = 1$ and denoted by $[u]$ the jump $u^+ - u^-$. We have then the functional

$$F(u) = \int_\Omega \phi(x, \nabla u)\, dx + \int_\Omega \phi^\infty(x, (Du)^c) + \int_{S_u} \psi(x, [u]\nu_u)\, d\mathcal{H}^{N-1}$$

For instance, in the homogeneous–isotropic case, when $\phi(x, v)$ and $\psi(x, v)$ are independent of $x$ and depend only on $|v|$, the formula above reduces to

$$F(u) = \int_\Omega \phi(|\nabla u|) dx + \beta |Du|^c(\Omega) + \int_{S_u} \psi(|[u]|) d\mathcal{H}^{N-1} \qquad [11]$$

where $\beta, \phi, \psi$ satisfy the compatibility condition

$$\beta = \phi^\infty(1) = \lim_{t \to 0^+} \frac{\psi(t)}{t} \qquad [12]$$

In the original Mumford–Shah model for computer vision, $\Omega$ is a rectangle of the plane, $u_0 : \Omega \to [0, 1]$ represents the gray level of a picture, $c_1$ and $c_2$ are positive scale and contrast parameters, and the variational problem under consideration is

$$\min\left\{ \int_\Omega |\nabla u|^2 dx + c_1 \int_\Omega |u - u_0|^2 dx + c_2 \mathcal{H}^{N-1}(S_u) \colon (Du)^c \equiv 0 \right\} \qquad [13]$$

The solution $u$ then represents the reconstructed image, whose contours are given by the jump set $S_u$. We refer to Giorgi and Ambrosio (1988) and to the book by Morel and Solimini (1995) for further details about this model.

Analogously, in the case of the study of fractures of an elastic membrane, a problem similar to [13] provides the vertical displacement $u$ of the membrane, together with its fracture set $S_u$. We refer to some recent papers (see Dal Maso and Toader (2002) and Francroft and Marigo (1998), and references therein) for a more detailed description of fracture mechanics problems, even in the more delicate vectorial setting of elasticity.

Using the functional $F$ in [11] we have the generalized Mumford–Shah problem,

$$\min\left\{ F(u) + c_1 \int_\Omega |u - u_0|^2 dx : u \in \mathrm{BV}(\Omega) \right\}$$

where $\phi$ is convex, $\psi$ is subadditive, and the compatibility condition [12] is fulfilled.

If we set $K = S_u$ and assume that it is closed, the Mumford–Shah problem can be rewritten as

$$\min\left\{ \int_{\Omega \setminus K} |\nabla u|^2 dx + c_1 \int_{\Omega \setminus K} |u - u_0|^2 dx + c_2 \mathcal{H}^{N-1}(K \cap \Omega) : K \subset \bar{\Omega} \text{ closed}, u \in H^1(\Omega \setminus K) \right\}$$

and this justifies the name "free discontinuity problems," which is often used in this setting.

The regularity properties of optimal pairs $(u, K)$ are far from being fully understood; some partial results are available but the Mumford–Shah conjecture:

- in the case $N = 2$ for an optimal pair $(u, K)$ the set $K$ is locally the finite union of $C^{1,1}$ arcs

remains still open. We refer to Ambrosio *et al.* (2000) for a list of the regularity results on the problem above that are known thus for.

# Free Probability Theory

**D-V Voiculescu**, University of California at Berkeley, Berkeley, CA, USA

## Introduction

Free probability is a probability theory adapted to quantities with the highest degree of noncommutativity. A basic feature of this is that the definition of independence is modified in such a way that the freely independent random variables will not commute in general. The exploration of this notion of independence, which was initially motivated by questions about operator algebras (Voiculescu 1985), has produced a theory that runs parallel to an unexpectedly large part of classical probability theory. The applications of the theory have also gone into unexpected directions, once it turned out that the large-$N$ limit of systems of random matrices is a key asymptotic model in the theory (Voiculescu 1991). There are several signs like the connections to large $N$ for random matrices and to the combinatorics of noncrossing partitions (Speicher 1998) (which correspond to certain planar diagrams), that perhaps these connections may go even further towards the large-$N$ limit of models in gauge theory.

In this article the noncommutative probability and the random matrix angle will be emphasized and very little will be said about the operator algebras and the combinatorics. After discussing free independence and models based on free products of groups and creation and annihilation operators on the Boltzmann full Fock space, we continue with the semicircle law, which is the substitute for the Gauss law in this context, and with the nonlinear free harmonic analysis arising from addition and multiplication of free random variables.

We then devote two longer sections to the asymptotic free independence of large random matrices and to free entropy, the free probability analog of Shannon's information-theoretic entropy for continuous random variables.

## Freeness of Noncommutative Random Variables

Classical probability deals with expectation values of numerical random variables, that is, with

numerical functions on a space of events and with their integrals with respect to a probability measure on the space of events. In noncommutative probability, the random variables, like quantum-mechanical quantities, are elements of a noncommutative algebra $A$ over $\mathbb{C}$, with unit $1 \in A$, which is endowed with a linear expectation functional $\varphi : A \to \mathbb{C}$, so that $\varphi(1) = 1$. Frequently, $A$ is a $*$-algebra of operators on some Hilbert space $\mathcal{H}$ and $\varphi(T) = \langle T\xi, \xi\rangle$ for some unit vector $\xi \in \mathcal{H}$. We call $(A,\varphi)$ a noncommutative probability space and the elements $a \in A$, noncommutative random variables. In this section we shall discuss the basics around the notion of freeness (Voiculescu 1985), which plays the role of independence in free probability.

If $\alpha = (a_i)_{i\in I} \subset A$ is a family of noncommutative random variables, the role of joint distribution is played by the collection of noncommutative moments $\varphi(a_{i_1} \dots a_{i_n})$. This can also be extended by linearity to a distribution functional $\Phi_\alpha : \mathbb{C}\langle X_i \mid i \in I\rangle \to \mathbb{C}$, where $\mathbb{C}\langle X_i \mid i \in I\rangle$ is the ring of polynomials in noncommutative indeterminates $X_i (i \in I)$ and

$$\Phi_\alpha(P(X_i|i \in I)) = \varphi(P(a_i|i \in I))$$

If $A$ is a $C^*$-algebra of operators on $\mathcal{H}$, $a = a^* \in A$ and $\varphi(\,\cdot\,) = \langle \cdot\,\xi, \xi\rangle$, the distribution of $a$ can also be identified with the probability measure $\mu_a$ on $\mathbb{R}$

$$\mu_a(\omega) = \langle E(\omega; a)\xi, \xi\rangle$$

where $E(\,\cdot\,; a)$ is the spectral measure of $a$. Indeed, then

$$\Phi_a(P(X)) = \int P(t)\mathrm{d}\mu_a(t)$$

A family $(A_i)_{i\in I} \subset A, 1 \in A_i$ of subalgebras is "free" (which is short for freely independent) if

$$\varphi(a_1 \dots a_n) = 0$$

whenever $a_j \in A_{i_j}, 1 \le j \le n$, $i_j \ne i_{j+1}$ and $\varphi(a_j) = 0$. (Here it is only required that consecutive $a_j$'s be in different $A_i$'s. Thus, we may have $i_1 = i_3$, provided $i_1 \ne i_2$.)

A family of sets of random variables $(\omega_i)_{i\in I}$, $\omega_i \subset A$ is free if the algebras $A_i$ generated by $1 \cup \{\omega_i\}$ are free in $(A,\varphi)$.

Except for rather trivial situations, free random variables in $(A,\varphi)$ do not commute.

Note also that, as in the case of classical independence, if $(\omega_i)_{i\in I}$ are disjoint freely independent sets of random variables, then, if the distributions $\Phi_{\omega_i}(i \in I)$ are given, the distribution $\Phi_\omega$ of $\omega = \bigcup_{i\in I} \omega_i$ is completely determined.

**Example 1** Let the group $G$ be the free product of its subgroups $(G_i)_{i\in I}$, that is, $G$ is generated by these subgroups and there is no nontrivial relation among elements of different $G_i$'s. Further, let $\lambda$ be the regular representation $\lambda(g)e_h = e_{gh}$ of $G$ on the Hilbert space with orthonormal basis $(e_g)_{g\in G}$. Then, with respect to the expectation functional $\tau(T) = \langle Te_e, e_e\rangle$ on operators on $l^2(G)$, the sets $(\lambda(G_i))_{i\in I}$ are freely independent.

**Example 2** If $\mathcal{H}$ is a complex Hilbert, let $\mathcal{TH} = \bigoplus_{k\ge 0} \mathcal{H}^{\otimes k}$ denote the full Boltzmann Fock space, with vacuum vector 1 so that $\mathcal{H}^{\otimes 0} = \mathbb{C}1$. If $h \in \mathcal{H}$ and $\xi \in \mathcal{TH}$, let $l(h)\xi = h \otimes \xi$ denote the left creation operator and $\varphi(X) = \langle X1, 1\rangle$ the vacuum expectation. Then, if the $\mathcal{H}_i (i \in I)$ are pairwise orthogonal subspaces in $\mathcal{H}$, the $*$-subalgebras of operators generated by $l(\mathcal{H}_i) \cup l^*(\mathcal{H}_i)$, indexed by $i \in I$, are freely independent with respect to $\varphi$.

## Free Independence with Amalgamation over a Subalgebra

The classical notion of conditional independence also has a free counterpart based on the notion of free independence with amalgamation over a subalgebra. This subject is technically more complicated and we will only aim at giving an idea about what kind of concepts are involved.

In the classical context, if $(X, \Sigma, \mu)$ is a probability space with a $\sigma$-algebra $\Sigma$, then the conditional independence with respect to a $\sigma$-subalgebra of events, $\Sigma_0 \subset \Sigma$, amounts to replacing in the definition of independence the expectation functional (which is the integral with respect to $\mu$) by the conditional expectation functional $L^\infty(X, \Sigma, \mu) \xrightarrow{E} L^\infty(X, \Sigma_0, \mu(\Sigma_0))$.

In free probability, one considers an extension of the theory, from the $(A,\varphi)$ framework to an $(A,\Phi, B)$ framework (Voiculescu 1995), where $A$ is an algebra with unit over $\mathbb{C}, B \ni 1$ is a subalgebra, and $\Phi : A \to B$ is $B$–$B$-bilinear and $\Phi|_B = \mathrm{id}_B$. Then the definition of $B$-freeness (or free independence with amalgamation over $B$) of a family of subalgebras $(A_i)_{i\in I}, B \subset A_i \subset A$ requires that

$$\Phi(a_1 \dots a_n) = 0$$

whenever $a_j \in A_{i_j}, i_j \ne i_{j+1}(1 \le j \le n)$, and $\Phi(a_j) = 0$.

In the case of a unital $*$-algebra of bounded operators $M$ with an expectation functional $\tau(\,\cdot\,) = \langle \cdot\,\xi, \xi\rangle$ which is tracial (i.e., $\tau([m_1, m_2]) = 0$ if $m_1, m_2 \in M$) and given a subalgebra $1 \in N \subset M$, as in the classical theory, there is a certain canonical construction in operator algebra theory of a "conditional expectation" $\Phi : \bar{M} \to \bar{N}$, where $\bar{M}, \bar{N}$ are

algebras of operators obtained as completion-separates from $M$ and $N$. With this construction, in the trace-state setting there is complete analogy with the classical notion of conditional independence.

Several other constructions of free probability have been extended to the $(A, \Phi, B)$ $B$-valued context.

A group-theoretic example similar to Example 1 can be constructed from a group $G$ which is a free product with amalgamation over a subgroup $H \subset G$ of subgroups $H \subset G_i \subset Gi \in I$. Then $A$ is the algebra constructed from the left-regular representation of $G$, whereas $B$ is an algebra constructed from the left-regular representation of $H$.

## The Semicircle Law

In free probability the semicircle law appears as the limit law in the free central limit theorem (Voiculescu 1985). Here is a weak, rather algebraic, version of this fact:

If $(a_n)_{n \in \mathbb{N}}$ are freely independent in $(A, \varphi)$ and satisfy the conditions that

$$\varphi(a_n) = 0 (n \in \mathbb{N})$$
$$\lim_{N \to \infty} N^{-1} \sum_{1 \le n \le N} \varphi\left(a_n^2\right) = 1$$
$$\sup_{n \in \mathbb{N}} \left| \varphi\left(a_n^k\right) \right| = C_k < \infty (k \in \mathbb{N})$$

then, if $S_N = N^{-1/2} \sum_{1 \le n \le N} a_n$, we have the convergence of moments of the distribution of $S_N$ to the semicircle distribution

$$\lim_{N \to \infty} \varphi(S_N^k) = (2\sigma)^{-1} \int_{-2}^{2} t^k (4 - t^2)^{1/2} \, \mathrm{d}t$$

Thus, the semicircle law, given by the density $(2\pi)^{-1}(4 - t^2)^{1/2}$ on $[-2, 2]$ is the free analog of the (0,1) Gauss law.

Two coincidences involving the semicircle law should be noted.

The field operators $s(h) = 2^{-1}(l(h) + l(h)^*)$ on the Boltzmann Fock space (Example 2) have semicircle distributions with respect to the vacuum expectation $\epsilon(\cdot) = \langle \cdot 1, 1 \rangle$. It turns out that this goes farther: if $\mathcal{H} = \mathcal{H}_{\mathbb{R}} \otimes_{\mathbb{R}} \mathbb{C}$ is the complexification of a real Hilbert space, then the map $\mathcal{H}_{\mathbb{R}} \ni h \to s(h)$ is the analog in free probability of the Gaussian process over the Hilbert space $\mathcal{H}_{\mathbb{R}}$ (Voiculescu 1985). It is often called the semicircular process over $\mathcal{H}_{\mathbb{R}}$. This points to an important connection of free probability to the full Boltzmann statistics.

The other coincidence is that the semicircle law is well known as the Wigner limit distribution of eigenvalues of large Gaussian random matrices. As we shall see, this is a clue to a deep connection of free probability to the large-$N$ limit of random matrices (Voiculescu 1991).

## Free Convolution Operations

In classical probability theory, the distribution of the sum of two independent random variables is computed by the convolution product of their distributions. This has a free probability analog. If $a$,$b$ are free random variables in $(A, \varphi)$ with distributions $\mu_a, \mu_b : \mathbb{C}[X] \to \mathbb{C}$, then the joint distribution $\mu_{\{a,b\}}$ is completely determined by $\mu_a, \mu_b$ and in particular $\mu_{a+b}$, the distribution of $a + b$, also depends only on $\mu_a, \mu_b$. It follows that there is an additive free convolution operation $\boxplus$ on distributions so that $\mu_a \boxplus \mu_b = \mu_{a+b}$ whenever $a, b$ are free (Voiculescu 1985). The same can be done with multiplication replacing addition, and this defines the multiplicative free convolution operation $\boxtimes$ by the equation $\mu_a \boxtimes \mu_b = \mu_{ab}$, when $a, b$ are free (Voiculescu 1985). A slightly surprising feature of $\boxtimes$ is that in spite of noncommutativity of $a$ and $b$, the multiplicative operation $\boxtimes$ turns out to be commutative, which of course is obvious for $\boxplus$.

In the classical context, convolutions are bilinear operations which can be computed using integrals. The free convolutions are quite nonlinear and their computation is via another route, which can also be explained by a classical analogy. Classically, the logarithm of the Fourier transform linearizes convolution, that is,

$$\log \mathcal{F}(\mu * \nu) = \log \mathcal{F}(\mu) + \log \mathcal{F}(\nu)$$

and we may compute $\mu * \nu$ as the $(\log \mathcal{F})^{-1}$ of $\log \mathcal{F}(\mu) + \log \mathcal{F}(\nu)$. The linearizing transform for $\boxplus$ is the $R$-transform (Voiculescu 1986), which is obtained by the following procedure.

If $\mu : \mathbb{C}[X] \to \mathbb{C}$ is a distribution, let $G_\mu(z) = z^{-1} + \sum_{n \ge 1} \mu(X^n) z^{-n-1}$, which, in case $\mu$ is a compactly supported probability measure on $R$, is the Laurent series at $\infty$ of the Cauchy transform

$$\int \frac{\mathrm{d}\mu(t)}{t - z}$$

From this, one obtains, by inversion at $\infty$, the series $K_\mu$, so that $G_\mu(K_\mu(z)) = z$ and one defines $R_\mu(z) = K_\mu(z) - z^{-1}$, which is a power series in $z$. Then

$$R_{\mu \boxplus \nu} = R_\mu + R_\nu$$

In case the distribution corresponds to a measure, the formal inversion amounts to inverting an analytic function.

For the multiplicative operation $\boxplus$, it is more convenient to describe an analog of the Mellin transform, that is, no logarithm will be taken. This is the $S$-transform (Voiculescu 1991), obtained as follows.

If $\mu : \mathbb{C}[X] \to \mathbb{C}$ is a distribution with $\mu(X) \neq 0$, one forms $\psi_\mu(z) = \sum_{n\geq 1} \mu(X^n) z^n$ and its inverse $\chi_\mu$ so that $\psi_\mu(\chi_\mu(z)) = z$. Then

$$S_\mu(z) = z^{-1}(1+z)\chi_\mu(z)$$

has the property that

$$S_{\mu \boxtimes \nu} = S_\mu S_\nu$$

The free central limit theorem can be easily proved using the $R$-transform. Another easy application of the $R$-transform is to find the free analog of the Poisson law, that is,

$$\lim_{n\to\infty} ((1-a/n)\delta_0 + a/n\delta_1)^{\boxplus}$$

where $a > 0$. The free Poisson law is

$$\mu = \begin{cases} (1-a)\delta_0 + \nu & \text{if } 0 \leq a \leq 1 \\ \nu & \text{if } a > 1 \end{cases}$$

where $\nu$ has support $[(1-a^{1/2})^2, (1+a^{1/2})^2]$ and density $(2\pi t)^{-1}(4a - (t-(1+a))^2)^{1/2}$. This distribution is well known in random matrix theory as the Marchenko–Pastur distribution, again a coincidence pointing to a random matrix theory connection.

Because probability measures on $\mathbb{R}$ are distributions of self-adjoint operators and a sum of self-adjoint operators is again such an operator, the additive free convolution $\boxplus$ yields an operation on probability measures on $\mathbb{R}$. Similarly, it can be shown that $\boxtimes$ gives rise to operations on probability measures on $\{z \in \mathbb{C} \mid |z| = 1\}$ and on probability measures on $[0,\infty)$.

With the $R$-transform machinery at hand, the free analogs of many of the classical results around addition of independent random variables have been developed (we recommend Voiculescu (1998c) for a survey of these developments). This includes the classification of infinitely divisible laws (Levy–Khintchine type theorem), classification of stable laws, domains of attraction, and convolution semigroups. Note that the free laws are rather different from the classical ones, but the classification results are quite parallel, that is, the indexing parameters are almost the same. The situation is similar in the multiplicative context. As in the classical case, these results about laws yield in particular processes with independent increments, which in the free framework are free increments.

As in the classical setting, also in the free setting, convolution semigroups are connected to differential equations. In the additive free case, a semigroup is a family $(\mu_t)_{t\geq 0}$ of probability measures on $\mathbb{R}$, so that $\mu_{t+s} = \mu_t \boxplus \mu_s$. If $G(t,z)$ is the Cauchy transform of $\mu_t$ (which is an analytic function on the half-plane $\operatorname{Im} z > 0$), the equation (Voiculescu 1986) is a semilinear complex PDE:

$$\frac{\partial G}{\partial t} + R_{\mu_1}(G)\frac{\partial G}{\partial z} = 0$$

where $R_{\mu_1}$ is the $R$-transform of $\mu_1$. In particular, when $\mu_1$ is the semicircle law, $R_{\mu_1}(z) = \alpha z$ $\alpha > 0$ and the PDE is a complex Burgers equation in the upper half-plane.

## Noncrossing Partitions

The series expansion of the $R$-transform

$$R_\mu(z) = \sum_{n\geq 0} R_n(\mu) z^n$$

has as coefficients polynomials $R_n(\mu)$ in the moments $\mu(X^k)$. More precisely, assigning to $\mu(X^k)$ a degree $k, R_n(\mu)$ is a polynomial of degree $n$ and $R_n(\mu) - \mu(X^n) =$ polynomial in $\mu(X^k)$ with $k < n$. The linearization property of the $R$-transform implies that

$$R_n(\mu \boxplus \nu) = R_n(\mu) + R_n(\nu)$$

For classical convolution, polynomials with similar properties satisfying

$$C_n(\mu * \nu) = C_n(\mu) + C_n(\nu)$$

are called cummulants and satisfy

$$\log \mu(e^{zX}) = \sum_{n\geq 1} C_m(\mu) z^n$$

There are combinatorial formulas involving the lattice of all partitions of the set $\{1, \ldots, n\}$ which give the classical cummulants. For free cummulants, like $R_n(\mu)$ and generalizations of these, there are similar formulas provided the lattice of all partitions is replaced by the lattice NC($n$) of noncrossing partitions (Speicher 1998). A partition $\pi = (V_1, \ldots, V_m)$ of $\{1, \ldots, n\}$ is noncrossing if there are no $a < b < c < d$ so that $\{a, c\} \subset V_k, \{b, d\} \subset V_l$ and $k \neq l$.

More generally, a family $R^{(n)}(a_1, \ldots, a_n)$ of free cummulants, where $a_1, \ldots, a_n$ are in some $(A,\varphi)$, is defined recursively as follows (Speicher 1998). For n = 1, one has $R^{(1)}(a) = \varphi(a)$. If $\pi = (V_1, \ldots, V_m) \in$ NC($n$), where $V_k = \{i(1,k) < \cdots < i(n_k, k)\}$, we define

$$R[\pi](a_1, \ldots, a_n) = \prod_{1\leq k\leq m} R^{(|V_k|)}(a_{i(1,k)}, \ldots, a_{i(n_k,k)})$$

The recurrence relation for cummulants is then

$$\varphi(a_1 \dots a_n) = \sum_{\pi \in \mathrm{NC}(n)} R[\pi](a_1, \dots, a_n)$$

Note that the right-hand side involves only $R^{(k)}$'s with $k \leq n$ and that actually $R^{(n)}$ appears only in and is equal to $R[(\{1, \dots, n\})](a_1, \dots, a_n)$ (the coarsest partition).

A key property of $R^{(n)}(a_1, \dots, a_n)$ is that if $\{1, \dots, n\} = \alpha \amalg \beta$ and $(a_k)_{k \in \alpha}, (a_l)_{l \in \beta}$ are freely independent, then $R^{(n)}(a_1, \dots, a_n) = 0$.

If $\mu$ is the distribution of $a \in (A, \varphi)$, then the cummulants $R_n(\mu)$ are given by

$$R_n(\mu) = R^{(n)}(a, \dots, a)$$

The noncrossing condition on partitions corresponds to a planarity requirement for diagrams and as such is very suggestive of connections to planar diagrams occurring in the constant term of large-$N$ expansions from random matrix theory and more generally gauge theory.

For more details on the subject of noncrossing partitions, we refer the reader to the memoir by Speicher (1998).

## Asymptotic Freeness of Random Matrices

The explanation for the coincidences between certain laws in free probability and in random matrix theory is that freeness occurs asymptotically among random matrices in the large-$N$ limit (Voiculescu 1991).

Random matrices can be put in a noncommutative probability framework $(\mathcal{A}_N, \varphi_N)$, where $\mathcal{A}_N = L^{\infty - 0}(\Omega, \mathcal{M}_N; \mathrm{d}\sigma)$ (the $N \times N$ complex matrix-valued functions on the probability space $(\Omega, \mathrm{d}\sigma)$ which are $p$-integrable for all $p \in [1,\infty)$) and the expectation functional is

$$\varphi_N(X) = N^{-1} \int_\Omega \mathrm{tr}\, X(\omega) \mathrm{d}\sigma(\omega)$$

The basic example is provided by an $n$-tuple of Gaussian random matrices (Voiculescu 1991). Let

$$T_j^{(N)} = \left(a_{p,q;j}^{(N)}\right)_{1 \leq p, q \leq N} \in N, \quad 1 \leq j \leq n$$

where $a_{p,q;j}^{(N)} = a_{q,p;j}^{(N)}$ and the $a_{p,q;j}^{(N)} 1 \leq p \leq q \leq N$, $1 \leq j \leq n$ are $(0, N^{-1})$-Gaussian and independent. Then $(T_j^{(N)})_{1 \leq j \leq n}$ as $N \to \infty$ converges in noncommutative distribution to the freely independent $n$-tuple $(l(e_j) + l^*(e_j))_{1 \leq j \leq n}$ in the Boltzmann Fock space context of Example 2 for an orthonormal system $e_1, \dots, e_n \in \mathcal{H}$, that is, convergence of moments:

$$\lim_{N \to \infty} \varphi_N \left(T_{i_1}^{(N)} \cdots T_{i_k}^{(N)}\right) = \langle (l(e_{i_1}) + l^*(e_{i_1})) \cdots (l(e_{i_k}) + l^*(e_{i_k}))1, 1 \rangle$$

In particular, the limit variables $(l(e_j) + l^*(e_j))_{1 \leq j \leq n}$ are free.

More generally, asymptotic freeness of variables or sets of variables in $(\mathcal{A}_N, \varphi_N)$ can be defined without the existence of a limit distribution, that is, by requiring only that the freeness relations among noncommutative moments hold asymptotically as $N \to \infty$.

Note that in these random matrix questions, the joint classical distribution of an $n$-tuple of random matrices $(X_1^{(N)}, \dots, X_n^{(N)})$ in $\mathcal{A}_N$ is a probability measure on $(\mathcal{M}_N)^n$ which contains more information than the collection of noncommutative moments, which is the distribution of the noncommutative variables in $(\mathcal{A}_N, \varphi_N)$. In particular, for one random matrix the classical distribution gives the joint distribution of all entries, whereas the noncommutative distribution gives information only about the distribution of eigenvalues.

From the Gaussian $n$-tuple using operator techniques much more general asymptotic freeness results have been obtained. For instance (Voiculesu 1998b):

Let $(X_1^{(N)}, \dots, X_m^{(N)}, Y_1^{(N)}, \dots, Y_n^{(N)})$ be $(m+n)$-tuples of self-adjoint $N \times N$ random matrices with classical joint distribution $\mu_N$ on $(\mathcal{M}_N^{\mathrm{sa}})^{m+n}$. Assume that $\mu_N$ is invariant under the action of the unitary group $\mathrm{U}(N)$ which takes $(X_1, \dots, X_m, Y_1, \dots, Y_n)$ into $(X_1, \dots, X_m, \mathrm{U}Y_1\mathrm{U}^*, \dots, \mathrm{U}Y_n\mathrm{U}^*)$ and assume that there is a bound $R$ on the operator norms $\|X_j^{(N)}\|$ and $\|Y_j^{(N)}\|$ independent of $N$. Then the sets $\{X_1^{(N)}, \dots, X_m^{(N)}\}$ and $\{Y_1^{(N)}, \dots, Y_n^{(N)}\}$ are asymptotically free as $N \to \infty$.

Note that the uniform bound on the operator norms can be easily replaced by weaker conditions.

Once we know that certain random matrices are asymptotically free and that the large-$N$ limit in noncommutative distribution exists, the results of free probability apply. For instance, if $X^{(N)}$ and $Y^{(N)}$ are asymptotically free and have limit distributions $\mu$ and $\nu$, then the limit distribution of $X^{(N)} + Y^{(N)}$ and of $X^{(N)}Y^{(N)}$ are the free convolutions $\mu \boxplus \nu$ and, respectively, $\mu \boxtimes \nu$.

Free probability techniques have also been successful in dealing with other questions about the asymptotic behavior of random matrices.

If $T_1^{(N)}, \dots, T_n^{(N)}$ is an $n$-tuple of i.i.d. Hermitian Gaussian random, then the uniform operator norms

of polynomials in noncommutative indeterminates have the property that

$$\lim_{N\to\infty} \|P(T_1^{(N)}, \ldots, T_n^{(N)})\| = \|P(l(e_1) + l(e_1)^*, \ldots, l(e_n) + l(e_n)^*)\|$$

almost surely (Haagerup and Thorbjoernsen).

This result is a far-reaching generalization of the results about largest eigenvalues of one Gaussian random matrix. The use of operator-valued free random variables (with respect to certain subalgebra) was an essential ingredient in the proof. Also, in another direction, freeness of operator-valued free random variables was used to obtain a free probability treatment of Gaussian random band matrices and generalizations of these (Shlyakhtenko 1996).

Finally, quite recently, extensions of the free probability framework have appeared which are adapted to the study of fluctuations of systems of random matrices in the large-$N$ limit.

## Free Entropy

There are free probability analogs also for information-theoretic quantities (Voiculescu 1994, 1998a).

Let $(f_1, \ldots, f_n)$ be an $n$-tuple of classical numerical random variables the joint distribution of which has density $p(t_1, \ldots, t_n)$ with respect to the $n$-dimensional Lebesgue measure $\lambda_n$ on $\mathbb{R}^n$. The entropy quantity associated by Shannon to $(f_1, \ldots, f_n)$ is

$$H(f_1, \ldots, f_n) = -\int_{\mathbb{R}^n} p \log p \, d\lambda_n$$

The free analog of $H(f_1, \ldots, f_n)$ is the free entropy quantity $\chi(X_1, \ldots, X_n)$. Here $X_j = X_j^*$, $1 \le j \le n$, are noncommutative self-adjoint random variables in $(M,\tau)$, where $M$ is a $*$-algebra of bounded operators on a Hilbert space $\mathcal{H}$. The expectation functional in addition to the positivity properties, equivalent to the requirement that it can be defined by a unit vector $\tau(\cdot) = \langle \cdot\xi, \xi\rangle$, also has the property of a trace $\tau(XY) = \tau(YX)$ for all $X, Y \in M$. For instance, the noncommutative random variables arising from the large-$N$ limit of $n$-tuples of self-adjoint random matrices live in noncommutative probability frameworks $(M,\tau)$ of this kind.

There are two approaches to defining free entropy and, since there are only partial results about the equivalence of these approaches, the quantities obtained are denoted by $\chi(X_1, \ldots, X_n)$ (Voiculescu 1994) and $\chi^*(X_1, \ldots, X_n)$ (Voiculescu 1998a). The quantity $\chi$ is often referred to as the "microstates free entropy," its definition being inspired by the Boltzmann formula $S = k \log W$, whereas the other entropy, sometimes called "microstates-free free entropy," is obtained via a free probability analog of the Fisher information (Voiculescu 1998a).

The microstates used to define $\chi$ are matricial and the reason why this choice produced a quantity with the right behavior with respect to free independence can be found in the asymptotic freeness properties of random matrices.

Given $X_j = X_j^* \in M, 1 \le j \le n$ and $m \in \mathbb{N}, k \in \mathbb{N}$, $\epsilon > 0$ the microstates $\Gamma(X_1, \ldots, X_n; m, k, \epsilon)$ are $n$-tuples $(A_1, \ldots, A_n)$ of self-adjoint $k \times k$ matrices, such that, for noncommutative moments of order up to $m$, we have

$$|k^{-1}\mathrm{tr}_k(A_{i_1} \ldots A_{i_p}) - \tau(X_{i_1} \ldots X_{i_p})| < \epsilon$$

where $1 \le p \le m, 1 \le i_j \le n, 1 \le j \le p$.

One obtains $\chi(X_1, \ldots, X_n)$ by taking the infimum over $\epsilon > 0$ and $m \in \mathbb{N}$ of

$$\limsup_{k\to\infty}\left(k^{-2} \log \mathrm{vol}\, \Gamma(\ldots) + \frac{n}{2}\log k\right)$$

where vol is the volume on $(\mathcal{M}_k^{\mathrm{sa}})^n$ corresponding to the Hilbert–Schmidt norm Hilbert space structure (Voiculescu 1994).

When $n = 1$, there is a simple formula for $\chi(X)$. If $\mu$ is the probability measure on $\mathbb{R}$ which represents the distribution of $X = X^* \in M$ with respect to the expectation $\tau$, then

$$\chi(X) = \iint \log|s - t| d\mu(s) d\mu(t) + C$$

where the exact value of the constant $C$ is $3/4 + 1/2 \log 2\pi$.

For $n > 1$ there is no simple formula for $\chi(X_1, \ldots, X_n)$, but there are several properties which provide a better understanding of this quantity.

If $X_j$ are such that $\chi(X_j) > -\infty$, then

$$\chi(X_1, \ldots, X_n) = \chi(X_1) + \cdots + \chi(X_n)$$

if and only if $X_1, \ldots, X_n$ are freely independent in $(M, \tau)$. Clearly, this property of $\chi$ with respect to free independence is analogous to the property of $H(f_1, \ldots, f_n)$ with respect to classical independence.

Further, if $F_1, \ldots, F_n$ are power series in $n$ noncommuting indeterminates, there is a change-of-variable formula

$$\chi(F_1(X_1, \ldots, X_n), \ldots, F_n(X_1, \ldots, X_n)) = \log|\det|(\mathcal{J}(F)) + \chi(X_1, \ldots, X_n)$$

involving the Kadison–Fuglede positive determinant $|\det|$ and a certain noncommutative Jacobian $\mathcal{J}(F), F = (F_1, \ldots, F_n)$ defined in $\mathcal{M}_n \otimes M \otimes M^{\mathrm{op}}$, where $M^{\mathrm{op}}$ is the opposite algebra of $M$. (For

definitions and the many technical conditions under which this formula holds, see Voiculescu (1994).)

The free entropy $\chi$ also satisfies semicontinuity, subadditivity, and a semicircular bound (analogous to the classical Gaussian bound) properties.

An unexpected feature of $\chi$ is a degeneration of convexity. If the trace state $\tau$ is a convex combination $\tau = \theta\tau' + (1-\theta)\tau''$, where $\tau', \tau''$ are trace states and where $\tau' \neq \tau''$ on the algebra generated by $X_1, \ldots, X_n$, and $n > 1$, then

$$\chi(X_1, \ldots, X_n) = -\infty$$

(for a reference consult the survey Voiculescu (2002)).

With the free entropy at hand, an important variational problem can be formulated for the noncommutative distribution of an $n$-tuple of self-adjoint noncommutative random variables $T_1, \ldots, T_n$ in the tracial context. The quantity to be maximized is

$$\chi(T_1, \ldots, T_n) - \tau(P(T_1, \ldots, T_n))$$

where $P$ is a given self-adjoint polynomial in noncommutative indeterminates (see Voiculescu (2002) for comments on this problem). If $n = 1$, this is a classical problem for the logarithmic energy

$$\iint \log|s-t|\mathrm{d}\mu(s)\mathrm{d}\mu(t) - \int P(t)\mathrm{d}\mu(t)$$

where $\mu$ is a probability measure on $\mathbb{R}$.

To explain the second approach, based on Fisher information, we begin by recalling some facts about Fisher information in the classical context.

If $f$ is a numerical random variable with distribution given by the density $p(t)$ on $\mathbb{R}$, then

$$\text{Fisher}(f) = \int \left(\frac{-p'}{p}\right)^2 p\,\mathrm{d}t = \left\| \left(\frac{\mathrm{d}}{\mathrm{d}t}\right)^* 1 \right\|_{L^2(R, p\,\mathrm{d}t)}$$

Here $\mathrm{d}/\mathrm{d}t$ is the differential operator defined on test functions in $L^2(R, p\,\mathrm{d}t)$. Then

$$\frac{p'}{p} = -\left(\frac{\mathrm{d}}{\mathrm{d}t}\right)^* 1$$

The classical connection to entropy is that the Fisher information is a derivative of the entropy when the variable becomes the starting point of a Brownian motion. This can be written as

$$\text{Fisher}(f) = \frac{\mathrm{d}}{\mathrm{d}t} H(f + t^{1/2}\mathfrak{g})|_{t=0}$$

where $\mathfrak{g}$ and $f$ are independent and $\mathfrak{g}$ is $(0,1)$ Gaussian.

The several-variables version is treated by using partial derivatives.

The analog in free probability of the Fisher information (Voiculescu 1998a) is obtained by using the free difference quotient derivations, which are the appropriate derivations in this maximally noncommutative setting. On the polynomials in $n$ noncommutative indeterminates, the $k$th partial free difference quotient

$$\partial_k : \mathbb{C}\langle X_1, \ldots, X_n\rangle \to \mathbb{C}\langle X_1, \ldots, X_n\rangle^{\otimes 2}$$

is defined on noncommutative monomials by the formula

$$\partial_k X_{i_1} \cdots X_{i_p} = \sum_{\{j | i_j = k\}} X_{i_1} \cdots X_{i_{j-1}} \otimes X_{i_{j+1}} \cdots X_{i_p}$$

If $X_j = X_j^*, 1 \leq j \leq n$, are noncommutative random variables in $(M, \tau)$, which do not satisfy any nontrivial algebraic relations, to simplify matters we can assume that $M$ is generated by $X_1, \ldots, X_n$ and identify $M$ with $\mathbb{C}\langle X_1, \ldots, X_n\rangle$. The trace state $\tau$ gives rise to a scalar product $\langle m_1, m_2\rangle = \tau(m_2^* m_1)$ on $M$. Let $L^2(M, \tau)$ denote the Hilbert space obtained from $M$. Then, skipping some technicalities, $\partial_k$ will give rise to a densely defined operator of $L^2(M, \tau)$ into $L^2(M, \tau) \otimes L^2(M, \tau)$. If $1 \otimes 1$ is in the domain of the adjoints $\partial_k^*$, the free Fisher information of the $n$-tuple $X_1, \ldots, X_n$ is defined to be

$$\Phi^*(X_1, \ldots, X_n) = \sum_{1 \leq k \leq n} \|\partial_k^*(1 \otimes 1)\|^2_{L^2(M, \tau)}$$

In case $1 \otimes 1$ is not in the domain of some $\partial_k^*$, the free Fisher information is given the value $\infty$.

The "microstates-free free entropy" $\chi^*$ is then defined by

$$\chi^*(X_1, \ldots, X_n) = \frac{n}{2}\log 2\pi e + \int_0^\infty \left(\frac{n}{1+t} - \Phi^* \times (X_1 + t^{1/2}S_1, \ldots, X_n + t^{1/2}S_n)\right)\mathrm{d}t$$

where $S_1, \ldots, S_n$ are $(0,1)$-semicircular and freely independent and also freely independent of $\{X_1, \ldots, X_n\}$.

For $n = 1$ it is known that $\chi^*(X) = \chi(X)$ and the free Fisher information is

$$\Phi^*(X) = \frac{2\pi^2}{3}\int p^3(t)\mathrm{d}t$$

if $p(t)$ is the density with respect to the Lebesgue measure of the distribution of $X$. The computation of $\partial^* 1 \otimes 1$ is possible in the one-variable case and up to a factor the result is $(Hp)(X)$, where $Hp$ is the Hilbert transform of $p$.

Several of the classical inequalities for the Fisher information have free probability analogs (Voiculescu 1998a) (Cramer–Rao inequality, Stam inequality, information-log-Sobolev inequality, and others).

For $n > 1$ only $\chi \leq \chi^*$, the easier of the inequalities among $\chi$ and $\chi^*$, has been established (Biane *et al.* 2003). This result was obtained based on an important connection of $\chi$ and $\chi^*$ to large deviations. The deviations studied are for the noncommutative distributions of $n$-tuples of matrices in the case of an $n$-tuple of Gaussian random matrices. In this context $\chi$ is related to the quantity to be estimated and $\chi^*$ is related to the rate function.

For more details on free entropy, the reader is referred to the survey articles by Voiculescu (1998c, 2002).

## Concluding Comments

For more details, additional results, and bibliography, we refer the reader to the expositions in Voiculescu (1998c), Voiculescu *et al.* (1992) and Speicher (1998). To get even more detail, the reader may consult, besides the original papers of the present author, those of P Biane, R Speicher, D Shlyakhtenko, K J Dykema, A Nica, U Haagerup, H Bercovici, L Ge, F Radulescu, A Guionnet, T Cabanal–Duvillard, M Anshelevich, to name a few of the main contributors.

Also, via random matrices, there are connections to physics models (especially large-$N$ 2D Yang–Mills QCD) in work of I M Singer, M Douglas, D Gross–R Gopakumar, P Zinn–Justin. In a loose sense, one may view the noncrossing partitions combinatorics as related to the work on planar diagrams and the large-$N$ limit of t'Hooft and Brezin–Itzykson–Parisi–Zuber in the 1970s.

# Functional Equations and Integrable Systems

**H W Braden**, University of Edinburgh, Edinburgh, UK

## Introduction

Functional equations have a long and interesting history in connection with mathematical physics and touch upon many branches of mathematics. They have arisen in the context of both classical and quantum completely integrable systems in several different ways and we shall survey some of these.

In the great majority of cases functional equations appear in the integrable system setting as the result of an ansatz: a particular form of a solution is either guessed or postulated, the consistency of which yields a functional equation. What the ansatz is for can vary significantly. As outlined below, amongst others, one may postulate algebraic structures in the form of the existence of a Lax pair or of conserved quantities; in the quantum setting, one may postulate properties of a ground-state wave function or the ring of commuting differential operators. Appearing in this way, functional equations are really just another of the (significant) tools-of-the-trade for constructing and discovering new integrable systems. However, as one surveys both the functional equations and the functions they describe one sees certain common features. The functions are most frequently associated with an elliptic curve, a genus-1 abelian variety. One can seek to associate these to another fundamental ingredient of modern integrable systems, the Baker–Akhiezer function. Indeed, very few of the ansätze made directly suggest that the systems being constructed will be completely integrable. This very desirable property usually is a bonus of the construction and hints of more fundamental connections. Another fundamental connection we shall mention is that with topology. The phase space of a completely integrable system is rather special, admitting (generically) a foliation by tori. The functional equations we encounter often also characterize the Hirzebruch genera associated with the index theorems of known elliptic operators. These are typically evaluated by Atiyah–Bott fixed-point theorems for circle actions on the manifold. A general understanding of the various interconnections has yet to be achieved.

To bring to focus our discussion we shall concentrate on functional equations arising from studying systems with an arbitrary number of particles ($n$ below). In principle, there could be many different interactions between the particles and symmetry will be used to limit these. The use of symmetry is a key ingredient, often implicit, in the various ansätze we shall describe. For simplicity, we shall most often focus on the situation where the particles are identical. In algebraic terms, we focus on the symmetric group $S_n$ and root systems of type $a_n$; generalizations frequently exist for other root systems and Weyl groups and we shall simply note this at the outset.

## Lax Pairs

The modern approach to integrable systems is to utilize a Lax pair, that is, a pair of matrices $L, M$ such that the zero curvature condition $\dot{L} = [L, M]$ is equivalent to the equations of motion. By construction, Lax pairs produce the conserved quantities tr $L^k$. To establish integrability, one must further show both that there are enough functionally independent conserved quantities and that these are in involution. ($R$-matrices are the additional ingredient of the modern approach to establishing involutivity.) Lax pairs can fail on both counts, and so the construction of a Lax pair is but the first step in establishing a system to be completely integrable. The great merit of the modern approach is that it provides a unified framework for treating the many disparate completely integrable systems known. Unfortunately the construction of a Lax pair is often far from straightforward and typically hides the "clever tricks" frequently employed in establishing integrability. In the present context, we shall outline how functional equations have been used to construct Lax pairs. The paradigm for this approach is the Calogero–Moser system.

Beginning with the ansatz (for $n \times n$ matrices)

$$L_{jk} = p_j \delta_{jk} + g(1 - \delta_{jk}) A(q_j - q_k)$$

$$M_{jk} = g \left[ \delta_{jk} \sum_{l \neq j} B(q_j - q_l) - (1 - \delta_{jk}) C(q_j - q_k) \right]$$

one finds $\dot{L} = [L, M]$ yields the equations of motion for the Hamiltonian system ($n \geq 3$)

$$H = \frac{1}{2} \sum_j p_j^2 + g^2 \sum_{j<k} U(q_j - q_k) \qquad [1]$$

$$U(x) = A(x)A(-x) + \text{const.}$$

provided $C(x) = -A'(x)$, and that $A(x)$ and $B(x)$ satisfy the functional equation

$$A(x+y)[B(x) - B(y)] = A(x)A'(y) - A(y)A'(x) \qquad [2]$$

This is a particular example of a more general functional equation whose solution will be described

below. For the present, we simply note that for this system the corresponding potential is the Weierstrass $\wp$-function, $A(x)A(-x) = \wp(\nu) - \wp(x)$, and the resulting Hamiltonian system [1] is known as the Calogero–Moser system. It is completely integrable though, as already remarked, the ansatz did not necessitate this. The Lax pair presented here and the reduction of its consistency to a functional equation and algebraic constraints follows Calogero (1976) in which he discovered the elliptic generalization of the model he had introduced in 1975.

A different ansatz for a Lax pair is

$$L_{jk} = \dot{q}_j \delta_{jk} + (1 - \delta_{jk})\sqrt{\dot{q}_j \dot{q}_k} A(q_j - q_k)$$

$$M_{jk} = \delta_{jk} \sum_{l \neq j} \dot{q}_l B(q_j - q_l) + (1 - \delta_{jk})\sqrt{\dot{q}_j \dot{q}_k} C(q_j - q_k)$$

Now the consistency of the Lax pair yields equations of motion of the form

$$\ddot{q}_j = \sum_{k \neq j} \dot{q}_j \dot{q}_k V(q_j - q_k)$$

$$V(x) = \begin{vmatrix} A(x) & A(-x) \\ C(x) & C(-x) \end{vmatrix} = -V(-x)$$

provided $B(x) = B(-x)$, $C(x) = A'(x) - A(x)G(x)$, where we have defined $G(x) = B(x) + (1/2)V(x)$, and the functions satisfy the functional equation

$$A(x+y) = A(x)A(y) + \frac{\begin{vmatrix} A(x) & A(y) \\ A'(x) & A'(y) \end{vmatrix}}{G(x) - G(y)} = \frac{\begin{vmatrix} A(x) & A(y) \\ C(x) & C(y) \end{vmatrix}}{G(x) - G(y)} \qquad [3]$$

Again we shall briefly defer describing the solution of this equation and simply note that the general solution for $V(x)$ is again given in terms of the Weierstrass $\wp$-function $V(x) = \wp'(x)/(\wp(\nu) - \wp(x))$ and that the equations of motion follow from the Hamiltonian

$$H = \sum_j e^{p_j} \prod_{k \neq j} \sqrt{\wp(\nu) - \wp(q_j - q_k)}$$

This is known as the Ruijsenaars–Schneider model and it too is completely integrable. The Lax pair here was constructed by Bruschi and Calogero.

In the two examples of Lax pairs just presented, each particle interacts with every other pairwise. By modifying the ansatz, it is possible to construct models that interact with just their nearest neighbors (which include the Toda systems). More generally, an ansatz exists for a Lax pair associated with equations of motion of the form

$$\ddot{q}_j = \sum_{k \neq j} (a + b\dot{q}_j)(a + b\dot{q}_k) V_{jk}(q_j - q_k) \qquad [4]$$

which unifies, for example, the Calogero–Moser, Ruijsenaars–Schneider, and Toda systems. The functional equations now encountered are typically (and whenever $b \neq 0$) of the form

$$\phi_1(x+y) = \frac{\begin{vmatrix} \phi_2(x) & \phi_2(y) \\ \phi_3(x) & \phi_3(y) \end{vmatrix}}{\begin{vmatrix} \phi_4(x) & \phi_4(y) \\ \phi_5(x) & \phi_5(y) \end{vmatrix}} \qquad [5]$$

This functional equation, for five *a priori* unknown functions, includes [2] and [3] as special cases.

The general analytic solution of [5] is, up to symmetries, given by

$$\phi_1(x) = \frac{\Phi(x;\nu_1)}{\Phi(x;\nu_2)}, \qquad \begin{pmatrix} \phi_2(x) \\ \phi_3(x) \end{pmatrix} = \begin{pmatrix} \Phi(x;\nu_1) \\ \Phi'(x;\nu_1) \end{pmatrix}$$

$$\begin{pmatrix} \phi_4(x) \\ \phi_5(x) \end{pmatrix} = \begin{pmatrix} \Phi(x;\nu_2) \\ \Phi'(x;\nu_2) \end{pmatrix}$$

where

$$\Phi(x;\nu) \equiv \frac{\sigma(\nu - x)}{\sigma(\nu)\sigma(x)} e^{\zeta(\nu)x} \qquad [6]$$

Here, $\zeta(x) = \sigma(x)'/\sigma(x)$ is the Weierstrass $\zeta$-function. The solution of [2] arises as the $\nu_2 \to 0$ limit of [5].

The proof of the general solution just stated is in fact constructive (Braden and Buchstaber 1997). The parameters appearing in the solution are determined as follows. Suppose $x_0$ is a generic point for [5]. Then (for $k = 1, 2$), we have that

$$\partial_y \ln \left| \begin{vmatrix} \phi_{2k}(x+x_0) & \phi_{2k}(y+x_0) \\ \phi_{2k+1}(x+x_0) & \phi_{2k+1}(y+x_0) \end{vmatrix} \right|_{y=0} = \zeta(\nu_k) - \zeta(x) - \zeta(\nu_k - x) - \lambda_k = -\frac{1}{x} - \lambda_k + \sum_{l=0} F_l \frac{x^{l+1}}{(l+1)!} \qquad [7]$$

The Laurent expansion determines the parameters $g_1, g_2$ (which are the same for both $k = 1, 2$) characterizing the elliptic functions of [6] by

$$g_2 = \tfrac{5}{3}(F_2 + 6F_0^2), \qquad g_3 = 6F_0^3 - F_1^2 + \tfrac{5}{3}F_0 F_2$$

and the parameters $\nu_k$ via $F_0 = -\wp(\nu_k)$. Here, $\wp(x) = -\zeta'(x)$ is the Weierstrass elliptic $\wp$-function

with periods $2\omega, 2\omega'$ that satisfies the differential equation

$$\wp'(x)^2 = 4\wp(x)^3 - g_2\wp(x) - g_3$$

The constructive nature of the solutions of [5] means that it is straightforward to construct solutions to various specializations of the equation such as

$$\phi_1(x+y) = \phi_4(x)\phi_5(y) + \phi_4(y)\phi_5(x)$$

(obtained by requiring $\phi_2(x) = \phi_4^2(x)$ and $\phi_3(x) = \phi_5^2(x)$). More complicated functional equations such as

$$\begin{aligned}\Psi_1(x+y) = &\Psi_2(x+y)\phi_2(x)\phi_3(y)\\ &+ \Psi_3(x+y)\phi_4(x)\phi_5(y)\end{aligned} \qquad [8]$$

may be solved using the solutions of [5].

Finally, let us note that the general system [4] may lead to functional equations not just of the form [5], for example,

$$\begin{aligned}\phi_6(x+y) = &\phi_1(x+y)(\phi_4(x) - \phi_5(y))\\ &+ \begin{vmatrix}\phi_2(x) & \phi_3(y)\\ \phi_2'(x) & \phi_3'(y)\end{vmatrix}\end{aligned} \qquad [9]$$

The general analytic solution to [9] has yet to be determined although particular solutions are known.

As a final example of a functional equation coming from an ansatz for a Lax pair, consider

$$L_{jk} = \sqrt{p_j p_k}A(q_j - q_k), \qquad M_{jk} = \sqrt{p_j p_k}C(q_j - q_k)$$

where we now assume $A(0)$ and $C(0)$ regular. Then the consistency of this Lax pair corresponds to the equations of motion for the Hamiltonian

$$H = \sum_{j,k}^{n} p_j p_k f(q_j - q_k) \qquad [10]$$

provided $f$ is even and the functional equation

$$\begin{aligned}&2A'(x+y)[f(x) - f(y)]\\ &\quad - A(x+y)[f'(x) - f'(y)] = \begin{vmatrix}A(x) & A(y)\\ C(x) & C(y)\end{vmatrix}\end{aligned} \qquad [11]$$

is satisfied. The Hamiltonian system [10] corresponds to geodesic motion. Nonanalytic solutions are known to the functional equation [11].

## An Algebraic Ansatz: Conserved Quantities

Another way in which functional equations may appear is by making an ansatz for an additional conserved quantity beyond the Hamiltonian. For two and three particles on the line, Hietarinta derived functional equations by seeking a second quartic or cubic integral (respectively). Here, a key ingredient is the assumption of a further invariant polynomial in the momenta. Polynomial invariance, together with symmetry, is quite constraining. Consider

**Theorem 1** *Let $H$ and $P$ be the (natural) Hamiltonian and center of mass momentum*

$$H = \frac{1}{2}\sum_{i=1}^{n} p_i^2 + V, \qquad P = \sum_{i=1}^{n} p_i$$

*Denote by $Q$ an independent third-order quantity*

$$Q = \sum_{i=1}^{n} p_i^3 + \frac{1}{6}\sum_{i\neq j\neq k} d_{ijk}p_i p_j p_k + \sum_{i\neq j} d_{ij}p_i^2 p_j + \frac{1}{2}\sum_{ij} a_{ij}p_i p_j + \sum_i b_i p_i + c$$

*If these are $S_n$-invariant and Poisson-commute,*

$$\{P, H\} = \{P, Q\} = \{Q, H\} = 0$$

*then*

$$V = \frac{1}{6}\sum_{i\neq j}\wp(q_i - q_j) + \text{const.}$$

*and we have the Calogero–Moser system.*

Here, the symmetric group invariance means that for any coefficient $\alpha_{ij}(q_1, q_2, \ldots, q_n)$ in the expansions above, we have $\alpha_{\sigma(i)\sigma(j)}(q_{\sigma(1)}, q_{\sigma(2)}, \ldots, q_{\sigma(n)})$ for all $\sigma \in S_n$. In particular, $V(q_1, q_2, \ldots, q_n) = V(q_{\sigma(1)}, q_{\sigma(2)}, \ldots, q_{\sigma(n)})$ for all $\sigma \in S_n$. We remark that had we begun with particles of possibly different particle masses, $H = (1/2)\ \sum_{i=1}^{n} m_i p_i^2 + V$; the effect of $S_n$-invariance is such as to require these masses to be the same. Thus, we are assuming the $S_n$-invariant Hamiltonian of the theorem. Finally, by "an independent third-order quantity" $Q$, we mean one functionally independent of $H$ and $P$ and for which one cannot obtain an invariant of lower degree by subtracting multiples of $P^3$ and $PH$. We are not dealing with quadratic conserved quantities here.

The assumed polynomial behavior of the conserved quantities means that when calculating Poisson brackets, the coefficients of independent monomials must vanish. This, together with symmetry, leads to the functional equation

$$\begin{vmatrix}1 & 1 & 1\\ F(x) & F(y) & F(z)\\ F'(x) & F'(y) & F'(z)\end{vmatrix} = 0, \quad x+y+z=0 \qquad [12]$$

The result follows in light of

**Theorem 2** *Let f be a three-times differentiable function satisfying the functional equation [12]. Up to the manifest invariance*

$$F(x) \to \alpha F(\delta x) + \beta$$

*the solutions of [12] are one of* $F(x) = \wp(x + d)$, $F(x) = e^x$ *or* $F(x) = x$. *Here,* $\wp$ *is the Weierstrass* $\wp$*-function and 3d is a lattice point of the* $\wp$*-function.*

Again we note that the ansatz *per se* has not established complete integrability: the ansatz leads us to the Calogero–Moser model whose complete integrability must be established by other means. This result may be interpreted as a rigidity theorem for the $a_n$ Calogero–Moser system and in part explains this models' ubiquity: demanding a cubic invariant together with $S_n$-invariance necessitates the model. A natural generalization is to replace the $S_n$-invariance with the invariance of a general Weyl group $W$ and make connection with the Calogero–Moser models associated to other root systems (Perelomov 1990).

We shall encounter the functional equation [12] again in this survey and now note that this may be generalized to

$$\begin{vmatrix} 1 & 1 & 1 \\ F(x) & G(y) & H(z) \\ F'(x) & G'(y) & H'(z) \end{vmatrix} = 0, \quad x + y + z = 0 \quad [13]$$

If $F, G$, and $H$ are three-times differentiable functions satisfying the functional equation [13], then, up to the manifest invariance,

$$F(x) \to \alpha F(\delta x + \gamma_1) + \beta$$

$$G(x) \to \alpha G(\delta x + \gamma_2) + \beta$$

$$H(x) \to \alpha H(\delta x + \gamma_3) + \beta$$

where $\gamma_1 + \gamma_2 + \gamma_3 = 0$, the nonconstant solutions of [13] are given by $F(x) = G(x) = H(x) = e^x$, $x$, or $\wp(x)$. If (say) $H(z)$ is a constant then either

1. one of the functions $F(x)$ or $G(y)$ is the same constant as $H(z)$, in which case the remaining function is arbitrary, or
2. $F(x) = G(x) = e^x$.

We remark that in fact the exponential and linear function solutions satisfy [12] and [13] without the constraint $x + y + z = 0$. Further, the theorems immediately give the general analytic solutions to the same functional equations viewed as functions of a complex variable, showing that the solutions are in fact meromorphic. These theorems were established in Braden and Byatt-Smith (1999) where earlier results are described.

## Quantum Calogero–Moser Systems

Quite a bit is known about the quantum generalizations of the Calogero–Moser system. The polynomial and Weyl group $W$-invariance of the classical conserved quantities is replaced by a commutative ring $\mathcal{R}$ of $W$-invariant, holomorphic, differential operators, whose highest-order terms generate $W$-invariant differential operators with constant coefficients. The Poisson bracket is then replaced by a commutator of operators. When this is done functional equations again ensue and one finds that the potential term for the Laplacian $\mathcal{H}$ (the quantum Hamiltonian) has Calogero–Moser potential appropriate to $W$ (Oshima and Sekiguchi 1995). In this setting, it is known that the commutativity of just a few low-order elements of $\mathcal{R}$ dictate the form of the potential and the commuting algebra (at least for the classical root systems). In particular, Theorem 1 above is the classical analog for the $a_n$ root system of a quantum result where a functional equation equivalent to [12] was obtained by requiring the commutativity of certain linear, quadratic, and cubic holomorphic differential operators. Taniguchi's results (Taniguchi 1997) are also indicative of the rigidity of these quantum models: if $\mathcal{H}$ is the quantum Hamiltonian just discussed, and $\mathcal{Q}_{1,2}$ are holomorphic (but not *a priori* $W$-invariant), differential operators of appropriate degrees for which $[\mathcal{Q}_{1,2}, \mathcal{H}] = 0$, then $\mathcal{Q}_{1,2} \in \mathcal{R}$ and consequently $[\mathcal{Q}_1, \mathcal{Q}_2] = 0$.

## An Algebraic Ansatz: The Poincaré Algebra

We have earlier encountered the Ruijssenaars–Schneider models when considering functional equations ensuing from ansatz for Lax pairs. These models were however discovered by another route (Ruijsenaars and Schneider 1986) in the course of investigating mechanical models obeying the Poincaré algebra

$$\{H, B\} = P, \qquad \{P, B\} = H, \qquad \{H, P\} = 0 \quad [14]$$

Here, $H$ will be the Hamiltonian of the system generating time translations, $P$ is a space-translation

generator, and $B$ the generator of boosts. Ruijsenaars and Schneider began with the ansatz

$$H = \sum_{j=1}^{n} \cosh p_j \prod_{k \neq j} f(x_j - x_k)$$

$$P = \sum_{j=1}^{n} \sinh p_j \prod_{k \neq j} f(x_j - x_k)$$

$$B = \sum_{j=1}^{n} x_j$$

With this ansatz and the canonical Poisson bracket $\{p_i, x_j\} = \delta_{ij}$, the first two Poisson brackets of [14] involving the boost operator $B$ are automatically satisfied. The remaining Poisson bracket is then

$$\begin{aligned}\{H, P\} = &-\sum_{j=1}^{n} \partial_j \prod_{k \neq j} f^2(x_j - x_k) \\ &-\frac{1}{2}\sum_{j \neq k} \cosh(p_j - p_k) \prod_{l \neq j} f(x_j - x_l) \\ &\times \prod_{m \neq k} f(x_k - x_m)\big(\partial_j \ln f(x_k - x_j) \\ &+ \partial_k \ln f(x_j - x_k)\big)\end{aligned}$$

and for the independent terms proportional to $\cosh(p_j - p_k)$ to vanish we require that $f'(x)/f(x)$ be odd. This entails that $f(x)$ is either even or odd (Ruijsenaars and Schneider assumed the function even) and in either case $F(x) = f^2(x)$ is even. Supposing that $f(x)$ is so constrained, then the final Poisson bracket is equivalent to the functional equation

$$\{H, P\} = 0 \Longleftrightarrow \sum_{j=1}^{n} \partial_j \prod_{k \neq j} f^2(x_j - x_k) = 0 \qquad [15]$$

For $n = 3$, eqn [15] takes precisely the form [12] with $F(x) = f^2(x)$. From Theorem 2, the even solutions to this have the form $F(x) = \wp(x) + c$. This was found by Ruijsenaars and Schneider who further showed this function satisfies [15] for all $n$. The general solution to [15] has recently been established.

**Theorem 3** (Byatt-Smith and Braden 2003). *The general even solution of [15] amongst the class of meromorphic functions whose only singularities on the real axis are either a double pole at the origin, or double poles at $np$ ($p$ real, $n \in \mathbb{Z}$) is:*

(i) *for all odd $n$ given by the solution of Ruijsenaars and Schneider while*

(ii) *for even $n \geq 4$, there are in addition to the Ruijsenaars–Schneider solutions the following:*

$$F_i(z) = \sqrt{(\wp(z) - e_j)(\wp(z) - e_k)} \qquad [16]$$

*where $i, j, k$ are a cyclic permutation of 1, 2, 3.*

These functions have simple expressions in terms of Weierstrass elliptic functions, theta functions, and the Jacobi elliptic functions (Whittaker and Watson 1927). For example,

$$\begin{aligned}F_1(z) &= \sqrt{(\wp(z) - e_2)(\wp(z) - e_3)} = \frac{\sigma_2(z)\sigma_3(z)}{\sigma^2(z)} \\ &= \frac{\theta_3(v)\theta_4(v)}{\theta_1^2(v)} \frac{\theta_1'^2(0)}{4\omega^2\theta_3(0)\theta_4(0)} = b\frac{\mathrm{dn}(u)}{\mathrm{sn}^2(u)}\end{aligned}$$

where

$$\sigma_\alpha(z) = \frac{\sigma(z + \omega_\alpha)}{\sigma(\omega_\alpha)} \mathrm{e}^{-z\zeta(\omega_\alpha)}$$

$$u = \sqrt{e_1 - e_3}z$$

$v = z/2\omega, b = e_1 - e_3$ with $\omega_1 = \omega$, $\omega_2 = -\omega - \omega'$, and $\omega_3 = \omega'$. For appropriate ranges of $z$ the solutions are real. Their degenerations yield all the even solutions with only a double pole at $x = 0$ on the real axis. These degenerations may in fact coincide with the degenerations of the Ruijsenaars–Schneider solution.

Thus far, complete integrability has not been mentioned. The models discovered by Ruijsenaars and Schneider not only exhibited an action of the Poincaré algebra but were completely integrable as well. In particular, Ruijsenaars and Schneider demonstrated the Poisson commutativity for their solutions of the light-cone quantities

$$S_{\pm k} = \sum_{\substack{I \subseteq \{1,2,\ldots,n\} \\ |I| = k}} \exp\left(\pm \sum_{i \in I} p_i\right) \prod_{\substack{i \in I \\ j \notin I}} f(x_i - x_j) \qquad [17]$$

Then, $H = (S_1 + S_{-1})/2$ and $P = (S_1 - S_{-1})/2$. (Note the even/oddness of the functions $f(x)$ means that there really are only $n$ functionally independent quantities.) It is an open problem whether the new solutions [16] of Theorem 3 yield integrable systems. We know that these new solutions do not always yield Poisson commuting quantities using the ansatz of Ruijsenaars and Schneider, but as yet one cannot rule out other Poisson commuting conserved quantities.

## Quantum Ruijsenaars–Schneider Models

Ruijsenaars later investigated the quantum version of the classical models he and Schneider introduced.

From the outset, he sought operator analogs of the light-cone quantities [17]. He showed that (for $k = 1, \ldots, n$)

$$\hat{S}_k = \sum_{\substack{I \subseteq \{1,2,\ldots,n\} \\ |I|=k}} \prod_{\substack{i \in I \\ j \notin I}} h(x_j - x_i)^{1/2} \times \exp\left(-\sqrt{-1}\beta \sum_{i \in I} \partial_i\right) \prod_{\substack{i \in I \\ j \notin I}} h(x_i - x_j)^{1/2}$$

pairwise commute if and only if

$$\sum_{\substack{I \subseteq \{1,2,\ldots,n\} \\ |I|=k}} \left( \prod_{\substack{i \in I \\ j \notin I}} h(x_j - x_i) h(x_i - x_j - i\beta) - \prod_{\substack{i \in I \\ j \notin I}} h(x_i - x_j) h(x_j - x_i - i\beta) \right) = 0 \qquad [18]$$

held for all $k$ and $n \geq 1$. Here, $\beta$ is an arbitrary positive number and the sum is over all subsets with $k$ elements. Observe that upon dividing [18] by $\beta$ and letting $\beta \to 0$ this yields [15] with $F(x) = h(x)h(-x)$ when $k = 1$.

Ruijsenaars found a solution to [18] which has subsequently been shown to be unique. The general solution of the functional equation [18] analytic in a neighborhood of the real axis with either a simple pole at the origin or an array of such poles at $np$ on the real axis ($n \in \mathbb{Z}$) is given by

$$h(x) = b \frac{\sigma(x + \nu)}{\sigma(x)\,\sigma(\nu)} \, e^{\alpha x} \qquad [19]$$

This solution is related to the earlier Ruijsenaars–Schneider solution via

$$\frac{\sigma(x + \nu)\sigma(x - \nu)}{\sigma^2(x)\sigma^2(\nu)} = \wp(\nu) - \wp(x)$$

## Geometric Ansatz

We have already encountered the Hamiltonian system [10] corresponding to geodesic motion while discussing Lax pairs. We shall now consider various ansätze with a geometric flavor and their attendant functional equations.

It is known that the Ruijsenaars–Schneider model has the Calogero–Moser system as a scaling limit. Other scaling limits also exist for the Ruijsenaars–Schneider model. In particular, we may consider one in which the Poincaré algebra scales to either the Galilean algebra or a central extension of the Galilean algebra.

Similar to our analysis of the Poincaré algebra, we find that the functions

$$H = \frac{1}{2} \sum_{j=1}^{n} p_j^2 \prod_{k \neq j} f(x_j - x_k),$$

$$P = \sum_{j=1}^{n} p_j \prod_{k \neq j} f(x_j - x_k), \qquad B = \sum_{j=1}^{n} x_j$$

obey the algebra

$$\{H, B\} = P, \qquad \{P, B\} = \lambda, \qquad \{H, P\} = 0 \qquad [20]$$

if and only if $f(x)$ is either an even or odd function satisfying

$$\sum_{j=1}^{n} \prod_{k \neq j} f(x_j - x_k) = \lambda \qquad [21]$$

where $\lambda$ is a constant. When $\lambda = 0$ this is the Galilean algebra, while $\lambda \neq 0$ is a central extension of the Galilean algebra. Again we are encountering models of the form $H = (1/2)\sum_{j=1}^{n} g^{jj} p_j^2$ and so dealing with diagonal metrics. We note that if [21] holds for $n = 3$ then it holds for all $n$; and if it holds for $n = 4$ then it holds for all "even" $n$. This type of behavior was already encountered in Theorem 3.

Some particular solutions of [21] are known although the general solution is not known as yet. The odd functions $f(x) = 1/x$ ($\lambda = 0$), $\coth(x)$ ($\lambda = 1$ for $n$ odd and $\lambda = 0$ for $n$ even), $\sqrt{\wp(x) - e_\alpha}$ ($\lambda = 0$) yield solutions for example. Interestingly, in the case of an even number of particles, particular cases of the elliptic Ruijsenaars–Schneider model are in this list.

Diagonal metrics arise in many settings in integrable systems. By taking the ansatz

$$ds^2 = \sum_{i=1}^{n} \left( \prod_{j \neq i} \Psi(x^i - x^j) \right) (dx^i)^2$$

we may construct and solve a functional equation to show that the potentially nonvanishing curvature components $R^i_{jik}, R^i_{jjk} (k \neq i, j)$, and $R^i_{jij}$ have

1. $R^i_{jik} = R^i_{jjk} = 0$ $(k \neq i, j)$ if and only if $\Psi(x) = \alpha(e^{2bx} - 1)^a$ or $\alpha x^a$. We may set $\alpha = 1$ by rescaling $x$.
2. $R^i_{jij} = (-1)^n b^2$ when $\Psi(x) = (e^{2bx} - 1)$.
3. $R^i_{jij} = 0$ when $\Psi(x) = x$.

Thus, $\Psi(x) = x$ yields a solution of the Lamé equations. These metrics are of Stäckel form. The rational degenerations of the Galilean models above are given by this theorem. They may be understood as a parabolic limit of Jacobi elliptic coordinates.

Similar techniques may be applied to the more general metric

$$\mathrm{d}s^2 = \sum_{i=1}^{n}\left(\chi_i(x^i)\prod_{j\neq i}\Psi(x^i - x^j)\right)(\mathrm{d}x^i)^2$$

to show that $R^i_{jik} = R^i_{jjk} = 0 (k \neq i, j)$ if and only if $\Psi(x) = \alpha(\mathrm{e}^{2bx} - 1)^a$ or $\alpha x^a$.

## Ground-State Factorization

Some years ago, Sutherland and Calogero considered the problem as to when the ground-state wave function of a one-dimensional $n$-body Schrödinger equation with pairwise interactions would factorize. Thus, the problem is to determine those potentials $v(x)$ for which

$$\left\{-\frac{\hbar^2}{2}\sum_{i=1}^{n}\partial_i^2 + \frac{1}{2}\sum_{i\neq j}v(x_i - x_j) - E\right\} \times \bar{\Psi}(x_1, x_2 \ldots x_n) = 0 \qquad [22]$$

and where

$$\bar{\Psi}(x_1, x_2 \ldots x_n) = \prod_{i<j}\psi(x_i - x_j)$$

It is convenient to set

$$\psi(x_i - x_j) = \exp\left(\frac{1}{\hbar}\int^{x_i - x_j} f(x)\,\mathrm{d}x\right)$$

Substitution now shows

$$\frac{\hbar^2}{2}\sum_{i=1}^{n}\partial_i^2\bar{\Psi} = \left\{\hbar\sum_{i<j}f'(x_i - x_j) + \sum_{i<j}f(x_i - x_j)^2 + \sum_{i<j<k}\left[f(x_i - x_j)f(x_i - x_k) - f(x_i - x_j)f(x_j - x_k) + f(x_j - x_k)f(x_i - x_k)\right]\right\}\bar{\Psi}$$

Comparison with [22] shows that this may be expressed in terms of two-body potentials if and only if we have the functional equation

$$f(a)f(-b) - f(a)f(c) + f(c)f(-b) = G_1(a) + G_1(c) + G_2(-b), \quad a + b + c = 0 \qquad [23]$$

Now [23] is not quite the functional equation studied by Sutherland and Calogero. On physical grounds, Sutherland implicitly, and Calogero explicitly, made the "assumption" that $f$ is an odd function. This ensured that the potential was even and so bounded from below; equally it may be imposed so that $\psi(x_i - x_j) = \psi(x_j - x_i)$ and the ground state describes bosons. With this assumption, one arrives at the functional equation of Sutherland:

$$f(a)f(b) + f(b)f(c) + f(c)f(a) = G(a) + G(b) + G(c) \qquad [24]$$

Actually the assumption of $f$ being odd is unnecessary. One can show that there is a bijection between analytic solutions of [23] and analytic solutions of [24] for which $f'(x)$ is even. Upon requiring a potential of the stated form then necessitates $f$ being odd. Whatever, we arrive at the functional equation [24]. This is connected with [12] by

**Lemma 4** *If $a + b + c = 0$, then*

$$\begin{vmatrix} f''(a) & f''(b) & f''(c) \\ f'(a) & f'(b) & f'(c) \\ 1 & 1 & 1 \end{vmatrix} = 0 \qquad [25]$$

$$\Longleftrightarrow (f(a) + f(b) + f(c))^2 = F(a) + F(b) + F(c) \quad [26]$$

$$\Longleftrightarrow f(a)f(b) + f(b)f(c) + f(c)f(a) = G(a) + G(b) + G(c) \qquad [27]$$

Now, we may use Theorem 2 to determine those potentials with factorizable ground-state wave functions. We remark that the $\delta$-function potential $a\delta(x)$ of many-body quantum mechanics on the line, which also has a factorizable ground-state wave function, can be viewed as the $\alpha \to 0$ limit of $-b/\alpha\sinh^2(-x/\alpha + \pi\mathrm{i}/3)$ with $\pi a\alpha = 6b$. Thus, all of the known quantum mechanical problems with factorizable ground-state wave function are included in [12].

## Baker–Akiezer Functions

Baker–Akiezer functions are one of the foundations of the algebro-geometric or finite-gap integration of integrable systems. These functions may be viewed as an extension of the exponential function to curves of arbitrary genus $g$. They have essential singularities at various points on the curve and a prescribed asymptotic expansion at these points. The functions may be described in terms of theta functions on the Jacobian of the curve, and suitable meromorphic differentials on the curve. The functions [6] and [19] may be viewed as the Baker–Akhiezer function for a genus-1 curve. Now, just as the exponential function satisfies Cauchy's functional equation one may ask what functional equations (if any) characterize the

Baker–Akiezer function. This is an area of research still ongoing. Theta functions of a general abelian variety are known to satisfy addition formulas with $N=2^g$ terms. It appears Baker–Akiezer functions satisfy a similar functional equation with far fewer terms. Such a characterization of Baker–Akiezer functions, if found, will provide an analogous answer to that of the Riemann–Schottky problem which seeks to describe the Jacobians of curves amongst general abelian varieties.

The functional equations [5], and after suitably symmetrizing [9], are particular cases of the functional equation

$$\sum_{i=0}^{N} \phi_{3i}(x+y)\begin{vmatrix} \phi_{3i+1}(x) & \phi_{3i+1}(y) \\ \phi_{3i+2}(x) & \phi_{3i+2}(y) \end{vmatrix} = 0 \qquad [28]$$

with $N=1$ in the former case and $N=2$ in the latter. In the case $\phi_{3i+2}=\phi'_{3i+1}$, these may be viewed as differentiated forms of

$$\sum_{i=0}^{N} \phi_{3i}(x+y)\phi_{3i+1}(x)\phi_{3i+1}(y) = 1 \qquad [29]$$

For $N=0$, this is Cauchy's equation characterizing the exponential function and for $N=2$ it is equivalent to [8]. For $N=1$ and $N=2$, Buchstaber and Krichever have shown that "all" the solutions to this equation are the Baker–Akhiezer functions corresponding to algebraic curves of genus 1 and 2, respectively. In general, the Baker–Akhiezer functions for a genus-$g$ curve are known to satisfy [29] for $N=g$. Thus, many of the equations we have encountered are related to Baker–Akhiezer functions. Dubrovin, Fokas, and Santini have shown that Baker–Akhiezer functions for a genus-$g$ curve are related to the functional equation

$$\frac{q(x,y)q(y,z)}{q(x,z)} = r(x,y) - r(z,y) + \sum_{k=1}^{g} s_k(y)p_k(x,z)$$

Multivariable generalizations of [29] have been sought as a means of characterizing Baker–Akhiezer functions but such a characterization remains unproved as yet.

## Topology

Several of the functional equations we have encountered also arise in topology, where the German and Russian schools have powerfully applied functional equations to formal group laws and genera. It is still unclear whether these common threads form part of a greater fabric. A genus is a ring homomorphism

$$\varphi : \Omega \otimes \mathbb{Q} \to R, \quad \varphi(1) = 1$$

where $\Omega$ is the cobordism ring and $R$ an integral domain over $\mathbb{Q}$. To each even power series $Q(x)$ with $Q(0)=1$, one can associate a genus $\varphi_Q$ and vice versa (Hirzebruch *et al.* 1992). Defining the odd power series $f(x)=x/Q(x)$ with first term 1 and coefficients in $R$, the inverse function $g=f^{-1}$ is such that

$$g'(y) = \sum_{n=0}^{\infty} \varphi_Q(\mathbb{CP}^n)y^n$$

The genus corresponding to $Q(x)=x/\tanh(x)$ is known as the $L$-genus; it takes the value 1 on every even complex projective space. The genus corresponding to $Q(x)=(x/2)/\sinh(x/2)$ is known as the $\hat{A}$-genus. The so-called (string-inspired) Witten or elliptic genus corresponds to $Q(x)=x/\sigma(x)$. Certain genera may be associated with the index of natural differential operators on the manifold. Thus, the signature of $M$, sign($M$), is given in terms of the de Rham differential $d$ and its adjoint $d^*$,

$$\mathrm{ind}(d+d^*) = \mathrm{sign}(M) = \left(\prod_{j=0}^{2n} \frac{x_j}{\tanh(x_j)}\right)[M]$$

with variants for the $\hat{A}$-genus and elliptic genus. Further, when a compact topological group acts on the manifold, Atiyah and Bott showed how these indices may be determined from the fixed point sets of the action.

Now, functional equations arise naturally in this context when seeking genera with special properties. Novikov's school has shown, for example, that the genera associated with the index theorems of known elliptic operators arise as solutions of functional equations which are particular examples of [5]. Similarly, one may seek the following property of a genus $\varphi$: for the fiber bundle $p: E \xrightarrow{F} B$ with smooth fiber and base, one has that

$$\varphi(E) = \varphi(F)\cdot\varphi(B)$$

Such a genus is said to be strictly multiplicative. It may be shown that a genus is strictly multiplicative in bundles with fiber $\mathbb{CP}^{n-1}$ if and only if

$$\sum_{j=1}^{n}\prod_{k\neq j}\frac{1}{f(x_j-x_k)} = \lambda \qquad [30]$$

which is essentially [21]. Following the remarks of that equation, a genus $\varphi$ is strictly multiplicative for all fiber bundles with fibers $\mathbb{CP}^{n-1}$ if and only if it is strictly multiplicative for all fiber bundles with fiber $\mathbb{CP}^2$, in which case the genus is the $L$-genus. If, on the other hand, we only demand strict multiplicativity for all fiber bundles with fibers $\mathbb{CP}^{2k-1}$, then this is equivalent to requiring it to hold for all fiber bundles with fiber $\mathbb{CP}^3$, in which case the genus is an elliptic

genus. That the same functional equations arise in both the integrable systems and topological settings may reflect something deeper. String theory physics, for example, allows some topology changes such as flops, and physical quantities such as the partition function should reflect this invariance; invariance under classical flops characterizes the elliptic genus. In addition, connections have been made between the complex cobordism ring and conformal field theory.

## Other Areas

The constraints placed on this review have meant that several further applications of functional equations and integrable systems can only be noted. Using an ansatz together with functional equations, Wojciechowski gives an analog of the Bäcklund transformation for integrable many-body systems. Similarly, Inozemtsev constructs generalizations of the Calogero–Moser models, while this route was used to construct new solutions to the Witten–Dijkgraaf–Verlinde–Verlinde (WDVV) equations by Braden, Marshakov, Mironov, and Morozov. In the quantum regime, Gutkin derived and solved several functional relations by requiring a nondiffractive potential, while functional equations have been used to construct $R$-operators, solutions of the quantum Yang–Baxter equation on a function space.

# Functional Integration in Quantum Physics

**C DeWitt-Morette**, The University of Texas at Austin, Austin, TX, USA

## The Domain of Integration

Functional integration is integration over function spaces, that is, the variable of integration is a function $f$ with values in a $D$-dimensional manifold:

$$f : U \longrightarrow \mathbb{M}^D \tag{1}$$

Generically a space of functions is an infinite-dimensional space. Our understanding of infinite-dimensional spaces has progressed significantly during the twentieth century, and we can formulate functional integration in its proper setting.

Let $\mathcal{F}$ be the domain of integration, and $f \in \mathcal{F}$ the variable of integration. If the domain of $f$ is a subset $U$ of $\mathbb{R}$, the functional integral is called a path integral; if $U$ is of dimension higher than 1 (e.g., spacetime), $\mathcal{F}$ is often called a space of histories.

The information necessary for defining a domain of integration includes

- the domain and the range of the variable of integration $f$,
- the analytical properties of $f$, and
- possibly additional information, such as requirements on the values of $f$ on its boundary.

### Examples of variables of integration *f* in [1]

The domain $U$ of $f$ may be a time interval, a scale range, or any parameter. The range $\mathbb{M}^D$ of $f$ may be a group manifold, a Riemannian manifold, a symplectic manifold, a multiply-connected space, etc., or simply $\mathbb{R}^D$. The domain of integration $\mathcal{F}$ may be a space of pointed paths, for example,

$$x := \boldsymbol{T} \rightarrow \mathbb{M}^D, \quad \boldsymbol{T} = [t_a, t_b] \tag{2}$$

$$x(t_b) = x_b \in \mathbb{M}^D \quad \text{for all } x \in \mathcal{F}$$

The paths $x$ may be continuous (e.g., Brownian paths), or may have square integrable derivatives; $\mathcal{F}$ is then an $L^{2,1}$ space (e.g., quantum physics).

$$\int_T \mathrm{d}t\, |\dot{x}(t)|^2 < \infty, \qquad x \in \mathcal{F} \tag{3}$$

Given a domain of integration $\mathcal{F}$, one needs to select a volume element appropriate to $\mathcal{F}$. This is a challenge which has been met in a number of cases (Cartier and DeWitt-Morette 2006). Examples are given below. Given a volume element, one can then characterize the functionals $F$ on $\mathcal{F}$ integrable with respect to the chosen volume element.

## Two Basic Techniques

The two most useful techniques for computing integrals are change of variable of integration and integration by parts. They follow from fundamental properties that apply to functional integrals as well as to ordinary integrals. Let us recall them in the context of ordinary integrals.

Let $f$ and $g$ be functions on $\mathbb{R}$ of compact support. Let $I$ stand for integration

$$I(f) = \int_{\mathbb{R}} \mathrm{d}x\, f(x), \quad x \in \mathbb{R}$$

and $D$ for derivation of $f$ with respect to $x$,

$$(Df)(x) = \frac{\mathrm{d}}{\mathrm{d}x} f(x)$$

The fundamental rule

$$DI = 0 \Longrightarrow 0 = \frac{\mathrm{d}}{\mathrm{d}x} \int_{\mathbb{R}} \mathrm{d}x\, f(x) \tag{4}$$

The functional $I(f)$ is invariant under a change of variable of integration.

Another fundamental rule is $ID = 0$:

$$\begin{aligned} ID = 0 \Longrightarrow 0 &= \int \mathrm{d}(f(x)g(x)) \\ &= \int \mathrm{d}f(x) \cdot g(x) + \int \mathrm{d}g(x) \cdot f(x) \end{aligned} \tag{5}$$

The fundamental rules [4] and [5] apply to functional integration. The derivation $D$ can be either a functional derivative or a Lie derivative defined as follows. Let $\mathbb{K}$ be the reals $\mathbb{R}$ or the complex $\mathbb{C}$, let $f$ be a differentiable functional on a Banach space $\mathbb{X}$

$$f : U \subset \mathbb{X} \longrightarrow \mathbb{K} \tag{6}$$

The functional derivative $Df|_{x_0}$ of $f$ at $x_0$ is defined by the equation

$$f(x_0 + h) - f(x_0) = Df|_{x_0} h + R(h) \tag{7}$$

with the norm $\|R(h)\|$ of order less than the norm $\|h\|$.

The Lie derivative $\mathcal{L}_V$ along the vector field $V$ is conceptually intuitive and of practical interest: an infinite-dimensional space $\mathbb{X}$ of paths $x$ is not an intuitive concept, but a one-parameter family of

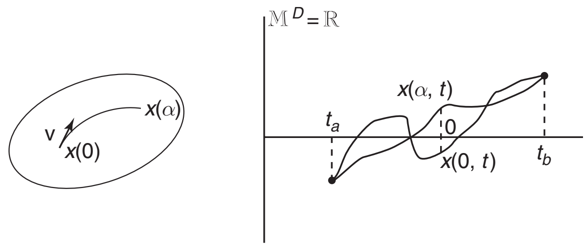

**Figure 1** A one-parameter family of paths with fixed endpoints.

paths $\{x(\alpha)\} \in \mathbb{X}$, with $\alpha \in [0,1]$, is a convenient tool for dealing with $\mathbb{X}$:

$$\begin{aligned} x(\alpha) &: T \to \mathbb{M}^D \\ x(\alpha, t) &:= (x(\alpha))(t) \in \mathbb{M}^D \end{aligned} \qquad [8]$$

Set $x(0) = x_0$. A differentiable family $\{x(\alpha)\}$ defines a vector field $V(x_0)$ along the path $x_0$ (see Figure 1):

$$\begin{aligned} V(x_0) &:= \frac{\mathrm{d}}{\mathrm{d}\alpha} x(\alpha)\Big|_{\alpha=0} \\ V(x_0(t)) &= \frac{\partial}{\partial \alpha} x(\alpha, t)\Big|_{\alpha=0} \end{aligned} \qquad [9]$$

The functional vector field $V$ on the tangent bundle of $\mathbb{X}$ defines a group of transformations on $\mathbb{X}$, and a Lie derivative $\mathcal{L}_V$ of tensor fields on $\mathbb{X}$.

The Lie derivative $\mathcal{L}_V$ obeys the Cartan (Elie and Henri) equation

$$\mathcal{L}_V = d\imath_V + \imath_V d \qquad [10]$$

where $d$ is the exterior differential and $\imath_V$ is the interior product, defined as usual on Banach spaces.

**Remark** (Berezin integrals). To show the power of the rules [4] and [5], we can mention that they provide Berezin rules of integration over Grassmann variables (Cartier and DeWitt-Morette 2006).

## Path Integrals and Quantum Dynamics

The history of path integrals in quantum physics did not begin with the definitions of domain of integration, volume elements, etc. It began with the Ph.D. thesis of R P Feynman in 1942. Feynman expressed the time evolution of a system as the limit $N = \infty$ of the following $N$-tuple integral:

$$\begin{aligned} (x_t|x_a) = \lim_{N=\infty} \int\!\!\int \cdots \int (x_t|x_N)\mathrm{d}x_N(x_N|x_{N-1}) \\ \times \mathrm{d}x_{N-1} \cdots (x_2|x_1)\,\mathrm{d}x_1\,(x_1|x_0) \end{aligned} \qquad [11]$$

where the time interval $T = [t, 0]$ has been replaced by $N$ of its points $\{t_i\}, 1 \le i \le N$:

$$t_0 < t_1 < \cdots < t_N < t \qquad [12]$$

and the path $x : T \to \mathbb{R}^D$ is replaced by $N$ of its values

$$x_i := x(t_i) \qquad [13]$$

Dirac (1933) had shown that $(x_t|x_0)$ defines the exponential of a quantum function $\mathcal{S}_Q$, by

$$\exp\big(\mathrm{i}\mathcal{S}_Q(x_t, x_0, t)/\hbar\big) := (x_t|x_0) \qquad [14]$$

such that the real part of $\mathcal{S}_Q$ is the classical action function (a.k.a. Hamilton's principal function; further studies have shown that the correct statement is: the real part is the classical action, up to order $\hbar$), and the imaginary part of $\mathcal{S}_Q$ is of order $\hbar$, the normalized Planck constant

$$\hbar = h/2\pi \qquad [15]$$

Feynman remarked that for a system with Lagrangian $L$ the short-time probability amplitude $(x_{t+\delta t}|x_t)$ is "often equal to

$$A^{-1} \exp\Big(\mathrm{i}\,\delta t\, L\Big(\frac{x_{t+\delta t} - x_t}{\delta t}, x_{t+\delta t}\Big)\Big/\hbar\Big) \qquad [16]$$

within a normalizing constant A as the limit $\delta t$ approaches zero." The absolute value of $A$ can be obtained from a unitary requirement (Morette 1951).

Feynman expressed the finite probability amplitude as a path integral, limit of the discretized expression [11]

$$(x_t|x_0) = \int \mathcal{D}x \exp(\mathrm{i}\mathcal{S}(x)/\hbar) \qquad [17]$$

where $S(x)$ is the action functional

$$\mathcal{S}(x) = \int_{t_0}^{t} \mathrm{d}sL(\dot{x}(s), x(s)) \qquad [18]$$

The undefined symbol $\mathcal{D}x$ is a "volume element" on the space of paths, corresponding to the infinite product of the normalization constant $A^{-1}$.

The issues raised by the path integral [17] are

- the definition of the volume element $\mathcal{D}x$; and
- a method for computing [17] for a given action functional $\mathcal{S}$.

The explicit calculation of the limit [11] of an $N$-tuple integral when $N = \infty$ is a Herculean task of very limited use. But two other methods of wide applications, leaving the volume element $\mathcal{D}x$ as a heuristic symbol, have vindicated the power of functional integration: the diagram technique and the semiclassical expansions.

Feynman devised practical rules for computing asymptotic expansions of path integrals, order by order in perturbation theory. The rules are depicted by graphs, known as the Feynman diagrams ('t Hooft and Veltmann 1973). Feynman's first explicit nontrivial calculation was the Lamb shift. It earned him the Nobel prize in 1965 (Feynman 1966). The diagram technique is widely used in quantum mechanics and quantum field theory. The time ordering provided by the time parameter in quantum mechanics becomes, in quantum field theory, a chronological ordering dictated by light cones.

Another explicit calculation of a path integral [17] uses the Taylor expansion of the action functional $\mathcal{S}(x)$ around one of its values. It is known as the background method (DeWitt 2004). It is called a semiclassical WKB approximation when one expands around an extremum $\mathcal{S}(x_{\rm cl})$ where $x_{\rm cl}$ is a solution of the Euler–Lagrange equation $\mathcal{S}'(x_{\rm cl})=0$ (Wenzel 1926, Kramers 1927, Brillouin 1926).

Introduced in 1951 (Morette (1951)) semiclassical approximations are now the subject of a rich literature reviewed briefly below.

## Gaussian Volume Elements

A lesson from Gaussians on $\mathbb{R}^D$ suggests a definition of volume elements on infinite-dimensional Banach spaces $\mathbb{X}$. Let

$$I_D(a) := \int_{\mathbb{R}^D} dx \exp\left(-\frac{\pi}{a}|x|^2\right) \quad \text{for } a>0 \qquad [19]$$

$$dx = dx^1 \cdots dx^D \text{ and } |x|^2 = \sum_{j=1}^{D} (x^j)^2 = \delta_{ij}x^i x^j$$

An elementary calculation gives $I_D(a)=a^{D/2}$. Therefore, when $D=\infty$,

$$I_\infty(a) = \begin{cases} 0 & \text{if } 0<a<1 \\ 1 & \text{if } a=1 \\ \infty & \text{if } 1<a \end{cases} \qquad [20]$$

This is clearly an unsatisfactory situation, but it can be corrected by introducing a dimensionless volume element:

$$\mathcal{D}_a x := \frac{1}{a^{D/2}} dx^1 \cdots dx^D \qquad [21]$$

The volume element $\mathcal{D}_a x$ can be defined by the integral

$$\int_{\mathbb{R}^D} \mathcal{D}_a x \exp\left(-\frac{\pi}{a}|x|^2 - 2\pi i\langle x', x\rangle\right) := \exp\left(-a\pi|x'|^2\right) \qquad [22]$$

where $x'$ is in the dual $\mathbb{R}_D$ of $\mathbb{R}^D$. Equation [22] suggests the following generalization of Gaussians on $\mathbb{R}^D$ to Gaussians on a Banach space $\mathbb{X}$:

$$\int_X \mathcal{D}_{s,Q}x \exp\left(-\frac{\pi}{s}Q(x)\right)\exp(-2\pi i\langle x',x\rangle) := \exp(-s\pi W(x')) \qquad [23]$$

where $s\in\{1,i\}$, $Q(x)$ is a quadratic form on $\mathbb{X}$ (see condition on $Q$ below). $W(x')$ is a quadratic form on the dual $\mathbb{X}'$ of $\mathbb{X}$, inverse of $Q(x)$ in the following sense. Set

$$Q(x)=\langle Dx,x\rangle \text{ and } W(x')=\langle x',Gx'\rangle \qquad [24]$$

where $\langle\,,\rangle$ is a duality product, for example, the product of $x\in\mathbb{X}$ and $Dx\in\mathbb{X}'$; then

$$DG = 1_{X'}, \qquad GD = 1_{\mathbb{X}} \qquad [25]$$

Equation [23] defines a Gaussian volume element $d\Gamma$ by its Fourier transform

$$\mathcal{F}\Gamma_{s,Q}(x') := \int_X d\Gamma_{s,Q}(x)\exp(-2\pi i\langle x',x\rangle) := \exp(-s\pi W(x')) \qquad [26]$$

where the Gaussian volume element

$$d\Gamma_{s,Q}(x) \underset{=}{\int} \mathcal{D}_{s,Q}(x)\exp\left(-\frac{\pi}{s}Q(x)\right) \qquad [27]$$

This is a qualified equality valid upon integration.

The definition of the Gaussian volume element by its Fourier transform $\mathcal{F}\Gamma$ is valid for $s=1$ (Wiener integral) when $Q(x)>0$; it is valid for $s=i$ (Feynman integral) when $\mathrm{Re}\,Q(x)>0$.

**Remark** Volume elements were introduced with the notation such as $dx$; later they were identified with forms such as $\omega=dx$. In [26] we omit d on the left-hand side (LHS) for visual clarity.

**Example** (diagram expansion). The following integrals follow readily (Cartier and DeWitt-Morette 2006) from the definition [26]. Let $x'$ be in the dual $\mathbb{X}'$ of $\mathbb{X}$,

$$\int_X d\Gamma_{s,Q}(x)\langle x',x\rangle^{2n+1} = 0 \qquad [28]$$

$$\int_X d\Gamma_{s,Q}(x)\langle x',x\rangle^{2n} = \frac{2n!}{2^n n!}\left(\frac{s}{2\pi}\right)^n W(x')^n \qquad [29]$$

$$\int_X d\Gamma_{s,Q}(x)\langle x'_1,x\rangle\cdots\langle x'_{2n},x\rangle = \left(\frac{s}{2\pi}\right)^n \sum W(x'_{i_1},x'_{i_2})\cdots W(x'_{i_{2n-1}},x'_{i_{2n}}) \qquad [30]$$

where $\sum$ is a sum without repetitions of identical terms.

For instance when $n=1$, eqn [30] reads

$$\int_X d\Gamma_{s,Q}(x)\langle x'_1, x\rangle\langle x'_2, x\rangle = \frac{s}{2\pi} W(x'_1, x'_2) \qquad [31]$$

$W(x'_1, x'_2)$ is called the two-point function (a.k.a. the propagator). In a diagram it stands for a line from $x'_1$ to $x'_2$.

Feynman diagrams represent Gaussian integrals of polynomials.

For instance when $n=2$, the diagram representation of [30] is the sum of three terms,

$$W(x'_1, x'_2)W(x'_3, x'_4) + W(x'_1, x'_3)W(x'_2, x'_4) + W(x'_1, x'_4)W(x'_2, x'_3)$$

**Example** (Linear maps). Linear maps on $\mathbb{R}^D$ are limited to $L: x \to Ax$, where $A$ is a $D \times D$ constant matrix. Linear maps on a Banach space $\mathbb{X}$ offer many possibilities:

(i) Projections. For example, let $x: \boldsymbol{T} \to \mathbb{R}$ and

$$L : x \in \mathbb{X} \longrightarrow \{x(t_1), x(t_2), \ldots, x(t_n)\} \in \mathbb{R}^n) \qquad [32]$$

This projection is a discretization of the path, useful in particular in numerical calculations of path integrals. Equation [32] is unambiguous, whereas the limit of the discretized expression [11] is ill-defined.

(ii) Liouville decomposition. For example, let $D$ be a second-order differential operator on a space of paths $x: [t_a, t_b] \to \mathbb{M}^D$ vanishing on the boundary, $x(t_a)=0, x(t_b)=0$. Let $\{\varphi_k\}$ be a complete, orthogonal set of eigenfunctions of $D$, then the decomposition of $x$ into the basis $\{\varphi_k\}$,

$$x^\alpha(t) = \sum_{k=1}^{\infty} u^\alpha \psi_k^\alpha(t) \qquad [33]$$

is a linear map

$$L : x \in \mathbb{X} \longrightarrow \{u^1, \ldots, u^\infty\} \in \mathbb{R}^\infty$$

It is useful in particular for diagonalizing (see, e.g., [107]) the Green function $G$ of $D$ [25] (a.k.a. the covariance in a Gaussian integral [24], or the two-point function in [31]).

(iii) Volterra maps. For example, let $L: \mathbb{X} \to \mathbb{Y}$ by

$$y(t) = \int_T ds\, \theta(t-s)x(s)$$

$$\theta(t-s) = 1 \quad \text{for } s < t, 0 \text{ otherwise} \qquad [34]$$

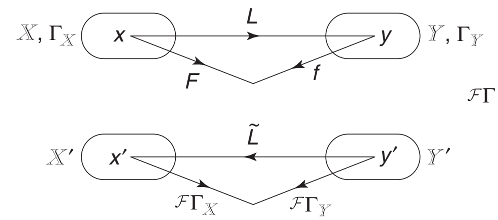

**Figure 2** Linear maps. (Published with permission by Elsevier, North Holland.)

Let $\mathbb{X}$ be the space of square-integrable functions on $T$ and $\mathbb{Y}$ be an $L^{2,1}$ space (square-integrable function for which the first derivative is also square integrable) then $L$ maps the canonical quadratic form on $\mathbb{X}$ into the canonical quadratic form on $\mathbb{Y}$, hence the canonical Gaussian on $\mathbb{X}$ into the canonical Gaussian on $\mathbb{Y}$. The identity mapping $i$ from $\mathbb{Y}$ into the space $\mathcal{C}$ of continuous functions maps the canonical Gaussian on $\mathbb{Y}$ into the Wiener Gaussian on $\mathcal{C}$ (DeWitt-Morette *et al.* 1979).

The linear maps [32]–[34] and their obvious generalizations have been used for computing explicitly many functional integrals (see **Figure 2**). The basic formula reads

$$\int_X d\Gamma_X(x)F(x) = \int_Y d\Gamma_Y(y)f(y), \quad F = f \circ L \qquad [35]$$

where the Fourier transform $\mathcal{F}\Gamma$ is given by

$$\mathcal{F}\Gamma_Y = \mathcal{F}\Gamma_X \circ \tilde{L} \qquad [36]$$

$\tilde{L}$ is the transpose of the linear map $L$ defined by

$$\langle \tilde{L}y', x\rangle = \langle y', Lx\rangle \qquad [37]$$

Computing $\mathcal{F}\Gamma_Y$ does not require any calculation. It can be read off eqn [36]. Computing $d\Gamma_Y$ is easy in a number of cases such as the following:

1. $\mathbb{Y}$ is finite-dimensional. In other words [35] is a cylindrical integral. Then

$$d\Gamma_Y(y) = dy^1 \cdots dy^D \left(\det Q_{ij}\right)^{1/2} \times \exp\left(-\frac{\pi}{s}Q(y)\right) \qquad [38]$$

where $Q(y)$ is an abbreviation of

$$Q_Y(y) = Q_{Yij}\, y^i y^j \qquad [39]$$

its inverse$W_{Y'}(y')$ in the sense of [24]–[25] is

$$W_{Y'}(y') = W^{ij}_{Y'} y'_i y'_j \qquad [40]$$

that is given by [36]:

$$W_{Y'}(y') = W_{X'} \circ \tilde{L} \qquad [41]$$

$W_{X'}$ is the quadratic form defining $\Gamma_X$ by [26]. When $D$ is small, say less than 4, and this is not an unusual situation, it is easy to compute [38].

**Example** (Wiener Gaussians and Brownian motion). The Wiener Gaussian on the space $\mathcal{P}_a\mathbb{R}$ of pointed paths $x: T \to \mathbb{R}$, $T = [t_a, t_b], x(t_a) = 0$ is defined by its variance [26]:

$$W(x') := \int_T \mathrm{d}x'(t') \int_T \mathrm{d}x'(s) \inf(t, s) \qquad [42]$$

Let $\mathbb{Y}$ be the Wiener differential space consisting of the differences of two consecutive values of $x$ on the $n$-discretized time interval. The space $\mathbb{Y}$ is finite dimensional,

$$L: \mathbb{X} \to \mathbb{Y}$$
$$\text{by} \quad y^j = x(t_{j+1}) - x(t_j) = \langle \delta_{t_{j+1}} - \delta_{t_j}, x \rangle$$

It follows from [37] that

$$\tilde{L}y' = \sum_j y'_j (\delta_{t_{j+1}} - \delta_{t_j})$$

and

$$\mathrm{d}\Gamma_Y(\Delta x) = \mathrm{d}y^1 \cdots \mathrm{d}y^n \frac{1}{\prod_{j=1}^n (s\Delta t_j)^{1/2}} \times \exp\left( -\frac{\pi}{s} \sum_j \frac{(\Delta x_j)^2}{\Delta t_j} \right) \qquad [43]$$

where $\Delta t_j := t_{j+1} - t_j$ and $\Delta x_j := x(t_{j+1}) - x(t_j)$.

When $s = 1$ the Gaussian $\Gamma_Y$ defines the distribution of a Brownian path. The Gaussian $\Gamma_X$ of covariance $\inf(t, s)$ is the Wiener measure. □

2. In semiclassical approximations, $Q_X$ is the Hessian (second variation) of an action functional $\mathcal{S}$:

$$Q_X(h) = \frac{\mathrm{d}^2}{\mathrm{d}\alpha^2} \mathcal{S}(x(\alpha)) \bigg|_{\alpha=0}$$
$$\text{with } h = \frac{\partial}{\partial \alpha} x(\alpha) \bigg|_{\alpha=0} \qquad [44]$$

where $\{x(\alpha)\}$ is a one-parameter family of paths [8]. The Jacobi field technology (the Jacobi operator is defined by [103]; a Jacobi field is a solution of [102]) yields the inverse of $W_{Y'}$ and its determinants (Cartier and DeWitt-Morette 2006); they have been worked out for a variety of boundary conditions on classical paths.

## Volume Elements Other than Gaussian

The definition [26]–[27] of Gaussian volume elements is a particular case of volume elements on a Banach space $\Phi$ defined by

$$\int_\Phi \mathcal{D}_{\Theta, Z}\varphi \cdot \Theta(\varphi, J) := Z(J) \qquad [45]$$

for $\varphi$ in $\Phi$, and $J$ in the dual $\Phi'$ of $\Phi$. The volume element $\mathcal{D}_{\Theta, Z}$ is defined by two continuous bounded functionals

$$\Theta: \Phi \times \Phi' \longrightarrow \mathbb{C} \quad \text{and} \quad Z: \Phi' \longrightarrow \mathbb{C} \qquad [46]$$

In quantum field theory, $\varphi$ is a field and $J$ is a source. The functional $Z(J)$ is then the Schwinger generating functional for the $n$-point functions. An axiomatic and applications of functional integrals on $\Phi$ with volume elements $\mathcal{D}_{\Theta, Z}$ can be found in (Cartier and DeWitt-Morette (1993)).

**Example** (Poisson volume elements) (Cartier and DeWitt-Morette (2006) and Collins (1997)). A Poisson random variable is a random variable $N$ taking values in the set $\mathbb{N}$ of non-negative integers such that the probability $p_n$ that $N = n$ is

$$p_n := \Pr(N = n) := \exp(-\lambda) \frac{\lambda^n}{n!}, \quad \lambda \geq 0 \qquad [47]$$

Thanks to the normalizing constant $\exp(-\lambda)$, $\sum_{n=0}^\infty p_n = 1$. The parameter $\lambda$ is the mean value of $N$:

$$\langle N \rangle = \lambda \qquad [48]$$

A record of fortuitous events occurring at random times $t_0 < T_1 < T_2 \cdots$ can consist either of the number $N(t)$ of events occurring at times less than or equal to $t$, or of the waiting times

$$W_k = T_k - T_{k-1} \qquad [49]$$

between two consecutive events.

When the waiting times are stochastically independent and when

$$\Pr(t < W_k < t + \mathrm{d}t) = p_a(t)\,\mathrm{d}t \qquad [50]$$

$$p_a(t) = a \exp(-at), \quad t > 0 \qquad [51]$$

the record is a Poisson random variable. It is related to the number of events $N(t)$ as follows.

Let $\boldsymbol{T}$ be a finite time interval $[t', t'']$, and

$$N_T = N(t'') - N(t') \qquad [52]$$

the number of events during $\boldsymbol{T}$. The random variable $N_T$ follows a Poisson law [47] with mean value

$$\lambda_a(\boldsymbol{T}) = a(t'' - t') \qquad [53]$$

For mutually disjoint time intervals $\boldsymbol{T}^{(1)}, \boldsymbol{T}^{(2)}, \ldots$ the random variables $N_{T^{(1)}}, N_{T^{(2)}}, \ldots$ are stochastically independent.

Whereas the parameter $\lambda$ must be real non-negative, the parameter $a$ can be pure imaginary; therefore, Poisson processes defined by waiting

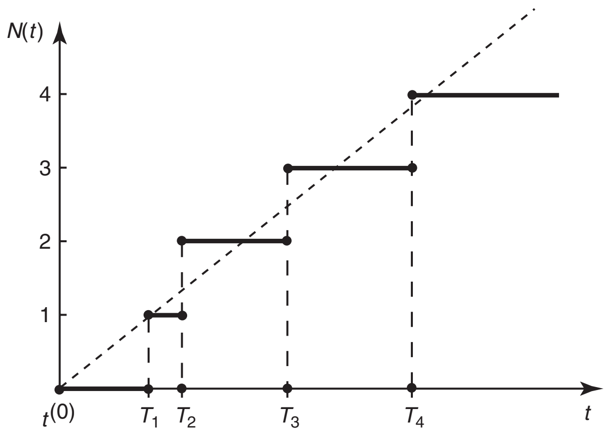

**Figure 3** A Poisson path in $\mathbb{X}_4$.

times can be used in quantum physics as well as in probability. When $a$ is real, it is called the decay constant because its physical dimension is $[\text{time}]^{-1}$.

A Poisson path $x \in \mathbb{X}_n$ is characterized by $n$ jumps and the jump times during a given time interval $T = [t_a, t_b]$ (**Figure 3** illustrates a Poisson path in $\mathbb{X}_4$). The space $\mathbb{X}$ of Poisson paths is the union of all $\mathbb{X}_n$:

$$\mathbb{X} = \cup \mathbb{X}_n \qquad [54]$$

One can define a volume element $\mathcal{D}_{a,T}$ on $\mathbb{X}$ by its Fourier transform:

$$\int_X \mathcal{D}_{a,T} x \cdot \exp(\mathrm{i}\langle x, f\rangle) := \exp\left(\int_T \mathrm{d}t\, a\, \mathrm{e}^{\mathrm{i}f(t)}\right) \qquad [55]$$

Here a path $x \in \mathbb{X}_n$, characterized by $n$ jump times $T_1, \ldots, T_n$, is represented by the sum

$$\delta_{T_1} + \cdots + \delta_{T_n}$$

Hence

$$\langle x, f\rangle = f(T_1) + \cdots + f(T_n) \qquad [56]$$

The dimensionless volume element on $\boldsymbol{T}$ is

$$\mathrm{d}v(t) = a\ \mathrm{d}t$$

Therefore,

$$\mathrm{vol}(T) = aT, \quad T = t_b - T_a$$

$$\mathrm{vol}(\mathbb{X}_n) = a^n T^n / n! \qquad [57]$$

$$\mathrm{vol}(\mathbb{X}) = \exp(\mathrm{vol}(\boldsymbol{T})) \qquad [58]$$

and it makes sense to write formally

$$\mathbb{X} = \exp \boldsymbol{T}$$

It can be proved that the volume element $\mathcal{D}_{a,T}x$ is a measure, in the technical sense of the word (Cartier and DeWitt-Morette 2006).

Functional integration on spaces of Poisson paths have been used extensively in solutions of Klein–Gordon equations, the telegrapher equation and the Dirac equation (Cartier and DeWitt-Morette 2006).

Other volume elements of interest in quantum physics include (LaChapelle 2004):

- gamma volume elements, which are to gamma probability distributions what Gaussian volume elements are to Gaussian probability distributions; and
- Hermite volume elements convenient for integrating Wick-ordered polynomials.

A Dirac "$\delta$-function" is formally the limit of a Gaussian integral. Formally, one can introduce a Dirac functional volume element as the limit of a Gaussian volume element.

## The Koszul Formula

There are several roadblocks on the road from finite to infinite-dimensional spaces. For instance, a volume in a $D$-dimensional space is a top-differential form, that is, a $D$-form. There is no top-form in an infinite-dimensional space – neither on Grassmann manifolds since Grassmann forms are totally symmetric tensors. A $D$-form in $\mathbb{R}^D$ has only one strict component and is equivalent to a scalar density of weight 1, but scalar densities of weight 1 do not form an algebra.

For these reasons, volume elements have so far been defined by integrals [26], [27], [43], and [55]. Short of giving an explicit expression for their differential forms, one can require them to satisfy the Koszul formula

$$\mathcal{L}_X \omega = \mathrm{Div}(X)\omega \qquad [59]$$

where $\omega$ is a volume element on a Banach space $\mathbb{X}$, $X$ a vector field generating a group of transformations on $\mathbb{X}$, $\mathcal{L}_X$ the Lie derivative defined by $X$, and $\mathrm{Div}(X)$ the standard generalization of div(ergence) on finite-dimensional spaces (see, e.g., Cartier and DeWitt-Morette (2006) for the explicit expression of divergences on Riemannian, symplectic, Grassmann manifolds). The Koszul formula dictates how a volume element changes under a group of transformations.

It often happens that an object cannot be defined *per se*, but that it is sufficient to define its variation. For example, one does not define potentials, but potential differences; the ratio of infinite-dimensional determinants can be defined without defining each determinant; the work of Wiener on "differential-spaces," which is a landmark in functional integration, is based

on differences between two consecutive values of a function, etc. Similarly, the Koszul formula does not define $\omega$ but gives its variation $\mathcal{L}_X\omega$.

## The Operator Formalism of Quantum Physics

Functional integrals can be used to represent operator matrix elements, and solutions of the Schrödinger equation.

1. Matrix elements of operators on Hilbert spaces. Symbolically,

$$\langle\beta|\exp(-\mathrm{i}Ht/\hbar)|\alpha\rangle = \int_{\mathbb{X}_{\alpha\beta}} \mathcal{D}x\exp(\mathrm{i}\mathcal{S}(x)/\hbar) \qquad [60]$$

   The domain of integration $\mathbb{X}_{\alpha\beta}$ is a space of paths $x$ on $[t, 0]$ satisfying initial conditions that characterize the quantum state $\alpha$, and final conditions that characterize the quantum state $\beta$. The action functional $\mathcal{S}$ yields the Hamiltonian $H$.

   A key property of path integrals is their representations of matrix elements of time-ordered operators. The path parameter (time, scale, or any other parameter) provides the operator ordering [11]. A simple example is the two-point function of the Wiener measure [42]:

$$\int_{\mathbb{X}} \mathrm{d}\Gamma(x)\, x(t)x(s) = \inf(t, s) \qquad [61]$$

   The function integral orders the time, that is, the argument of the variable of integration. In quantum field theory, time ordering becomes a chronological ordering dictated by light cones.
2. Schrödinger equation and other parabolic equations (Cartier and DeWitt-Morette 2006).

The following theorem provides the mathematical underpinning for a great variety of functional integrals. It also provides a construction of functional integrals, which begins with the symmetries of a given physical system rather than its action functional. The theorem consists of two parts: the definition of a functional integral, and the partial differential equation satisfied by the value of the functional integral, as a function of a set of parameters.

Given a manifold $\mathbb{M}$, consider the contractible space $\mathcal{P}_0\mathbb{M}$ of pointed $L^{2,1}$ paths over $\boldsymbol{T}=[t_a, t_b]$:

$$x : T \to \mathbb{M}, \quad \text{e.g., } x(t_b) = x_b, \quad \text{i.e., } x \in \mathcal{P}_0\mathbb{M} \qquad [62]$$

Given $D+1$ vector field $Y$, $\{X_{(\alpha)}\}$, generators of group of transformations on $\mathbb{M}$, define a map

$$P : \mathcal{P}_0\mathbb{R}^D \to \mathcal{P}_b\mathbb{M} \quad \text{by } z \to x \qquad [63]$$

explicitly

$$\mathrm{d}x(t, z) = X_{(\alpha)}(x(t, z))\mathrm{d}z^\alpha + Y(x(t, z))\mathrm{d}t \qquad [64]$$

$$x(t_b, z) = x_b, \qquad z(t_b) = 0 \qquad [65]$$

In general, the vector fields do not commute and the solution of [64]–[65] is of the form

$$x(t, z) = x_b \cdot \sum(t, z) \qquad [66]$$

where $\Sigma(t, z)$ is an element of a group of right actions on $\mathbb{M}$, defined by the $D+1$ generators $Y$, $\{X_{(\alpha)}\}$:

$$x_b \cdot \sum(t + t', z \times z') = x_b \cdot \sum(t, z) \cdot \sum(t', z')$$

The path $z$ defined on $[t_a, t]$ is followed by the path $z'$ on $[t, t']$.

Consider the following functional integral over $\mathcal{P}_0\mathbb{R}^D$ of a functional of paths on $\mathcal{P}_b\mathbb{M}$:

$$(U_T\phi)(x_b) := \int_{\mathcal{P}_0\mathbb{R}^D} \mathcal{D}_{s,Q}z \exp\Big(-\frac{\pi}{s}Q(z)\Big) \times \phi\Big(x_b \cdot \sum(t, z)\Big) \qquad [67]$$

where

$$Q(z) = \int_T \mathrm{d}t\; h_{\alpha\beta}\dot{z}^\alpha(t)\dot{z}^\beta(t) \qquad [68]$$

The functional $(U_T\phi)$ at $x_b$ is a function $\Psi(T, x_b)$. It is a solution of the generalized Schrödinger equation,

$$\frac{\partial\Psi}{\partial T} = \frac{s}{\pi}h^{\alpha\beta}\mathcal{L}_{X_{(\alpha)}}\mathcal{L}_{X_{(\beta)}}\Psi + \mathcal{L}_Y\Psi \qquad [69]$$

This equation is valid on manifolds $\mathbb{M}$ (e.g., frame bundles, U($N$) bundles, multiply connected spaces, symplectic manifold phase space) in arbitrary systems of coordinates.

**Example** (Polar coordinates on $\mathbb{R}^D$). Let us abbreviate $z^\alpha(t)$ to $z^\alpha, x^1(t)$ to $r$, and $x^2(t)$ to $\theta$. It follows from

$$z^1 = r\cos\theta, \qquad z^2 = r\sin\theta \qquad [70]$$

that

$$\begin{cases} \mathrm{d}r = \cos\theta\cdot\mathrm{d}z^1 + \sin\theta\cdot\mathrm{d}z^2 \\ \quad =: X^1_{(1)}\mathrm{d}z^1 + X^1_{(2)}\mathrm{d}z^2 \\ \mathrm{d}\theta = -\dfrac{\sin\theta}{r}\mathrm{d}z^1 + \dfrac{\cos\theta}{r}\mathrm{d}z^2 \\ \quad =: X^2_{(1)}\mathrm{d}z^1 + X^2_{(2)}\mathrm{d}z^2 \end{cases} \qquad [71]$$

The dynamical vector fields are, therefore,

$$X_{(1)} = \cos\theta \frac{\partial}{\partial r} - \frac{\sin\theta}{r}\frac{\partial}{\partial\theta} \qquad [72]$$

$$X_{(2)} = \sin\theta \frac{\partial}{\partial r} + \frac{\cos\theta}{r}\frac{\partial}{\partial\theta} \qquad [73]$$

Here $h^{\alpha\beta} = \delta^{\alpha\beta}$ and eqn [69] reads

$$\frac{\partial\Psi}{\partial t} = \frac{s}{4\pi}\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2}{\partial\theta^2} + \frac{1}{r}\frac{\partial}{\partial r}\right)\Psi \qquad [74]$$

This example is trivial because $x(t,z)$ is not a functional of $z$ but a function of $z(t)$ given by [70]. In the following example, $x(t,z)$ is a functional of $z$.

**Example** (Paths with values on a Riemannian manifold $(\mathbb{M}^D, g)$). Consider the frame bundle over $\mathbb{M}^D$ and a connection $\sigma$ defining the horizontal lift $\dot\rho(t)$ of a vector $\dot x(t)$,

$$\dot\rho(t) = \sigma(\rho(t)) \cdot \dot x(t) \qquad [75]$$

In order to bring eqn [75] in the form [64], we think of a frame $u(t)$ as a linear map from $\mathbb{R}^D$ into the tangent space $T_{x(t)}\mathbb{M}^D$:

$$u(t) : \mathbb{R}^D \to T_{x(t)}\mathbb{M}^D \qquad [76]$$

Let

$$\dot z(t) := u(t)^{-1}\dot x(t) \qquad [77]$$

Choose a basis $\{e_{(A)}\}$ in $\mathbb{R}^D$ and $\{e_{(\alpha)}\}$ in $T_{x(t)}\mathbb{M}^D$ such that

$$\dot z(t) = \dot z^A(t) e_{(A)} = u(t)^{-1}(\dot x^\alpha(t) e_{(\alpha)}) \qquad [78]$$

Insert $u(t) \circ u(t)^{-1}$ into [75], then

$$\dot\rho(t) = X_{(A)}(\rho(t))\, \dot z^A(t) \qquad [79]$$

where the dynamical vector fields are

$$X_{(A)}(\rho(t)) = (\sigma(\rho(t)) \circ u(t)) \cdot e_{(A)} \qquad [80]$$

The construction [64]–[69] gives a parabolic equation on the bundle. If the connection $\sigma$ is the metric connection, then the parabolic equation on the bundle gives, by projection on the base space, the parabolic equation with the Laplace–Beltrami operator. Explicitly, the projection on the base space of [67] is

$$\psi(t_b, x_b) := \int_{\mathcal{P}_b\mathbb{R}^D} \mathcal{D}_{s,Q}(z) \exp\left(-\frac{\pi}{s}Q(z)\right) \times \phi((\mathrm{Dev}\, z)(t_a)) \qquad [81]$$

where Dev is the Cartan development map, namely the bijection, defined by [82], from the space of pointed paths $z$ on $T_b\mathbb{M}^D$ (identified to $\mathbb{R}^D$ via the frame $u_B$) into the space of pointed paths $x$ on $\mathbb{M}^D$ (paths such that $x(t_b) = x_b$):

$$(\Pi \circ \rho)(t) =: (\mathrm{Dev}\, z)(t) \qquad [82]$$

$\Pi$ is the projection on the base space. The path integral [81] is the solution of the equations

$$\frac{\partial}{\partial t_b}\psi(t_b, x_b) = \frac{s}{4\pi}\Delta\psi(t_b, x_b) \qquad [83]$$

$$\psi(t_a, x) = \phi(x) \qquad [84]$$

where $\Delta$ is the Laplace–Beltrami operator on $(\mathbb{M}^D, g)$,

$$\Delta = g^{ij} D_i D_j \qquad [85]$$

and $D_i$ is the covariant derivative defined by the Riemann connection $\sigma$.

## Semiclassical Expansions

Classical mechanics is a limit of quantum mechanics; therefore, it is natural to expand the action functional $S$ of a given system around, or near, its classical value – namely its minimum $\mathcal{S}(q)$, where $q$ is a solution of the Euler–Lagrange equation,

$$\mathcal{S}'(q) = 0 \qquad [86]$$

Set

$$\mathcal{S}(x) = \mathcal{S}(q) + \mathcal{S}'(q)\cdot\xi + \frac{1}{2!}\mathcal{S}''(q)\cdot\xi\xi + \frac{1}{3!}\mathcal{S}'''(q)\cdot\xi\xi\xi + \cdots \qquad [87]$$

where $x \in \mathbb{X}$ is a path

$$x : \boldsymbol{T} \to \mathbb{M}^D$$

and $\xi, \eta \in T_q\mathbb{X}$ is a vector field at $q \in \mathbb{X}$. The second variation of $\mathcal{S}$ is called its Hessian

$$\mathcal{S}''(q)\xi\eta =: \mathrm{Hess}(q; \xi, \eta) \qquad [88]$$

The arena of semiclassical expansions of a functional integral schematically written as

$$I = \int_{X_{a,b}} \mathcal{D}x \exp(\mathrm{i}\mathcal{S}(x)/\hbar)\cdot\phi((x(t_a))) \qquad [89]$$

consists of the intersection $U_{a,b}$ of two spaces $\mathbb{X}_{a,b} \subset \mathbb{X}$ the space of paths satisfying $D$ initial conditions $(a)$ and $D$ final conditions $(b)$, and $U^{2D}(\mathcal{S})$ the space of critical points of $\mathcal{S}$

$$q \in U^{2D}(\mathcal{S}), \quad \mathcal{S}'(q) = 0 \qquad [90]$$

$$U_{a,b} := \mathbb{X}_{a,b} \cap U^{2D}(\mathcal{S}) \qquad [91]$$

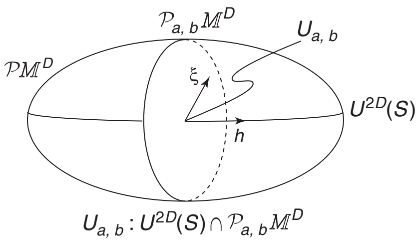

**Figure 4** Intersection of the space $\mathcal{P}_{a,b}\mathbb{M}^D$ (abbreviated to $\mathbb{X}_{a,b}$) of paths on $\mathbb{M}^D$ with fixed points, and the 2$D$-dimensional space $U^{2D}(\mathcal{S})$ of critical points of the system $\mathcal{S}$. (Adapted from a Plenum Press publication with permission by Springer-Verlag.)

The nature of the intersection $U_{a,b}$ determines the behavior of the system $\mathcal{S}$. Figure 4 shows the intersection of the space $\mathbb{X}_{a,b}$ of paths on $\mathbb{M}^D$ with fixed points. It also shows the space $U^{2D}(\mathcal{S})$ of critical points of $\mathcal{S}$.

We consider first the case in which $U_{a,b}$ consists of a single point $q$, or several isolated points $q_{(i)}$. The semiclassical expansion consists in dropping the terms beyond the Hessian:

$$I_{\text{WKB}} := \int_{\mathbb{X}_b} \mathcal{D}\xi \exp\left(\frac{2\pi i}{h}\left(\mathcal{S}(q) + \frac{1}{2}\mathcal{S}''(q)\cdot\xi\xi\right)\right) \times \phi(x(t_a)) \qquad [92]$$

where the initial wave function $\phi$ accounts for the $D$ initial conditions of the system, and $\mathbb{X}_b$ is the space of pointed paths

$$x(t_b) = x_b, \text{ and } \xi(t_b) = 0 \quad \text{for every } x \in \mathbb{X}_b \qquad [93]$$

### WKB Approximations

The integral $I_{\text{WKB}}$ is the Gaussian defined by the Hessian. Explicit calculations of $I_{\text{WKB}}$ exploit the power of Jacobi fields of $\mathcal{S}$ at $q$.

**Example** (Momentum-to-position transitions) (e.g., Cartier and DeWitt-Morette 2006). We have

$$I_{\text{WKB}}(x_b, t_b; p_a, t_a) = \exp\frac{2\pi i}{h} S(q(t_b), p(t_a)) \times \left(\det\frac{\partial^2 S}{\partial q^i(t_b)\partial p_j(t_a)}\right)^{1/2} \qquad [94]$$

where $S$ is the action function (a.k.a. Hamilton's principal function)

$$S(q(t_b), p(t_a)) = \mathcal{S}(q) + \langle p_a, x(t_a)\rangle \qquad [95]$$

where the classical path $q$ is characterized by its initial momentum $p_a$ and its final position $x_b$. The proof of [94] rests on the following property of quadratic forms $Q$. Let $L : \mathbb{X} \to \mathbb{Y}$ linearly and

$$Q_X = Q_Y \circ L \qquad [96]$$

According to the notations used in [26], [27],

$$\int_X \mathcal{D}_X(x) \exp\left(-\frac{\pi}{s} Q_X(x)\right) = 1 \qquad [97]$$

According to [35], [27],

$$1 = \int_X \mathcal{D}_X(x) \exp\left(-\frac{\pi}{s} Q_X(x)\right) = \int_Y \mathcal{D}_Y(Lx) \exp\left(-\frac{\pi}{s} Q_Y(Lx)\right) \qquad [98]$$

$$= |\det L| \int \mathcal{D}_Y(x) \exp\left(-\frac{\pi}{s} Q_X(x)\right) \qquad [99]$$

If $s = 1$, that is, if $Q_X$ and $Q_Y$ are positive definite, then

$$\int_X \mathcal{D}_Y(x) \exp(-\pi Q_X(x)) == \det(Q_X/Q_Y)^{-1/2} \qquad [100]$$

If $s = i$, that is, for Feynman integrals

$$\int_X \mathcal{D}_Y(x) \exp(-\pi Q_X(x)) = |\det(Q_X/Q_Y)|^{-1/2} i^{\text{Ind}(Q_X/Q_Y)} \qquad [101]$$

where "Ind($Q_X/Q_Y$)" is the ratio of the numbers of negative eigenvalues of $Q_X$ and $Q_Y$ respectively, and $i = \sqrt{-1} = e^{i\pi/2}$.

Equation [100] is a key equation for semiclassical expansions where it is convenient to break up the second variation $\mathcal{S}''(q)\xi\xi$ into two quadratic forms:

$$\mathcal{S}''(q)\xi\xi = Q_0(\xi) + Q(\xi) \qquad [102]$$

where $Q_0$ is the kinetic energy. The quadratic form $Q_0$ is a convenient Gaussian volume element for computing [92]. Moreover, splitting the Hessian into $Q_0 + Q$ corresponds to splitting the system into a "free" system and a perturbation.

In eqns [100] and [101] the determinant of the ratios of the infinite-dimensional quadratic forms $Q_X/Q_Y$ have been shown (Cartier and DeWitt-Morette 2006) to be a finite-dimensional determinant, thanks to Jacobi field technology.

### Degenerate Hessians; Beyond WKB

When $U_{a,b}$ consists of isolated points, the Hessian is not degenerate, and the semiclassical expansion is usually called the (strict) WKB approximation. When the Hessian is degenerate,

$$\mathcal{S}''(q)\xi\xi = 0 \quad \text{for} \quad \xi \neq 0 \qquad [103]$$

there is at least one nonzero Jacobi field $h$ along $q$,

$$\mathcal{S}''(q)h = 0, \quad h \in T_q U^{2D}(\mathcal{S}) \qquad [104]$$

with $D$ vanishing initial conditions ($a$) and $D$ vanishing final conditions ($b$). Equation [104] is the defining equation of Jacobi fields. The vanishing boundary conditions imply that $h \in T_q\mathbb{X}_{a,b}$ as well as being a Jacobi field.

For understanding the intersections $U_{a,b}$ when the Hessian is degenerate, one can construct the following basis for the intersecting tangent spaces $T_qU^{2D}(\mathcal{S})$ and $T_q\mathbb{X}_{a,b}$:

- Basis for $T_qU^{2D}(\mathcal{S})$: a complete set (if it exists) of linearly independent Jacobi fields. It can be constructed by varying the $2D$ conditions ($a$), ($b$) satisfied by $q \in \mathbb{X}_{a,b}$.
- Basis for $T_q\mathbb{X}_{a,b}$: a complete set of orthonormal eigenvectors $\{\Psi_k\}$ of the Jacobi operator $\mathcal{J}(q)$ defined by the Hessian

$$\mathcal{S}''(q) \cdot \xi\xi =: \langle\langle \mathcal{J}(q), \xi\rangle, \xi\rangle \qquad [105]$$

$$\mathcal{J}(q)\Psi_k = \alpha_k\Psi_k, \quad k \in \{0, 1, \ldots\} \qquad [106]$$

The basis $\{\Psi_k\}$ diagonalizes the Hessian. When the Hessian is degenerate, there is at least one eigenvector of $\mathcal{J}(q)$ with zero eigenvalue.

1. The intersection $U_{a,b}$ is of dimension $l > 0$. Let $\{u^k\}$ be the coordinates of $\xi$ in the $\{\Psi_k\}$ basis of $T_q\mathbb{X}_{a,b}$. Then the diagonalized Hessian is

$$\mathcal{S}''(q) \cdot \xi\xi = \sum_{k=0}^{\infty} \alpha_k (u^k)^2 \qquad [107]$$

There are $l$ zero eigenvalues $\{\alpha_k\}$ when the system of Euler–Lagrange equations decouples (possibly after a change of variable in $\mathbb{X}_{a,b}$) into two sets: $l$ constraint equations, and $D - l$ equations determining $D - l$ coordinates $\{q^A\}$ of $q$. Say $l = 1$, for simplicity. Then

$$\mathcal{S}(x) = \mathcal{S}(q) + c_0u^0 + \frac{1}{2}\sum_{k=1}^{\infty} \alpha_k (u^k)^2 + \mathcal{O}(|u|^3) \qquad [108]$$

where

$$c_0 = \int_T \mathrm{d}t \frac{\delta\mathcal{S}}{\delta q^j(t)} \Psi_0^j(t) \qquad [109]$$

The change of variable $\xi \to \{u^k\}$ is a linear change of variable of type [33]. The integral [92] decomposes into the product of an ordinary integral over $u^0$ and a Gaussian functional integral defined by a nondegenerate quadratic form. The integral over $u^0$ yields a Dirac $\delta$-function, $\delta(c_0/h)$. The propagator vanishes unless the conservation law $c_0 = 0$ is satisfied.

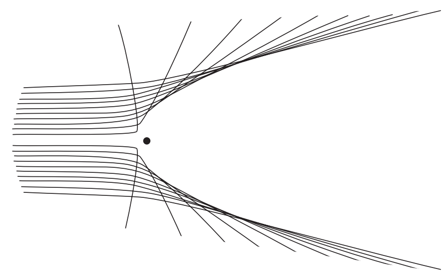

**Figure 5** A flow of particles scattered by a repulsive Coulomb potential. (Reprinted from *Physical Review D* with permission by the American Physical Society.)

Conservation laws appear in the classical limit of quantum physics. The quantum system may have less symmetry than its classical limit.

2. The intersection $U_{a,b}$ is a multiple root of the Euler–Lagrange equation. The flow of classical solutions has an envelope, known as a caustic. Caustics abound in physics: the soap bubble problem, scattering of particles by a repulsive Coulomb potential (see **Figure 5**), rainbow scattering from a source at infinity, glory scattering etc. (Cartier and DeWitt-Morette 2006).

Let us consider a specific example for simplicity. For instance, the scattering of particles of given momenta $p_a$ by a repulsive Coulomb potential. Let $q$ and $q^\Delta$ be two solutions of the Euler–Lagrange equation with slightly different boundary conditions at $t_b$. Compute $I(x_b^\Delta, t_b; p_a, t_a)$ by expanding the action functional not around $q^\Delta$ but around $q$. The path $q^\Delta$ is not in $\mathbb{X}_{a,b}$ and the expansion of the action functional has to be carried up to and including the third variation. As before, let $\{u^k\}$ be the coordinates of $\xi$ in the base $\{\Psi_k\}, k \in \{0, 1 \ldots\}$. The integral over $u^0$ is an Airy integral

$$\nu^{-1/3}\mathrm{Ai}\left(\nu^{-1/3}c\right) \int_{\mathbb{R}} \mathrm{d}u^0 \exp\left(\mathrm{i}\left(cu^0 + \frac{\nu}{3}\left(u^0\right)^3\right)\right) \qquad [110]$$

where

$$\nu = \frac{\pi}{\hbar}\int_T \mathrm{d}r \int_T \mathrm{d}s \int_T \mathrm{d}t \frac{\delta^3\mathcal{S}}{\delta q^\alpha(r)\delta q^\beta(s)\delta q^\gamma(t)} \times \Psi_0^\alpha(r)\Psi_0^\beta(s)\Psi_0^\gamma(t) \qquad [111]$$

$$c = -\frac{2\pi}{h}\int_T \mathrm{d}t \frac{\delta\mathcal{S}}{\delta q(t)} \cdot \Psi_0(t)\left(x_b^\Delta - x_b\right) \qquad [112]$$

The leading contribution of the Airy function when $\hbar$ tends to zero can be computed by the stationary phase method. When $x_b^\Delta$ is in the "illuminated" region, the probability amplitude $I(x_b^\Delta, t_b; p_a, t_a)$ oscillates rapidly as $\hbar$ tends to zero. When $x_b^\Delta$ is in the "dark" region, the probability amplitude decays exponentially. Quantum mechanics softens up the caustics.

The two kinds of degeneracies described in sections (1) and (2) may occur simultaneously. This happens, for instance, in glory scattering for which the cross section, to leading terms in the semiclassical expansions, has been obtained by functional integration in closed form in terms of Bessel functions (Cartier and DeWitt-Morette 2005).

3. The intersection $U_{a,b}$ is the empty set. There is no classical solution corresponding to the quantum transition. This phenomenon, called "tunneling" or "barrier penetration," is a rich chapter of quantum physics which can be found in most of the books listed under "Further reading."

## A Multipurpose Tool

Functional integration provides insight and techniques to quantum physics not available from the operator formalism. Just as an example, one can quote the section "Beyond WKB" which has often been dismissed in the operator formalism by stating that "WKB breaks down" in such cases.

The power of functional integration stems from the power of infinite-dimensional spaces. For instance, compare the Lagrangian of a system with its action functional

$$\mathcal{S}(x) = \int_{\boldsymbol{T}} \mathrm{d}t\, L(\dot{x}(t), x(t)), \quad x \in \mathbb{X}_{a,b}$$
$$x : \boldsymbol{T} \to \mathbb{M}^D, \qquad \mathcal{S} : \mathbb{X}_{a,b} \to \mathbb{R} \qquad [113]$$

A classical solution $q$ of the system can be defined either by a solution of the Euler–Lagrange equation, together with the boundary conditions dictated by $q \in \mathbb{X}_{a,b}$ or by an extremum of the action functional, $\mathcal{S}'(q) = 0$. The path $q$ is a significant point in $\mathbb{X}_{a,b}$ but it is not isolated and the Hessian $\mathcal{S}''(q)$ gives much information on $q$, such as conservation laws, caustics, tunneling.

A list of applications is beyond the scope of this article. We treat only two applications, then give in the "Further reading" section a short list of books that develop such applications as polarons, phase transitions, properties of quantum gases, scattering processes, many-body theory of bosons and fermions, knot invariants, quantum crystals, quantum field theory, anomalies, etc.

### The Homotopy Theorem for Paths Taking Their Values in a Multiply-Connected Space

The space $\mathbb{X}_{a,b}$ of paths $x$

$$x : \boldsymbol{T} \to \mathbb{M}^D, \quad x \in \mathbb{X}_{a,b}$$

probes the global properties of their ranges $\mathbb{M}^D$. When $\mathbb{M}^D$ is multiply connected, $\mathbb{X}_{a,b}$ is the sum of distinct homotopy classes of paths. The integral over $\mathbb{X}_{a,b}$ is a linear combination of integrals over each homotopy class of paths. The coefficients of this linear combinations are provided by the homotopy theorem.

The principle of superposition of quantum states requires the probability amplitude for a given transition to be a linear combination of probability amplitudes. It follows that the absolute value of the probability amplitude for a transition from the state $a$ at $t_a$ to the state $b$ at $t_b$ has the form

$$|K(b, t_b; a, t_a)| = \left| \sum_\alpha \chi(\alpha) K^\alpha(b, t_b; a, t_a) \right| \qquad [114]$$

where $K^\alpha$ is the interval over paths in the same homotopy class. The homotopy theorem (Laidlaw and Morette-DeWitt 1971) and (Schulman 1971) in Cartier and DeWitt-Morette (2006)) states that the set $\{\chi(\alpha)\}$ forms a representation of the fundamental group of the multiply connected space $\mathbb{M}^D$. One cannot label a homotopy class by an element of the fundamental group unless one has chosen a point $c \in \mathbb{M}^D$ and a homotopy class for paths going from $c$ to $a$ and for paths going from $c$ to $b$ – in brief, unless one has chosen a homotopy mesh on $\mathbb{M}^D$. The fundamental group based at $c$ is isomorphic to the fundamental group based at any other point of $\mathbb{M}^D$ but not canonically so. Therefore, eqn [114] is only an equality between absolute values of probability amplitudes. The proof of the homotopy theorem consists in requiring [114] to be independent of the chosen homotopy mesh.

### Application: Systems of *n*-Indistinguishable Particles in $\mathbb{R}^D$

In order that there be a one-to-one correspondence between the system and its configuration space,

$$x : \boldsymbol{T} \to \mathbb{R}^{D \otimes n}/S_n =: \mathbb{R}^{D,n}$$

where $S_n$ is the symmetric group for $n$ permutations; the coincidence points in $\mathbb{R}^{D,n}$ are excluded so that $S_n$ acts effectively on $\mathbb{R}^{D,n}$. Note that $\mathbb{R}^{1,n}$ is not connected, but $\mathbb{R}^{2,n}$ is multiply connected. When $D \geq 3$, $\mathbb{R}^{D,n}$ is simply connected and the fundamental group on $\mathbb{R}^{D,n}$ is isomorphic to $S_n$.

There are only two scalar unitary representations of $S_n$:

$$\chi^B : \alpha \in S_n \to 1 \qquad \text{for all permutations } \alpha$$
$$\chi^F : \alpha \in S_n \to \begin{cases} 1 & \text{for even permutations} \\ -1 & \text{for odd permutations} \end{cases}$$

Therefore, in $\mathbb{R}^3$ there are two different propagators of indistinguishable particles:

$$K^{\text{bose}} = \sum_{\alpha} \chi^B(\alpha) K^{\alpha} \qquad [115]$$

is a symmetric propagator

$$K^{\text{fermi}} = \sum_{\alpha} \chi^F(\alpha) K^{\alpha} \qquad [116]$$

is an antisymmetric propagator.

The arguments leading to the existence of (scalar) bosons and fermions in $\mathbb{R}^3$ fails in $\mathbb{R}^2$. Statistics cannot be assigned to particles in $\mathbb{R}^2$; particles "without" statistics have been called anyons.

### Application: a Spinning Top

Schulman's analysis of the Schrödinger equation for a spinning top (Schulmann 1968) motivated the formulation of the homotopy theorem. Therefore, Schulman's results can easily be formulated as an application of [114].

### Application: Instantons (DeWitt 2004)

The homotopy theorem reformulated for functional integrals applies to the total $\langle \text{out} | \text{in} \rangle$ amplitude of instantons in Minkowski spacetime.

### Scaling Properties of Gaussians

We rewrite the definition [26] of Gaussian volume elements as

$$\int_X d\Gamma_G(x) \exp(-2\pi i \langle x', x \rangle) := \exp(-\pi i W(x')) \qquad [117]$$

where the covariance $G$ is defined by the variance $W$,

$$W(x') = \langle x', Gx' \rangle$$

In quantum field theory the definition [26] reads

$$\int_\Phi d\Gamma_G(\varphi) \exp(-2\pi i \langle J, \varphi \rangle) := \exp(-\pi i W(J)) \qquad [118]$$

where $\varphi$ is a field on spacetime (Minkowski, or Euclidean) and $J$ is called the source. A Gaussian $\Gamma_G$ can be decomposed into the convolution of any number of Gaussians. For example, if

$$W = W_1 + W_2 \longrightarrow G = G_1 + G_2 \qquad [119]$$

then

$$\Gamma_G = \Gamma_{G_1} * \Gamma_{G_2} \qquad [120]$$

Explicitly, in QFT

$$\int_\Phi d\Gamma_G(\varphi) \exp(-2\pi i \langle J, \varphi \rangle) = \int_\Phi d\Gamma_{G_2}(\varphi_2) \int d\Gamma_{G_1}(\varphi_1) \times \exp(-2\pi i \langle J, \varphi_1 + \varphi_2 \rangle) \qquad [121]$$

where

$$\varphi = \varphi_1 + \varphi_2 \qquad [122]$$

The additive property [119] makes it possible to express a covariance $G$ as an integral over an independent scale variable.

Let $\lambda \in [0, \infty]$ be an independent scale variable. (some authors use $\lambda \in [1, \infty[$ and $\lambda^{-1} \in [0, 1[$). A scale variable has no physical dimension:

$$[\lambda] = 0 \qquad [123]$$

The scaling operator $S_\lambda$ acting on a function $f$ of length dimension $[f]$ is by definition

$$S_\lambda f(x) := \lambda^{[f]} f(x/\lambda) \qquad [124]$$

the scaling of an interval $[a, b[$ is given by $S_\lambda[a, b[ = \{s/\lambda | s \in [a, b[\}$, that is,

$$S_\lambda[a, b[ = [a/\lambda, b/\lambda[ \qquad [125]$$

The scaling of a functional $F$ is

$$(S_\lambda F)(\varphi) = F(S_\lambda \varphi) \qquad [126]$$

In order to decompose a covariance into an integral of scale-dependent contributions we note that a covariance $G$ is a two-point function [31]. In quantum field theory [118], the engineering length dimension of $G$ is twice the field dimension

$$[G] = 2[\varphi] \qquad [127]$$

Let $x, y \in$ spacetime and $G$ be a Laplacian Green function. One can introduce a scaled (truncated) Green function

$$G_{[l_0, l[}(x, y) := \int_{l_0}^{l} d^\times s\, S_{s/l_0} u(|x - y|) \qquad [128]$$

where

$$[l] = 1, \quad [s] = 1, \quad d^\times s = ds/s$$
$$l_0 \leq l, \quad [u] = [G] \qquad [129]$$

such that

$$\lim_{l_0 = 0, l = \infty} G_{[l_0, l[}(x, y) = G(x, y) \qquad [130]$$

**Example** $G(x,y)=c_D/|x-y|^{D-2}$; then the only requirement on the function $u$ in [128] is

$$\int_0^\infty \mathrm{d}^\times r r^{-2[\varphi]} u(r) = c_D, \quad [r]=1 \qquad [131]$$

All objects defined by the scaled covariance [128] are labeled with the interval $[l_0, l[$. For instance, a Gaussian volume element $\Gamma_{G_{[l_0,l[}}$ is abbreviated to $\Gamma_{[l_0,l[}$.

### A Coarse-Graining Operator

The following coarse-graining operator has been used for constructing a parabolic semigroup equation in the scaling variable (Brydges *et al.* 1998):

$$P_l F := S_{l/l_0} \cdot \Gamma_{[l_0,l[} * F \qquad [132]$$

where the convolution product is by definition

$$(\Gamma_{[l_0,l[} * F)(\varphi) = \int_\Phi \mathrm{d}\Gamma_{[l_0,l[}(\psi) F(\varphi + \psi)$$

The coarse-graining operator $P_l$ rescales the convolution of a Gaussian volume element $\Gamma_{[l_0,l[}$ so that all volume elements entering the construction of the semigroup renormalization equation are scale independent.

Some properties of the coarse-graining operator:

- $P_{l_2} P_{l_1} = P_{l_2 l_1 / l_0}$.
- The scaled eigenfunctions of the coarse-graining operator are Wick-ordered monomials (Wurm and Berg 2002)

$$P_l : \varphi^n(x) :_{[l_0,\infty[} = \left(\frac{l}{l_0}\right)^{n[\varphi]} : \varphi^n\left(\frac{l_0}{l} x\right) :_{[l_0,\infty[} \qquad [133]$$

  Note that $P_l$ preserves the scale range.
- Let $H$ be the generator of the coarse-graining operator

$$H := \frac{\partial^\times}{\partial l} P_l \Big|_{l=l_0}, \quad \frac{\partial^\times}{\partial l} = l \frac{\partial}{\partial l} \qquad [134]$$

  The semigroup renormalization equation (a.k.a. the flow equation)

$$\frac{\partial^\times}{\partial l} P_l F(\varphi) = H P_l F(\varphi)$$
$$P_{l_0} F(\varphi) = F(\varphi) \qquad [135]$$

Brydges *et al.* have applied the coarse-graining operator to the quantum field theory known as "$\lambda\varphi^4$" (more precisely the Wick-ordered Lagrangian of $\lambda\varphi^4$). The flow equation [135] plays the role of the "$\beta$-function" equation in perturbative quantum field theory.

### Functional Integrals in Quantum Field Theory

Functional integrals in quantum field theory have been modeled to some extent on path integrals in quantum mechanics: mutatis mutandis, the definition [23] of Gaussian volume elements, the diagram expansion [30], the property [36] of linear maps, semiclassical expansions [87], the homotopy theorem [114], and the scaling eqns [135] apply to functional integrals in quantum field theory. The time ordering encoded in a path integral becomes a chronological ordering dictated by light cones in functional integrals of fields on Minkowski fields.

The fundamental difference between quantum mechanics (systems with a finite number of degrees of freedom) and quantum field theory (systems with an infinite number of degrees of freedom) can be said to be "radiative corrections." In quantum field theory, the concept of "particle" is intrinsically associated to the concept of "field." A particle is affected by its field. Its mass and charge are modified by the surrounding fields, namely its own and other fields interacting with it. One speaks of "bare mass" and "renormalized mass" when the bare mass is renormalized by surrounding fields. Computing radiative corrections is a delicate procedure because the Green functions $G$ defined by [25] are singular. Regularization techniques have been developed for handling singular Green functions.

Particles in quantum mechanics are simply particles, and bosons and fermions can be treated separately. Not so in quantum field theory. Therefore, the configuration space in quantum field theory is a supermanifold. For functional integrals in this theory, we refer the reader to the "Further reading" section, in particular to the book of A Das for an introduction, to the book of B DeWitt for an in-depth study, and to the book of K Fujikawa and H Suzuki for applications to quantum anomalies.

## Concluding Remarks

The key issue in functional integration is the domain of integration, that is, a function space. This infinite-dimensional space, say $\mathbb{X}$, cannot be considered as the limit $n=\infty$ of $\mathbb{R}^n$.

Concepts of $\mathbb{R}^D$ stated without reference to $D$ are likely to be meaningful on $\mathbb{X}$. Other approaches which have been used for exploring $\mathbb{X}$ are

- projective system of finite-dimensional spaces coherently defined on $\mathbb{X}$ (DeWitt-Morette *et al.* 1979),
- one-parameter curves on $\mathbb{X}$ (**Figure 1**), and
- projecting $\mathbb{X}$ on finite-dimensional spaces (cylindrical integrals).

Functional integration has advanced our understanding of infinite-dimensional spaces, and like all good mathematical tools, it improves with usage.

## Γ-Convergence and Homogenization

**G Dal Maso**, SISSA, Trieste, Italy

### Introduction

Several asymptotic problems in the calculus of variations lead to the following question: given a sequence $\mathcal{F}_k$ of functionals, defined on a suitable function space, does there exist a functional $\mathcal{F}$ such that the solutions of the minimum problems for $\mathcal{F}_k$ converge to the solutions of the corresponding minimum problems for $\mathcal{F}$? Γ-convergence, introduced by Ennio De Giorgi and his collaborators in 1975, and developed as a powerful tool to attack a wide range of applied problems, provides a unified answer to this kind of question.

### Definition and Main Properties

Let $\mathcal{U}$ be a topological space with a countable base and let $\mathcal{F}_k$ be a sequence of functions defined on $\mathcal{U}$ with values in the extended real line $\overline{\boldsymbol{R}} := \boldsymbol{R} \cup \{-\infty, +\infty\}$. We say that $\mathcal{F}_k$ Γ-converges to a function $\mathcal{F}:\mathcal{U} \to \overline{\boldsymbol{R}}$, or that $\mathcal{F}$ is the Γ-limit of $\mathcal{F}_k$, if for every $u \in \mathcal{U}$ the following conditions are satisfied:

1. For every sequence $u_k$ converging to $u$ in $\mathcal{U}$ we have
$$\mathcal{F}(u) \le \liminf_{k\to\infty} \mathcal{F}_k(u_k)$$
2. There exists a sequence $u_k$ converging to $u$ in $\mathcal{U}$ such that
$$\mathcal{F}(u) = \lim_{k\to\infty} \mathcal{F}_k(u_k)$$

Property (1) appears to be a variant of the usual definition of lower semicontinuity. Property (2) requires the existence, for every $u \in \mathcal{U}$, of a "recovery sequence," which provides an approximation of the value of $\mathcal{F}$ at $u$ by means of values attained by $\mathcal{F}_k$ near $u$.

It follows immediately from the definition that, if $\mathcal{F}_k$ Γ-converges to $\mathcal{F}$, then $\mathcal{F}_k + \mathcal{G}$ Γ-converges to $\mathcal{F} + \mathcal{G}$ for every continuous function $\mathcal{G}:\mathcal{U} \to \boldsymbol{R}$.

The first general property of Γ-limits is lower semicontinuity: if $\mathcal{F}_k$ Γ-converges to $\mathcal{F}$, then $\mathcal{F}$ is lower semicontinuous on $\mathcal{U}$; that is,
$$\mathcal{F}(u) \le \liminf_{k\to\infty} \mathcal{F}(u_k)$$
for every $u \in \mathcal{U}$ and for every sequence $u_k$ converging to $u$ in $\mathcal{U}$.

Another important property of Γ-convergence is compactness: every sequence $\mathcal{F}_k$ has a Γ-convergent subsequence.

For every $k$ assume that the function $\mathcal{F}_k$ has a minimum point $u_k$. The following property is the link between Γ-convergence and convergence of minimizers: if $\mathcal{F}_k$ Γ-converges to $\mathcal{F}$ and $u_k$ converges to $u$, then $u$ is a minimum point of $\mathcal{F}$ and $\mathcal{F}_k(u_k)$ converges to $\mathcal{F}(u)$, hence
$$\min_{v\in\mathcal{U}} \mathcal{F}(v) = \lim_{k\to\infty} \min_{v\in\mathcal{U}} \mathcal{F}_k(v) \qquad [1]$$

Under suitable coerciveness assumptions, the convergence of $u_k$ is obtained by a compactness argument. We recall that a sequence of functions $\mathcal{F}_k$ is said to be equicoercive if for every $t \in \boldsymbol{R}$ there exists a compact set $\mathcal{K}_t$ (independent of $k$) such that
$$\{u \in \mathcal{U}: \mathcal{F}_k(u) \le t\} \subset \mathcal{K}_t \qquad [2]$$
for every $k$.

If $\mathcal{F}_k$ is equicoercive and Γ-converges to $\mathcal{F}$, the previous result implies that [1] holds. If, in addition, $\mathcal{F}$ is not identically $+\infty$, then the sequence $u_k$ of minimizers considered above has a subsequence $u_{k_j}$ which converges to a minimizer $u$ of $\mathcal{F}$. The whole sequence $u_k$ converges to $u$ whenever $\mathcal{F}$ has a unique minimizer $u$.

In many applications to the calculus of variations, $\mathcal{U}$ is the Lebesgue space $L^p(\Omega;\boldsymbol{R}^m)$, with $\Omega$ a bounded open subset of $\boldsymbol{R}^n$ and $1 \le p < +\infty$, but the effective domains of the functionals $\mathcal{F}_k$, defined as $\{u \in \mathcal{U}: \mathcal{F}_k(u) \in \boldsymbol{R}\}$, are often contained in the Sobolev space $W^{1,p}(\Omega;\boldsymbol{R}^m)$, composed of all functions $u \in L^p(\Omega;\boldsymbol{R}^m)$ whose distributional gradient

$\nabla u$ belongs to $L^p(\Omega;\boldsymbol{R}^{m\times n})$. When one considers homogeneous Dirichlet boundary conditions, the effective domains of the functionals $\mathcal{F}_k$ are often contained in the smaller Sobolev space $W_0^{1,p}(\Omega;\boldsymbol{R}^m)$, composed of all functions of $W^{1,p}(\Omega;\boldsymbol{R}^m)$ which vanish on the boundary $\partial\Omega$, technically defined as the closure of $C_0^\infty(\Omega;\boldsymbol{R}^m)$ in $W^{1,p}(\Omega;\boldsymbol{R}^m)$.

In this case, the equicoerciveness condition [2] can be obtained by using Rellich's theorem, which asserts that the natural embedding of $W_0^{1,p}(\Omega;\boldsymbol{R}^m)$ into $L^p(\Omega;\boldsymbol{R}^m)$ is compact. Therefore, a sequence of functionals $\mathcal{F}_k$ defined on $L^p(\Omega;\boldsymbol{R}^m)$ is equicoercive if there exists a constant $\alpha > 0$ such that

$$\mathcal{F}_k(u) \geq \alpha \int_\Omega |\nabla u|^p \mathrm{d}x$$

for every $u \in W_0^{1,p}(\Omega;\boldsymbol{R}^m)$, while $\mathcal{F}_k(u) = +\infty$ for every $u \notin W_0^{1,p}(\Omega;\boldsymbol{R}^m)$.

## Homogenization Problems

Many problems for composite materials (fibered or stratified materials, porous media, materials with many small holes or fissures, etc.) lead to the study of mathematical models with many interacting scales, which may differ by several orders of magnitude. From a microscopic viewpoint, the systems considered are highly inhomogeneous. Typically, in such composite materials, the physical parameters (such as electric and thermal conductivity, elasticity coefficients, etc.) are discontinuous and oscillate between the different values characterizing each component.

When these components are intimately mixed, these parameters oscillate very rapidly and the microscopic structure becomes more and more complex. On the other hand, the material becomes quite simple from a macroscopic point of view, and it tends to behave like an ideal homogeneous material, called "homogenized material." The purpose of the mathematical theory of homogenization is to describe this limit process when the parameters which describe the fineness of the microscopic structure tend to zero.

Homogenization problems are often treated by studying the partial differential equations that govern the physical properties under investigation. Due to the small scale of the microscopic structure, these equations contain some small parameters. The mathematical problem consists then in the study of the limit of the solutions of these equations when the parameters tend to zero. Γ-convergence is a very useful tool to obtain homogenization results for systems governed by variational principles, which are the only ones described in this article.

Let $Q := (-1/2, 1/2)^n$ be the open unit cube in $\boldsymbol{R}^n$ centered at 0. We say that a function $u$ defined on $\boldsymbol{R}^n$ is $Q$-periodic if, for every $z \in \boldsymbol{R}^n$ with integer coordinates, we have $u(x+z) = u(x)$ for every $x \in \boldsymbol{R}^n$.

Let $f : \boldsymbol{R}^n \times \boldsymbol{R}^{m\times n} \to [0,+\infty)$ be a function such that $x \mapsto f(x,\xi)$ is measurable and $Q$-periodic on $\boldsymbol{R}^n$ for every $\xi \in \boldsymbol{R}^{m\times n}$ and $\xi \mapsto f(x,\xi)$ is convex on $\boldsymbol{R}^{m\times n}$ for every $x \in \boldsymbol{R}^n$. Given a bounded open set $\Omega \subset \boldsymbol{R}^n$ and a constant $p > 1$, let $\mathcal{F}_\varepsilon : L^p(\Omega;\boldsymbol{R}^m) \to [0,+\infty]$ be the family of functionals defined by

$$\mathcal{F}_\varepsilon(u) := \begin{cases} \int_\Omega f(x/\varepsilon, \nabla u)\,\mathrm{d}x & \text{if } u \in W_0^{1,p}(\Omega;\boldsymbol{R}^m) \\ +\infty & \text{otherwise} \end{cases}$$

In the applications to composite materials, the functional $\mathcal{F}_\varepsilon$ represents the energy of the portion of the material occupying the domain $\Omega$. The fact that the energy density depends on $x/\varepsilon$ reflects the $\varepsilon$-periodic structure of the material, which implies that the energy density oscillates faster and faster as $\varepsilon \to 0$.

Assume that there exist two constants $\beta \geq \alpha > 0$ such that

$$\alpha|\xi|^p \leq f(x,\xi) \leq \beta(1+|\xi|^p) \qquad [3]$$

for every $x \in \Omega$ and every $\xi \in \boldsymbol{R}^{m\times n}$. Then for every sequence $\varepsilon_k \to 0$ the functionals $\mathcal{F}_{\varepsilon_k}$ Γ-converge to the functional $\mathcal{F}_{\text{hom}} : L^p(\Omega;\boldsymbol{R}^m) \to [0,+\infty]$ defined by

$$\mathcal{F}_{\text{hom}}(u) := \begin{cases} \int_\Omega f_{\text{hom}}(\nabla u)\,\mathrm{d}x & \text{if } u \in W_0^{1,p}(\Omega;\boldsymbol{R}^m) \\ +\infty & \text{otherwise} \end{cases} \qquad [4]$$

The integrand $f_{\text{hom}} : \boldsymbol{R}^{m\times n} \to [0,+\infty)$ is obtained by solving the cell problem

$$f_{\text{hom}}(\xi) := \min_{w \in W^{1,p}_{\text{per}}(Q;\boldsymbol{R}^m)} \int_Q f(x, \xi + \nabla w)\,\mathrm{d}x \qquad [5]$$

where $W^{1,p}_{\text{per}}(Q;\boldsymbol{R}^m)$ denotes the space of functions $w \in W^{1,p}_{\text{loc}}(\boldsymbol{R}^n;\boldsymbol{R}^m)$ which are $Q$-periodic.

The function $f_{\text{hom}}$ is always convex and satisfies [3]. If it is strictly convex, the basic properties of Γ-convergence imply that for every $g \in L^q(\Omega;\boldsymbol{R}^m)$, with $1/p + 1/q = 1$, the solutions $u_\varepsilon$ of the minimum problems

$$\min_{v \in W_0^{1,p}(\Omega;\boldsymbol{R}^m)} \int_\Omega \left[ f\left(\frac{x}{\varepsilon}, \nabla v\right) - g(x)v \right] \mathrm{d}x \qquad [6]$$

converge in $L^p(\Omega;\boldsymbol{R}^m)$, as $\varepsilon \to 0$, to the solution $u$ of the minimum problem

$$\min_{v \in W_0^{1,p}(\Omega;\boldsymbol{R}^m)} \int_\Omega [f_{\text{hom}}(\nabla v) - g(x)v]\,\mathrm{d}x \qquad [7]$$

Similar results can be proved for nonhomogeneous Dirichlet boundary conditions, as well as for Neumann boundary conditions.

In the special case $m=1$, $p=2$, and

$$f(x,\xi) = \frac{1}{2}\sum_{i,j=1}^{n} a_{ij}(x)\xi_j\,\xi_i \qquad [8]$$

with $a_{ij}(x)$ $Q$-periodic, the function $f_{\text{hom}}$ takes the form

$$f_{\text{hom}}(\xi) = \frac{1}{2}\sum_{i,j=1}^{n} a_{ij}^{\text{hom}}\xi_j\,\xi_i$$

for suitable constant coefficients $a_{ij}^{\text{hom}}$.

By considering the Euler equations of the problems [6] and [7] in this special case, from the previous result we obtain the homogenization theorem for symmetric elliptic operators in divergence form, which asserts that for every $g \in L^2(\Omega)$ the solutions $u_\varepsilon$ of the Dirichlet problems

$$-\sum_{i,j=1}^{n} D_i\Big(a_{ij}\Big(\frac{x}{\varepsilon}\Big)D_j u_\varepsilon(x)\Big) = g(x) \quad \text{on } \Omega$$
$$u_\varepsilon(x) = 0 \quad \text{on } \partial\Omega$$

converge in $L^2(\Omega)$ to the solution $u$ of the Dirichlet problem

$$-\sum_{i,j=1}^{n} a_{ij}^{\text{hom}}\, D_i D_j u(x) = g(x) \quad \text{on } \Omega$$
$$u(x) = 0 \quad \text{on } \partial\Omega$$

An extensive literature is devoted to precise estimates of the homogenized coefficients $a_{ij}^{\text{hom}}$, depending on various structure conditions on the periodic coefficients $a_{ij}(x)$. Some of these estimates are based on a clever use of the variational formula [5].

Explicit formulas for $a_{ij}^{\text{hom}}$ are known in the case of layered materials, which correspond to the case where $\boldsymbol{R}^n$ is periodically partitioned into parallel layers on which the coefficients $a_{ij}(x)$ take constant values.

Easy examples show that, even if the composite material is isotropic at a microscopic layer (i.e., $a_{ij}(x) = a(x)\delta_{ij}$ for some scalar function $a(x)$), the homogenized material can be anisotropic (i.e., $a_{ij}^{\text{hom}} \neq a\delta_{ij}$), due to the anisotropy of the periodic function $a(x)$, which describes the microscopic distribution of the different components of the composite material.

In the vector case $m > 1$, the convexity hypothesis on $\xi \mapsto f(x,\xi)$ is not satisfied by the most interesting functionals related to nonlinear elasticity. If $\xi \mapsto f(x,\xi)$ is not convex, one can still prove that $\mathcal{F}_{\varepsilon_k}$ Γ-converges to a functional $\mathcal{F}_{\text{hom}}: L^p(\Omega;\boldsymbol{R}^m) \to [0,+\infty]$ of the form [4], but this time $f_{\text{hom}}: \boldsymbol{R}^{m\times n} \to [0,+\infty)$ cannot be obtained by solving a problem in the unit cell. Instead, it is given by the asymptotic formula

$$f_{\text{hom}}(\xi) := \lim_{R\to\infty} \frac{1}{R^n} \min_{w \in W_0^{1,p}(Q_R;\boldsymbol{R}^m)} \int_{Q_R} f(x, \xi + \nabla w)\,dx$$

where $Q_R := (-R/2, R/2)^n$ is the open cube of side $R$ centered at 0. Similar formulas can be obtained for quasiperiodic integrands $f$ and for stochastic homogenization problems.

In the nonperiodic case one can prove that, if $g_\varepsilon: \boldsymbol{R}^n \times \boldsymbol{R}^{m\times n} \to [0,+\infty)$ are arbitrary Borel functions satisfying [3], with constants independent of $\varepsilon$, and $\mathcal{G}_\varepsilon : L^p(\Omega;\boldsymbol{R}^m) \to [0,+\infty]$ are defined by

$$\mathcal{G}_\varepsilon(u) := \begin{cases} \int_\Omega g_\varepsilon(x,\nabla u)\,dx & \text{if } u \in W_0^{1,p}(\Omega;\boldsymbol{R}^m) \\ +\infty & \text{otherwise} \end{cases}$$

then there exists a sequence $\varepsilon_k \to 0$ such that the functionals $\mathcal{G}_{\varepsilon_k}$ Γ-converge to a functional $\mathcal{G}$ of the form

$$\mathcal{G}(u) := \begin{cases} \int_\Omega g(x,\nabla u)\,dx & \text{if } u \in W_0^{1,p}(\Omega;\boldsymbol{R}^m) \\ +\infty & \text{otherwise} \end{cases}$$

with $g$ satisfying [3].

In this case, no easy formula provides the integrand $g(x,\xi)$ in terms of simple operations on the integrands $g_{\varepsilon_k}(x,\xi)$. The indirect connection between these integrands can be obtained by introducing the functions $M_\varepsilon(x,\xi,\rho)$ defined, for $x \in \Omega$, $\xi \in \boldsymbol{R}^{m\times n}$, and $0 < \rho < \operatorname{dist}(x,\partial\Omega)$, by

$$M_\varepsilon(x,\xi,\rho) := \min_{w \in W_0^{1,p}(B(x,\rho))} \int_{B(x,\rho)} g_\varepsilon(y, \xi + \nabla w)\,dy$$

where $B(x,\rho)$ is the open ball with center $x$ and radius $\rho$. These functions describe the local behavior of the integrands $g_\varepsilon$ in some special minimum problems. The sequence $\mathcal{G}_{\varepsilon_k}$ Γ-converges to $\mathcal{G}$ if and only if

$$g(x,\xi) = \liminf_{\rho\to 0}\,\liminf_{k\to\infty} \frac{M_{\varepsilon_k}(x,\xi,\rho)}{|B(x,\rho)|} = \limsup_{\rho\to 0}\,\limsup_{k\to\infty} \frac{M_{\varepsilon_k}(x,\xi,\rho)}{|B(x,\rho)|}$$

for almost every $x \in \Omega$ and every $\xi \in \boldsymbol{R}^{m\times n}$.

Similar results have also been proved for integral functionals of the form

$$\mathcal{G}_\varepsilon(u) := \begin{cases} \int_\Omega g_\varepsilon(x,u,\nabla u)\,dx & \text{if } u \in W_0^{1,p}(\Omega;\boldsymbol{R}^m) \\ +\infty & \text{otherwise} \end{cases}$$

under suitable structure conditions for the integrands $g_\varepsilon$.

## Perforated Domains

In some homogenization problems, the integrand is fixed, but the domain depends on a small parameter $\varepsilon$ and its boundary becomes more and more fragmented as $\varepsilon \to 0$. A typical example is given by periodically perforated domains with small holes. Given a bounded open set $\Omega \subset \boldsymbol{R}^n$ and a compact set $K \subset Q$, both with smooth boundaries, for every $\varepsilon > 0$ we consider the perforated sets

$$\Omega_\varepsilon := \Omega \setminus \bigcup_{z \in Z_\Omega^\varepsilon} (\varepsilon z + \varepsilon K) \qquad [9]$$

where $Z_\Omega^\varepsilon$ is the set of vectors $z \in \boldsymbol{R}^n$ with integer coordinates such that $\varepsilon z + \varepsilon Q \subset \Omega$.

Given $g \in L^2(\Omega)$, let $\mathcal{F}_\varepsilon : L^2(\Omega) \to [0, +\infty]$ be the functionals defined by

$$\mathcal{F}_\varepsilon(u) := \begin{cases} \int_{\Omega_\varepsilon} \left[\frac{1}{2}|\nabla u|^2 - gu\right] \mathrm{d}x & \text{if } u \in W_0^{1,2}(\Omega) \\ +\infty & \text{otherwise} \end{cases} \qquad [10]$$

Minimizing [10] is equivalent to solving the mixed problems

$$\begin{aligned} -\Delta u_\varepsilon &= g && \text{on } \Omega_\varepsilon \\ u_\varepsilon &= 0 && \text{on } \partial\Omega \\ \frac{\partial u_\varepsilon}{\partial \nu} &= 0 && \text{on } \partial\Omega_\varepsilon \setminus \partial\Omega \end{aligned} \qquad [11]$$

The homogenization formula [5] is still valid, with minor modifications. It leads to a matrix of coefficients $a_{ij}^{\text{hom}}$ such that

$$\sum_{i,j=1}^n a_{ij}^{\text{hom}} \xi_j \xi_i := \min_{w \in W_{\text{per}}^{1,2}(Q)} \int_{Q\setminus K} |\xi + \nabla w|^2 \, \mathrm{d}x$$

for every $\xi \in \boldsymbol{R}^n$. For every sequence $\varepsilon_k \to 0$ the Γ-limit of the functionals $\mathcal{F}_{\varepsilon_k}$ is the functional $\mathcal{F} : L^2(\Omega) \to [0, +\infty]$ defined by

$$\mathcal{F}(u) := \begin{cases} \int_\Omega \left[\frac{1}{2}\sum_{i,j=1}^n a_{ij}^{\text{hom}} \, D_j u \, D_i u - mgu\right] \mathrm{d}x \\ \qquad \text{if } u \in W_0^{1,2}(\Omega) \\ +\infty \qquad \text{otherwise} \end{cases}$$

where $m := |Q \setminus K|$ is the volume fraction of the sets $\Omega_\varepsilon$.

Since a slight modification of the functionals $\mathcal{F}_\varepsilon$ satisfies an equicoerciveness condition, it follows from the basic properties of Γ-convergence that the solutions $u_\varepsilon$ of the mixed problems [11] in the perforated domains [9], extended to the holes so that $u_\varepsilon$ are harmonic on $\Omega \setminus \bar{\Omega}_\varepsilon$ and $u_\varepsilon \in W_0^{1,2}(\Omega)$, converge in $L^2(\Omega)$ to the solution $u$ of the Dirichlet problem

$$\begin{aligned} -\sum_{i,j=1}^n a_{ij}^{\text{hom}} D_i D_j u &= mg && \text{on } \Omega \\ u &= 0 && \text{on } \partial\Omega \end{aligned}$$

Therefore, the asymptotic effect of the small holes with Neumann boundary condition is a change in the coefficients of the elliptic equation.

In the case of Dirichlet boundary conditions, it is interesting to consider perforated domains with holes of a different size, namely

$$\Omega_\varepsilon := \Omega \setminus \bigcup_{z \in Z_\Omega^\varepsilon} (\varepsilon z + \varepsilon^{n/(n-2)} K) \qquad [12]$$

with $\varepsilon^{n/(n-2)}$ replaced by $\exp(-1/\varepsilon^2)$ if $n = 2$, while the case $n = 1$ gives only trivial results.

Given $g \in L^2(\Omega)$, let $\mathcal{G}_\varepsilon : L^2(\Omega) \to [0, +\infty]$ be the functionals defined by

$$\mathcal{G}_\varepsilon(u) := \begin{cases} \int_{\Omega_\varepsilon} \left[\frac{1}{2}|\nabla u|^2 - gu\right] \mathrm{d}x & \text{if } u \in W_0^{1,2}(\Omega_\varepsilon) \\ +\infty & \text{otherwise} \end{cases} \qquad [13]$$

Minimizing [13] is equivalent to solving the Dirichlet problems

$$\begin{cases} -\Delta u_\varepsilon = g & \text{on } \Omega_\varepsilon \\ u_\varepsilon = 0 & \text{on } \partial\Omega_\varepsilon \end{cases} \qquad [14]$$

For every sequence $\varepsilon_k \to 0$ the Γ-limit of the functionals $\mathcal{G}_{\varepsilon_k}$ is the functional $\mathcal{G} : L^2(\Omega) \to [0, +\infty]$ defined by

$$\mathcal{G}(u) := \begin{cases} \int_\Omega \left[\frac{1}{2}|\nabla u|^2 + \frac{c}{2}u^2 - gu\right] \mathrm{d}x & \text{if } u \in W_0^{1,2}(\Omega) \\ +\infty & \text{otherwise} \end{cases}$$

where, for $n \geq 3$,

$$c := \operatorname{cap}(K) := \inf_{\substack{w \in C_c^\infty(\boldsymbol{R}^n) \\ w = 1 \text{ on } K}} \int_{\boldsymbol{R}^n} |\nabla w|^2 \mathrm{d}x$$

Since a slight modification of the functionals $\mathcal{G}_\varepsilon$ satisfies an equicoerciveness condition, it follows from the basic properties of Γ-convergence that the solutions $u_\varepsilon$ of the Dirichlet problems [14] in the perforated domains [12], extended as zero on $\Omega \setminus \Omega_\varepsilon$, converge in $L^2(\Omega)$ to the solution $u$ if the Dirichlet problem

$$\begin{aligned} -\Delta u + cu &= g && \text{on } \Omega \\ u &= 0 && \text{on } \partial\Omega \end{aligned} \qquad [15]$$

In the electrostatic interpretation of these problems, the boundary $\partial\Omega_\varepsilon$ is a conductor kept at potential

zero. The extra term $cu$ in [15] is due to the electric charges induced on $\partial\Omega_\varepsilon$ by the charge distribution $g$.

These results on Dirichlet and Neumann boundary conditions have been extended to more general functionals and also to a wide class of nonperiodic distributions of small holes.

## Dimension Reduction Problems

In the study of thin elastic structures, like plates, membranes, rods, and strings, it is customary to approximate the mechanical behavior of a thin three-dimensional body by an effective theory for two- or one-dimensional elastic bodies. Γ-convergence provides a useful tool for a rigorous deduction of the lower-dimensional theory.

Let us focus on the derivation of plate theory from three-dimensional finite elasticity. The reference configuration of the thin three-dimensional elastic body is a cylinder of the form

$$\Omega_\varepsilon := S \times \left(-\frac{\varepsilon}{2}, \frac{\varepsilon}{2}\right)$$

where $\varepsilon > 0$ and $S$ is a bounded open subset of $\boldsymbol{R}^2$ with smooth boundary. We assume that the body is hyperelastic, with stored elastic energy

$$\int_{\Omega_\varepsilon} W(\nabla u)\, \mathrm{d}x$$

where $u : \Omega_\varepsilon \to \boldsymbol{R}^3$ is the deformation. The energy density $W : \boldsymbol{R}^{3\times 3} \to [0, +\infty]$, depending on the material, is continuous and frame indifferent; that is, $W(QF) = W(F)$ for every rotation $Q$ and every $F \in \boldsymbol{R}^{3\times 3}$, where $QF$ denotes the usual product of $3\times 3$ matrices. We assume that $W$ vanishes on the set SO(3) of rotations, is of class $C^2$ in a neighborhood SO(3), and satisfies the inequality

$$W(F) \geq \alpha \operatorname{dist}^2(F, \mathrm{SO}(3)) \quad \text{for every } F \in \boldsymbol{R}^{3\times 3} \qquad [16]$$

with a constant $\alpha > 0$.

Plate theory is obtained in the limit as $\varepsilon \to 0$ when the densities of the volume forces applied to the body have the form $\varepsilon^2 f(x_1, x_2)$, with $f \in L^2(S; \boldsymbol{R}^3)$. We assume that $f$ is balanced; that is,

$$\int_{\Omega_\varepsilon} f\, \mathrm{d}x = 0, \qquad \int_{\Omega_\varepsilon} x \wedge f\, \mathrm{d}x = 0$$

Stable equilibria are then obtained by minimizing the functionals

$$\int_{\Omega_\varepsilon} \left[W(\nabla u) - \varepsilon^2 f \cdot u\right] \mathrm{d}x \qquad [17]$$

on $W^{1,2}(\Omega_\varepsilon; \boldsymbol{R}^3)$.

To study the behavior of [17] as $\varepsilon \to 0$, it is convenient to change variables, so that the scaled deformations $v(x_1, x_2, x_3) := u(x_1, x_2, \varepsilon x_3)$ are defined on the same domain

$$\Omega := S \times \left(-\frac{1}{2}, \frac{1}{2}\right)$$

The scaled energy density $W_\varepsilon : \boldsymbol{R}^{3\times 3} \to [0, +\infty]$ is then defined as

$$W_\varepsilon(F_1|F_2|F_3) := W\left(F_1|F_2|\frac{1}{\varepsilon}F_3\right)$$

where $(F_1|F_2|F_3)$ denotes the $3\times 3$ matrix with columns $F_1, F_2$, and $F_3$. This implies that

$$\int_{\Omega_\varepsilon} \left[W(\nabla u) - \varepsilon^2 f \cdot u\right] \mathrm{d}x = \varepsilon \int_{\Omega} \left[W_\varepsilon(\nabla v) - \varepsilon^2 f \cdot v\right] \mathrm{d}x$$

The asymptotic behavior of the minimizers of these functionals can be obtained from the knowledge of the Γ-limit of the functionals $\mathcal{F}_\varepsilon : L^2(\Omega; \boldsymbol{R}^3) \to [0, +\infty]$ defined by

$$\mathcal{F}_\varepsilon(v) := \begin{cases} \dfrac{1}{\varepsilon^2} \displaystyle\int_\Omega W_\varepsilon(\nabla v)\, \mathrm{d}x & \text{if } v \in W^{1,2}(\Omega; \boldsymbol{R}^3) \\ +\infty & \text{otherwise} \end{cases}$$

Let us fix a sequence $\varepsilon_k \to 0$. The Γ-limit of $\mathcal{F}_{\varepsilon_k}$ turns out to be finite on the set $\Sigma(S; \boldsymbol{R}^3)$ of all isometric embeddings of $S$ into $\boldsymbol{R}^3$ of class $W^{2,2}$; that is, $v \in \Sigma(S; \boldsymbol{R}^3)$ if and only if $v \in W^{2,2}(S; \boldsymbol{R}^3)$ and $(\nabla v)^T \nabla v = I$ a.e. on $S$. The elements of $\Sigma(S; \boldsymbol{R}^3)$ will be often regarded as maps from $\Omega$ into $\boldsymbol{R}^3$, independent of $x_3$.

To describe the Γ-limit, we introduce the quadratic form $Q_3$ defined on $\boldsymbol{R}^{3\times 3}$ by

$$Q_3(F) := \tfrac{1}{2} D^2 W(I)[F, F]$$

which is the density of the linearized energy for the three-dimensional problem, and the quadratic form $Q_2$ defined on the space of symmetric $2 \times 2$ matrices by

$$Q_2\begin{pmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{pmatrix} := \min_{(b_1, b_2, b_3) \in \boldsymbol{R}^3} Q_3 \begin{pmatrix} a_{11} & a_{12} & b_1 \\ a_{12} & a_{22} & b_2 \\ b_1 & b_2 & b_3 \end{pmatrix}$$

The Γ-limit of $\mathcal{F}_{\varepsilon_k}$ is the functional $\mathcal{F} : L^2(\Omega; \boldsymbol{R}^3) \to [0, +\infty]$ defined by

$$\mathcal{F}(v) := \begin{cases} \frac{1}{12} \int_\Omega Q_2(A)\, \mathrm{d}x & \text{if } v \in \Sigma(S; \boldsymbol{R}^3) \\ +\infty & \text{otherwise} \end{cases}$$

where $A(x_1, x_2)$ denotes the second fundamental form of $v$; that is,

$$A_{ij} := -D_i D_j v \cdot \nu \quad [18]$$

with normal vector $\nu := D_1 v \wedge D_2 v$.

The equicoerciveness of the functionals $\mathcal{F}_\varepsilon$ in $L^2(\Omega; \mathbf{R}^3)$ is not trivial for this problem: it follows from [16] through a very deep geometric rigidity estimate which generalizes Korn's inequality (see Friesecke *et al.* (2002)). The basic properties of Γ-convergence imply that

$$\min_{u \in W^{1,2}(\Omega_\varepsilon; \mathbf{R}^3)} \int_{\Omega_\varepsilon} \left[W(\nabla u) - \varepsilon^2 f \cdot u\right] dx = \varepsilon^3 \min_{v \in \Sigma(S; \mathbf{R}^3)} \int_S \left[\frac{1}{12} Q_2(A) - f \cdot v\right] dx' + o(\varepsilon^3)$$

with $x' := (x_1, x_2)$ and $A$ defined by [18].

For every $\varepsilon > 0$ let $u_\varepsilon$ be a minimizer of [17] and let $v_\varepsilon(x_1, x_2, x_3) := u_\varepsilon(x_1, x_2, \varepsilon x_3)$. Then the basic properties of Γ-convergence imply that there exists a sequence $\varepsilon_k \to 0$ such that $v_{\varepsilon_k}(x_1, x_2, x_3)$ converges in $L^2(\Omega; \mathbf{R}^3)$ to a solution $v(x_1, x_2)$ of the minimum problem

$$\min_{v \in \Sigma(S; \mathbf{R}^3)} \int_S \left[\frac{1}{12} Q_2(A) - f \cdot v\right] dx' \quad [19]$$

These results provide a sound mathematical justification of the reduced two-dimensional theory of plates based on the minimum problem [19].

Similar results have been proved for shells, membranes, rods, and strings.

## Phase Transition Problems

The Cahn–Hilliard gradient theory of phase transitions deals with a fluid with mass $m$, under isothermal conditions, confined in a bounded open subset $\Omega$ of $\mathbf{R}^n$ with smooth boundary, whose Gibbs free energy, per unit volume, is a prescribed function $W$ of the density distribution $u$. Given a small parameter $\varepsilon > 0$, the energy functional $\mathcal{F}_\varepsilon : L^1(\Omega) \to [0, +\infty]$ has the form

$$\mathcal{F}_\varepsilon(u) := \begin{cases} \int_\Omega \left[W(u) + \varepsilon^2 |\nabla u|^2\right] dx & \text{if } u \in A(m) \\ +\infty & \text{otherwise} \end{cases} \quad [20]$$

where $A(m)$ is the set of all functions $u \in W^{1,2}(\Omega)$ with $\int_\Omega u = m$.

We assume that $W : \mathbf{R} \to [0, +\infty)$ is continuous and that there exist $\alpha, \beta \in \mathbf{R}$, with $\alpha|\Omega| < m < \beta|\Omega|$, such that $W(t) = 0$ if and only $t = \alpha$ or $t = \beta$. Moreover, we assume that $W(t) \to +\infty$ as $t \to \pm\infty$. In the minimization of $\mathcal{F}_\varepsilon$, the Gibbs free energy $W(u)$ favors the functions whose values are close to $\alpha$ and $\beta$, which represent the pure phases, while the gradient term penalizes the transitions between different phases.

It is easy to see that for every sequence $\varepsilon_k \to 0$ the sequence $\mathcal{F}_{\varepsilon_k}$ Γ-converges to the functional $\mathcal{F} : L^1(\Omega) \to [0, +\infty]$ defined by

$$\mathcal{F}(u) := \begin{cases} \int_\Omega W(u)\, dx & \text{if } \int_\Omega u = m \\ +\infty & \text{otherwise} \end{cases}$$

The set $M(\alpha, \beta, m)$ of minimum points of $\mathcal{F}$ is composed of all measurable functions $u$ on $\Omega$ which take only the values $\alpha$ and $\beta$ (on $E_\alpha$ and $E_\beta$, respectively), and satisfy the mass constraint $\alpha|E_\alpha| + \beta|E_\beta| = m$, which is equivalent to

$$|E_\alpha| = \frac{\beta|\Omega| - m}{\beta - \alpha} \quad [21]$$

From the basic properties of Γ-convergence, we deduce that

$$\min_{u \in A(m)} \int_\Omega \left[W(u) + \varepsilon^2 |\nabla u|^2\right] dx \to 0 \quad [22]$$

and that there exists a sequence $\varepsilon_k \to 0$ such that the minimizers $u_{\varepsilon_k}$ of $\mathcal{F}_{\varepsilon_k}$ converge in $L^1(\Omega)$ to a function $u$ which takes only the values $\alpha$ and $\beta$ and satisfies [21].

This result can be improved by considering the rescaled functionals

$$\mathcal{G}_\varepsilon(u) := \frac{1}{\varepsilon} \mathcal{F}_\varepsilon(u) \quad [23]$$

where $\mathcal{F}_\varepsilon$ is defined by [20]. Then for every sequence $\varepsilon_k \to 0$ the sequence $\mathcal{G}_{\varepsilon_k}$ Γ-converges to the functional $\mathcal{G} : L^1(\Omega) \to [0, +\infty]$ defined by

$$\mathcal{G}(u) := \begin{cases} 2cP(E_\alpha, \Omega) & \text{if } u \in M(\alpha, \beta, m) \\ +\infty & \text{otherwise} \end{cases}$$

where

$$c := \int_\alpha^\beta \sqrt{W(t)}\, dt$$

and

$$P(E, \Omega) := \sup\left\{\int_E \operatorname{div} \varphi\, dx : \varphi \in C_c^1(\Omega; \mathbf{R}^n), |\varphi| \le 1\right\}$$

is the Caccioppoli–De Giorgi perimeter of $E$ in $\Omega$, which coincides with the $(n-1)$-dimensional measure of $\Omega \cap \partial E$ when $E$ is smooth enough.

Note that the effective domain $A(m)$ of the functionals $\mathcal{G}_\varepsilon$ is disjoint from the effective domain of the limit functional $\mathcal{G}$, which is the set of all functions $u \in M(\alpha, \beta, m)$ with $P(E_\alpha, \Omega) < +\infty$.

As the functionals [20] and [23] have the same minimizers, we deduce that there exists a sequence $\varepsilon_k \to 0$ such that the minimizers $u_{\varepsilon_k}$ of $\mathcal{F}_{\varepsilon_k}$ converge in $L^1(\Omega)$ to a function $u$ which takes only the values $\alpha$ and $\beta$, satisfies [21], and fulfills the minimal interface criterion

$$P(E_\alpha, \Omega) \le P(E, \Omega)$$

for every measurable set $E \subset \Omega$ with $|E| = |E_\alpha|$. Moreover, [22] can be improved, and we obtain

$$\min_{u \in W^{1,2}(\Omega)} \mathcal{F}_\varepsilon(u) = \varepsilon 2cP(E_\alpha, \Omega) + o(\varepsilon)$$

Similar results have been proved when the term $|\nabla u|^2$ in [20] is replaced by a general quadratic form like [8], which leads to an anisotropic notion of perimeter.

## Free-Discontinuity Problems

Free-discontinuity problems are minimum problems for functionals composed of two terms of different nature: a bulk energy, typically given by a volume integral depending on the gradient of an unknown function $u$; and a surface energy, given by an integral on the unknown discontinuity surface of $u$. These problems arise in many different fields of science and technology, such as liquid crystals, fracture mechanics, and computer vision.

The prototype of free-discontinuity problems is the minimum problem proposed by David Mumford and Jayant Shah:

$$\min_{(u,K)\in\mathcal{A}} \left\{ \int_{\Omega\setminus K} |\nabla u|^2 \mathrm{d}x + \mathcal{H}^{n-1}(K \cap \Omega) + \int_{\Omega\setminus K} |u-g|^2 \mathrm{d}x \right\} \qquad [24]$$

where $\Omega$ is a bounded open subset of $\boldsymbol{R}^n$, $\mathcal{H}^{n-1}$ denotes the $(n-1)$-dimensional Hausdorff measure, $g \in L^\infty(\Omega)$, and $\mathcal{A}$ is the set of all pairs $(u, K)$ with $K$ compact, $K \subset \boldsymbol{R}^n$, and $u \in C^1(\Omega \setminus K)$.

In the applications to image segmentation problems the dimension $n$ is 2 and the function $g$ represents the grey level of an image. Given a solution $(u, K)$ of the minimum problem [24], the set $K$ is interpreted as the set of the relevant boundaries of the objects in the image, while $u$ provides a smoothed version of the image. The first term in [24] has a regularizing effect, the purpose of the second term is to avoid over-segmentation, while the last term, called "fidelity term," forces $u$ to be close to $g$. Of course, in the applications these terms are multiplied by different coefficients, whose relative values are very important for image segmentation problems, since they determine the strength of the effect of each term. However, the mathematical analysis of the problem can be easily reduced to the case where all coefficients are equal to 1.

To solve [24], it is convenient to introduce a weak formulation of the problem based on the space $\mathrm{GSBV}(\Omega)$ of generalized special functions with bounded variation (see Ambrosio *et al.* (2000)). Without entering into details, here it is enough to say that every $u \in \mathrm{GSBV}(\Omega)$ has, at almost every point, an approximate gradient $\nabla u$ in the sense of geometric measure theory. This is a measurable map from $\Omega$ into $\boldsymbol{R}^n$ which coincides with the usual gradient in the sense of distributions on every open subset $U$ of $\Omega$ such that $u \in W^{1,1}(U)$.

The functional $\mathcal{F} : L^1(\Omega) \to [0, +\infty]$ used for the weak formulation of [24] is defined by

$$\mathcal{F}(u) := \begin{cases} \int_\Omega |\nabla u|^2 \mathrm{d}x + \mathcal{H}^{n-1}(J_u) & \text{if } u \in GSBV(\Omega) \\ +\infty & \text{otherwise} \end{cases} \qquad [25]$$

where $J_u$ is the jump set of $u$, defined in a measure-theoretical way as the set of points $x \in \Omega$ such that

$$\limsup_{\rho\to 0} \frac{1}{|B(x,\rho)|} \int_{B(x,\rho)} |u(y) - a| \, \mathrm{d}y > 0$$

for every $a \in \boldsymbol{R}$.

For every $g \in L^\infty(\Omega)$, the functional

$$\mathcal{F}(u) + \int_\Omega |u-g|^2 \mathrm{d}x$$

is lower semicontinuous and coercive on $L^1(\Omega)$; therefore, the minimum problem

$$\min_{u\in L^1(\Omega)} \left\{ \mathcal{F}(u) + \int_\Omega |u-g|^2 \mathrm{d}x \right\} \qquad [26]$$

has a solution. The connection with the Mumford–Shah problem is given by the following regularity result, proved by Ennio De Giorgi and his collaborators: if $u$ is a solution of [26] and $\overline{J_u}$ is its closure, then $\mathcal{H}^{n-1}(\Omega \cap (\overline{J_u} \setminus J_u)) = 0$, $u \in C^1(\Omega \setminus \overline{J_u})$, and $(u, \overline{J_u})$ is a solution of [24].

Since the numerical treatment of [24] and [26] is quite difficult, Γ-convergence has been used to approximate [26] by means of minimum problems for integral functionals, whose minimizers can be obtained by standard numerical techniques.

Let us consider the nonlocal functionals $\mathcal{F}_\varepsilon : L^1(\Omega) \to [0, +\infty]$ defined by

$$\mathcal{F}_\varepsilon(u) := \begin{cases} \dfrac{1}{\varepsilon} \displaystyle\int_\Omega f\Big(\varepsilon \, \mathrm{Av}(|\nabla u|^2, x, \varepsilon)\Big) \mathrm{d}x & \text{if } u \in W^{1,2}(\Omega) \\ +\infty & \text{otherwise} \end{cases}$$

where

$$\mathrm{Av}(|\nabla u|^2, x, \varepsilon) := \frac{1}{|B(x,\varepsilon)\cap\Omega|}\int_{B(x,\varepsilon)\cap\Omega} |\nabla u(y)|^2 \mathrm{d}y$$

and $f:[0,+\infty)\to[0,+\infty)$ is any increasing continuous function with $f(0)=0, f'(0)=1$, and $f(t)\to 1/2$ as $t\to+\infty$. Then for every sequence $\varepsilon_k\to 0$ the sequence $\mathcal{F}_{\varepsilon_k}$ Γ-converges to $\mathcal{F}$.

Given $g\in L^\infty(\Omega)$, for every $\varepsilon>0$ let $u_\varepsilon$ be a solution of the minimum problem

$$\min_{u\in W^{1,2}(\Omega)}\left\{\frac{1}{\varepsilon}\int_\Omega f\Big(\varepsilon\,\mathrm{Av}(|\nabla u|^2, x,\varepsilon)\Big)\,\mathrm{d}x + \int_\Omega |u-g|^2\mathrm{d}x\right\}$$

From the basic properties of Γ-convergence it follows that there exists a sequence $\varepsilon_k\to 0$ such that $u_{\varepsilon_k}$ converges in $L^1(\Omega)$ to a solution $u$ of [26], so that $(u,\overline{J_u})$ is a solution of [24].

Other approximations by nonlocal functionals use finite differences instead of averages of gradients.

A different approximation can be obtained by using the local functionals $\mathcal{G}_\varepsilon:(L^1(\Omega))^2\to[0,+\infty]$ defined by

$$\mathcal{G}_\varepsilon(u,v) := \begin{cases} \displaystyle\int_\Omega\left[g_{\eta_\varepsilon}(v)|\nabla u|^2 + \frac{\varepsilon}{2}|\nabla v|^2 + \frac{1}{2\varepsilon}h(v)\right]\mathrm{d}x \\ \qquad \text{if } (u,v)\in(W^{1,2}(\Omega))^2 \\ +\infty \quad \text{otherwise}\end{cases}$$

where $g_{\eta_\varepsilon}(t) := \eta_\varepsilon + t^2, 0<\eta_\varepsilon << \varepsilon$, and $h(t) := (1-t)^2$ for $0\le t\le 1$, while $h(t) := +\infty$ otherwise. Let $\mathcal{G}:(L^1(\Omega))^2\to[0,+\infty]$ be the functional defined by

$$\mathcal{G}(u,v) := \begin{cases}\mathcal{F}(u) & \text{if } v=1 \text{ a.e. on } \Omega \\ +\infty & \text{otherwise}\end{cases}$$

where $\mathcal{F}$ is defined [25]. Then for every sequence $\varepsilon_k\to 0$ the sequence $\mathcal{G}_{\varepsilon_k}$ Γ-converges to $\mathcal{G}$.

Given $g\in L^\infty(\Omega)$, for every $\varepsilon>0$ let $(u_\varepsilon, v_\varepsilon)$ be a solution of the minimum problem

$$\min_{(u,v)\in(W^{1,2}(\Omega))^2}\int_\Omega\left[g_{\eta_\varepsilon}(v)|\nabla u|^2 + \frac{\varepsilon}{2}|\nabla v|^2 + \frac{1}{2\varepsilon}h(v) + |u-g|^2\right]\mathrm{d}x \qquad [27]$$

From the basic properties of Γ-convergence it follows that there exists a sequence $\varepsilon_k\to 0$ such that $u_{\varepsilon_k}$ converges in $L^1(\Omega)$ to a solution $u$ of [26], so that $(u,\overline{J_u})$ is a solution of [24].

The approximation of the solutions of [24] based on [27] has been used to construct numerical algorithms for image segmentation.

Free discontinuity problems similar to [24] appear in the mathematical treatment of Griffith's model in fracture mechanics. In this case, $u$ is a vector-valued function, which represents the deformation of an elastic body, the first term in [24] is replaced by a more general integral functional which represents the energy stored in the elastic region $\Omega\backslash K$, while the second term is interpreted as the energy dissipated to produce the crack $K$. An approximation based on minimum problems similar to [27] has been used to construct numerical algorithms to study the process of crack growth in brittle materials.

An important research line, connected with these problems, has been developed in the last years to derive the macroscopic theories of fracture mechanics from the microscopic theories of interatomic interactions. Using Γ-convergence, some theories expressed in the language of continuum mechanics can be obtained as limits of discrete variational models on lattices, as the distance between neighboring points tends to zero.

# Gauge Theoretic Invariants of 4-Manifolds

**S Bauer**, Universität Bielefeld, Bielefeld, Germany

## Introduction

Poincaré duality is fundamental in the study of manifolds. In the case of an orientable closed manifold $X$, this duality appears as an isomorphism

$$\psi : H^k(X;\mathbb{Z}) \to H_{n-k}(X;\mathbb{Z})$$

between integral cohomology and homology. The map $\psi$ is defined by cap product with a chosen orientation class. This article focuses on dimension $n = 4$, where Poincaré duality induces a bilinear form $Q$ on $H_2(X;\mathbb{Z})$ by use of the Kronecker pairing

$$Q(\xi, \xi') = \langle \psi^{-1}(\xi), \xi' \rangle \in \mathbb{Z}$$

One of the outstanding achievements of modern topology, the classification of simply connected topological 4-manifolds by Freedman (1982), can be phrased in terms of the intersection pairing $Q$. Indeed, two simply connected differentiable 4-manifolds $X$ and $X'$ are orientation preservingly homeomorphic if and only if the associated pairings $Q$ and $Q'$ are equivalent. Freedman's classification scheme has been extended to also cover a wide range of fundamental groups, resulting in a fair understanding of topological 4-manifolds (Freedman and Quinn 1990).

When it comes to differentiable 4-manifolds, the situation changes drastically. On the one hand, there is an abundance of topological 4-manifolds which do not admit a differentiable structure at all. On the other hand, there also are topological 4-manifolds supporting infinitely many distinct differentiable structures. A classification of differentiable 4-manifolds up to differentiable equivalence seems out of reach of current technology, even in the most simple cases.

The discrepancy between topological and differentiable 4-manifolds was uncovered by gauge-theoretic methods, applying the concepts of instantons and of monopoles. In order to study these, one has to equip a 4-manifold both with a Riemannian metric and some additional structure: a Hermitian rank-2 bundle in the case of instantons and a spin$^c$-structure in the case of monopoles. Given such data, instantons and monopoles arise as solutions to partial differential equations the gauge equivalence classes of which form finite-dimensional moduli spaces. As it turns out, these moduli spaces encode significant information about the differentiable structures of the underlying 4-manifolds.

A decoding of such information contained in the instanton moduli and in the monopole moduli is achieved through Donaldson invariants and Seiberg–Witten invariants, respectively. This article outlines these theories from a mathematical point of view.

## Instantons and Donaldson Invariants

Let $X$ denote a closed, connected, oriented differentiable Riemannian 4-manifold. We will consider a principal bundle $P$ over $X$ with fiber a compact Lie group $G$ with Lie algebra $\mathfrak{g}$. Connections on $P$ form an infinite-dimensional affine space $\mathcal{A}(P) = A_0 + \Omega^1(X;\mathfrak{g}_P)$ modeled on the vector space of 1-forms with values in the adjoint bundle

$$\mathfrak{g}_P = P \times_{\mathrm{Ad}(G)} \mathfrak{g}$$

The curvature $F_A \in \Omega^2(X, \mathfrak{g}_P)$ of a connection $A$ is a $\mathfrak{g}_P$-valued 2-form satisfying the Bianchi identity $D_A F_A = 0$. The group $\mathcal{G}$ of principal bundle automorphisms of $P$ acts in a natural way on the space of connections with quotient space

$$\mathcal{B}(P) = \mathcal{A}(P)/\mathcal{G}$$

The Yang–Mills functional

$$\mathrm{YM} : \mathcal{A}(P) \to \mathbb{R}_{\geq 0}$$

associates to a connection $A$ the norm square

$$\|F_A\|^2 = -\int_X \mathrm{tr}(F_A \wedge *F_A)$$

of its curvature. Here $*$ denotes the Hodge star operator defined by the metric on $X$ and the orientation. The metric $-\mathrm{tr}: \mathfrak{g} \otimes \mathfrak{g} \to \mathbb{R}$ is $\mathrm{Ad}(G)$-invariant and hence YM is invariant under the

action of $\mathcal{G}$. In particular, the Yang–Mills functional descends to a function on the space $\mathcal{B}(P)$ of a gauge equivalence class of connections.

The Euler–Lagrange equations for the critical points of YM, called Yang–Mills equations, are of the form

$$D_A(*F_A) = 0$$

and can be derived easily from the formula

$$F_{A+a} = F_A + D_A(a) + [a \wedge a]$$

Satisfying the equations

$$D_A(*F_A) = 0 \quad \text{and} \quad D_A(F_A) = 0$$

a Yang–Mills connection is characterized by the fact that it is harmonic with respect to its own Laplacian.

The bundle $\wedge^2 T^*X$ of 2-forms on $X$ decomposes into $(\pm 1)$-eigenbundles of the Hodge operator. This orthogonal splitting leads to a decomposition of curvature forms

$$F_A = F_A^+ + F_A^-$$

into self-dual and anti-self-dual components. The differential form $-(1/4\pi^2)\mathrm{tr}(F_A \wedge F_A)$ represents a characteristic class of the principal bundle $P$. In particular, the integral

$$\begin{aligned}\kappa(P) &= -\int_X \mathrm{tr}(F_A \wedge F_A) \\ &= \|F_A^+\|^2 - \|F_A^-\|^2\end{aligned}$$

is independent of the connection A. The Yang–Mills functional therefore is bounded

$$\mathrm{YM}(P) \geq |\kappa(P)|$$

and attains this minimum at connections $A$ which satisfy the equation

$$*F_A = \pm F_A$$

Such connections are either self-dual, anti-self-dual or both, that is, flat, depending on whether $\kappa(P)$ is negative, positive, or zero. The moduli space of instantons on $P$ is the subset of minima of the Yang–Mills functional

$$M(P) = \mathrm{YM}^{-1}(|\kappa(P)|) \subset \mathcal{B}(P)$$

The moduli space thus consists of gauge equivalence classes of connections which are either self-dual or anti-self-dual. Donaldson theory indeed considers anti-self-dual connections on principal bundles with structure group $\mathrm{PU}(2) = \mathrm{SO}(3)$.

The Hodge $*$ operator induces a decomposition of the second cohomology

$$H^2(X) = H^2_+(X) \oplus H^2_-(X)$$

into $(\pm 1)$-eigenspaces of dimension $b^+$ and $b^-$. Unless specified differently, cohomology groups are meant with real coefficients. In order to simplify the exposition, we will assume $X$ to be simply connected. The Donaldson invariants then are defined if $b^+$ is odd and greater than 1.

A "homology orientation" consists of an orientation of $H^2_+(X)$ and an integral homology class $c \in H_2(X; \mathbb{Z})$. The Donaldson invariant $D_{X,c} = D_c$ is defined after fixing such a homology orientation. It is a linear function

$$D_c : A(X) \to \mathbb{R}$$

where $A(X)$ is the graded algebra

$$A(X) = \mathrm{Sym}_*(H_0(X) \oplus H_2(X))$$

in which $H_i(X)$ has degree $(1/2)(4 - i)$. The significance of $D_c$ is its functoriality

$$D_{X', f(c)}(f(\alpha)) = D_{X,c}(\alpha)$$

under diffeomorphisms $f : X \to X'$ which preserve both orientation and homology orientation. Switching the orientation of $H^2_+(X; \mathbb{R})$ reverses the sign of $D_c$. Similarly,

$$D_{c'} = (-1)^{((c-c')/2)^2} D_c$$

if $c - c' \in 2H_2(X, \mathbb{Z}) \subset H_2(X; \mathbb{Z})$.

The construction of this invariant makes use of the following facts:

1. An SO(3) principal bundle $P$ over $X$ is determined by its first Pontrjagin number $p_1(P)$ and its Stiefel–Whitney class $w_2(P) \in H^2(X; \mathbb{Z}/2)$. As $X$ is simply connected, this Stiefel–Whitney class admits integer lifts. Let $c$ be such a lift and let $c^2$ be shorthand for the intersection pairing $Q(c, c)$. A pair $(p_1, w_2)$ is realized by a principal bundle provided it satisfies the relation $p_1 \equiv c^2$ modulo 4.

2. If $b^+$ is nonvanishing, then for generic metrics on $X$, the moduli space $M(P)$ is a manifold of dimension

$$-2p_1(P) - 3(1 + b^+)$$

This follows from a transversality theorem whose main ingredient in the Sard–Smale theorem. The dimension is computed by use of the Atiyah–Singer index theorem: to an anti-self-dual connection $A$ on $P$ there is an associated elliptic complex

$$\begin{aligned}0 \to \Omega^0(X; \mathfrak{g}_P) &\xrightarrow{D_A} \Omega^1(X; \mathfrak{g}_P) \\ &\xrightarrow{D_A^+} \Omega^2_+(X; \mathfrak{g}_P) \to 0\end{aligned}$$

where $\Omega^i(X; \mathfrak{g}_P)$ denotes $\mathfrak{g}_P$-valued $i$-forms on $X$. This complex describes the tangential structure of

the moduli space at the equivalence class of $A$. The space $\Omega^1(X;\mathfrak{g}_P)$ is the tangent space of $\mathcal{A}(P)$ at $A$, $\Omega^0(X;\mathfrak{g}_P)$ is the tangent space of the group $\mathcal{G}$ at the identity, and $D_A$ is the differential of the orbit map. The differential operator $D_A^+$ is the linearization of the anti-self-duality map

$$a \longmapsto F_{A+a}^+ = D_A^+(a) + [a \wedge a]^+$$

3. The moduli space $M(P)$ can be oriented if it is a manifold. The orientation depends on an orientation of $H_+^2(X)$ and on a U(2)-principal bundle which has $P$ as its PU(2)-quotient bundle. It is determined by an integer lift of $w_2(P)$. The elliptic complex above then can be compared with a corresponding elliptic complex where the differentials are given by a complex Dirac operator. This leads to an almost-complex structure on the tangent space for each point in the moduli space and in particular to an orientation on the moduli space itself.

4. Over the product $M(P)\times X$ there is a universal PU(2)-bundle $\mathbb{P}$ with first Pontrjagin class $p_1(\mathbb{P})$. Taking slant product with the class $-(1/4)p_1(\mathbb{P})$ results in a homomorphism

$$\mu : H_i(X) \to H^{4-i}(M(P))$$

5. The moduli space $M(P)$ in general is noncompact. There is an Uhlenbeck compactification $\overline{M(P)}$ describing "ideal instantons." Such an ideal instanton consists of an element $(x_1,\ldots,x_n)\in \mathrm{Sym}_n(X)$ and an anti-self- dual connection $A'$ on the principal bundle $P'$ on $X$ with $w_2(P')=w_2(P)$ for which the equality

$$p_1(P') - p_1(P) = 4n$$

of Pontrjagin numbers holds. Uhlenbeck's compactness theorem describes what happens if a sequence of anti-self-dual connections has no convergent subsequence: after passing to a subsequence, the sequence converges to an anti-self-dual connection on the restriction of $P$ to $X\backslash\{x_1,\ldots,x_n\}$. This limit connection extends to a connection $A'$ on the principal bundle $P'$. The functions $|F_{A_n}|^2$ on $X$ converge to the measure

$$|F_{A'}|^2 + \sum_{i=1}^{n} 8\pi^2\delta_{x_i}$$

The compactification $\overline{M(P)}$ is a stratified space and not usually a manifold. If $w_2(P)\neq 0$, then the singular set of codimension at least 2 and thus the space $\overline{M(X)}$ carries a fundamental class. In the case $w_2(P)=0$, such a fundamental class in general can only be defined if $-p_1(P) > 4 + 3b^+$. In practice, this problem can be circumvented by blowing up $X$ and considering bundles with $w_2(P)\neq 0$ over the connected sum $X\#\overline{\mathbb{C}P}^2$. Note that the complex projective plane $\mathbb{C}P^2$ as a complex manifold carries a natural orientation. The notation $\overline{\mathbb{C}P}^2$ indicates a reversed orientation.

6. The classes $\mu(\alpha)\in H^2(M(P))$ for $\alpha \in H^2(X)$ extend over the compactification. The same holds for the class $\mu(x)$, where $x\in H_0(X;\mathbb{Z})$ is the generator corresponding to the orientation, as long as $w_2(P)\neq 0$. Otherwise, there are certain dimension restrictions. However, the same blow-up trick as mentioned above allows to handle the case $w_2(P)=0$ as well.

Now fix an element $c\in H_2(X;\mathbb{Z})$ and let

$$M_c = \bigsqcup_{d\geq 0} \overline{M(P_{c,d})}$$

denote the disjoint union of all moduli spaces of anti-self-dual connections on principal PU(2)-bundles $P_{c,d}$ whose second Stiefel–Whitney class is Poincaré-dual to $c$ modulo 2 and whose Pontrjagin number equals $-d-(3/2)(b^+ + 1)$.

Our assumption of $b^+$ being odd corresponds to the fact that the dimension $2d$ of the moduli space $M(c,d)$ is even and congruent to $-c^2 + (1/2)(1+b^+)$ modulo 4. Neglecting the difficulties in the case $w_2(P)=0$ mentioned above, we may use the cup product on $H^*(M_c)$ to extend $\mu$ to an algebra homomorphism

$$\mu : A(X) \to H^*(M_c)$$

The Donaldson invariant $D_c$ is nonzero only on elements $z$ of $A(X)$ whose total degree $d$ is congruent to $-c^2 + (1/2)(1+b^+)$ modulo 4. For such an element it is defined by

$$D_c(z) = \langle \mu(z), \overline{M(P_{c,d})}\rangle = \int_{\overline{M(P_{c,d})}} \mu(z)$$

The Donaldson series $\mathbb{D}_c$ is defined as a formal power series

$$\mathbb{D}_c(\alpha) = D_c(\exp(\hat{\alpha})) = \sum_{d=0}^{\infty} \frac{D_c(\hat{\alpha}^d)}{d!}$$

for $\alpha\in H_2(X)$ and $\hat{\alpha} = (1+(x/2))\alpha$.

## Computations and Structure Theorems

The first results about these invariants are due to S Donaldson. He proved both a vanishing and a nonvanishing theorem (Donaldson and Kronheimer 1990):

**Theorem 1** *If both $b^+(X)>0$ and $b^+(Y)>0$, then all Donaldson invariants vanish for the connected sum $X\#Y$.*

**Theorem 2** *If c represents a divisor on a complex algebraic surface X and $\alpha$ represents an ample divisor, then*

$$D_c(\alpha^r) \neq 0 \quad \text{for } r \gg 0$$

The second theorem is a consequence of the fact that in the case of an algebraic surface the instanton moduli can be described in algebraic geometric terms: the moduli space $\overline{M(P_{c,d})}$ associated to the metric induced from the Fubini–Study metric on $\mathbb{C}P^n$ by an embedding $X \hookrightarrow \mathbb{C}P^n$ carries the structure of a projective variety. This variety is reduced and of complex dimension $d$, as soon as $d$ is large enough. Furthermore, $\mu(d)$ is the first Chern class of an ample line bundle.

The translation of instanton moduli into algebraic geometry uses two steps: suppose the first Chern class of a U($r$)-principal bundle $P$ on a Kähler surface is also the first Chern class of a holomorphic line bundle. Then the absolute minima of the Yang–Mills functional are achieved by Hermite–Einstein connections. These are connections for which the Ricci curvature is a constant multiple of the identity. The second step, the translation from differential geometry into algebraic geometry, is called the Kobayashi–Hitchin correspondence, which again was proved by Donaldson.

The Donaldson invariants have been computed for a number of 4-manifolds. A simply connected 4-manifold is said to have simple type, if the relation

$$D_c(x^2 z) = 4D_c(z)$$

is satisfied by its Donaldson invariant for all $z \in A(X)$ and $c \in H_2(X;\mathbb{Z})$. It is known that this simple type condition holds for many 4-manifolds. Indeed, it is an open question whether there are 4-manifolds which are not of simple type. For manifolds of simple type the Donaldson series $\mathbb{D}_c$ completely determines the Donaldson invariant $D_c$. A main result is due to Kronheimer and Mrowka (1995):

**Theorem 3** *Let X be a simply connected 4-manifold of simple type. Then, there exist finitely many basic classes $\kappa_1, \ldots, \kappa_n \in H_2(X;\mathbb{Z})$ such that*

$$\mathbb{D}_c = \exp(Q/2) \sum_{i=1}^{n} (-1)^{(c^2-\kappa_i c)/2} a_i \exp(\kappa_i)$$

*as analytic functions on $H_2(X)$. The numbers $a_i$ are rational and each basic class $\kappa_i$ is characteristic, that is, it satisfies $\alpha^2 \equiv Q(\alpha, \kappa_i)$ modulo 2 for all $\alpha \in H_2(X;\mathbb{Z})$. The homology class $\kappa_i$ in this formula acts on an arbitrary homology class by intersection.*

The geometric significance of the basic classes is underlined by the following theorem (Kronheimer and Mrowka 1995):

**Theorem 4** *If $\alpha \in H_2(X:\mathbb{Z})$ is represented by an embedded surface of genus g with self-intersection $\alpha^2 \geq 2$, then for each basic class $\kappa$ the following adjunction inequality is satisfied:*

$$2g - 2 \geq \alpha^2 + |Q(\kappa, \alpha)|$$

There are many 4-manifolds for which the Donaldson series have been computed (Friedman and Morgan 1997). The basic classes for complete intersections, for example, are the canonical divisor and its negative. Another example is given by elliptic surfaces. Let $E(n;p,q)$ be a minimal elliptic surface, that is, a holomorphic surface admitting a holomorphic map to $\mathbb{C}P^1$ with generic fiber $f$ an elliptic curve. For any numbers $n, p$, and $q$ with $p < q$ coprime, there exists such a simply connected elliptic surface with Euler characteristic $12n$ and two multiple fibers of multiplicity $p$ and $q$, respectively. The Donaldson series of $E(n;p,q)$ for $c = 0$ then is given by

$$\mathbb{D} = \exp\left(\frac{Q}{2}\right) \frac{\sinh^n(f)}{\sinh(f/p)\sinh(f/q)}$$

Another important formula relates the Donaldson series $\mathbb{D}$ a manifold $X$ of simple type and the Donaldson series $\hat{\mathbb{D}}$ of the blow-up $X \# \overline{\mathbb{C}P^2}$:

$$\hat{\mathbb{D}}_c = \mathbb{D}_c \cdot \exp(-e^2/2)\cosh(e)$$
$$\hat{\mathbb{D}}_{c+e} = -\mathbb{D}_c \cdot \exp(-e^2/2)\sinh(e)$$

Here $e \in H_2(\overline{\mathbb{C}P^2};\mathbb{Z})$ denotes a generator. Indeed, a more general blow-up formula is known which relates the Donaldson invariants for $X$ and its blow-up even in case $X$ is not of simple type. This formula, due to Fintushel and Stern (1996), involves Weierstraß sigma-functions.

The instanton moduli space carries nontrivial information about 4-manifolds even in the case $b^+(X) \leq 1$. However, one has to deal with singularities in the moduli space. Let us first consider the case $b^+(X) = 0$. If the intersection form on $X$ is negative definite, the instanton moduli spaces in general are bound to have singularities. Indeed, Donaldson examined the case with the Pontrjagin number $p_1(P) = -4$ and $w_2(P) = 0$. In this case, the moduli space for a generic metric on $X$ will be an orientable smooth manifold except at isolated singular points. The singularities are cones over $\overline{\mathbb{C}P^2}$ and they correspond to reducible connections, that is, reductions of the structure group of $P$ to U(1). These reductions are in bijective correspondence to pairs $\pm\alpha \in H_2(X;\mathbb{Z})$ with $\alpha^2 = -1$. The Uhlenbeck compactification of the moduli space thus leads to an oriented cobordism between $X$ and the disjoint union $\sqcup_\alpha \overline{\mathbb{C}P^2}$ over all pairs $\pm\alpha$ in $H_2(X;\mathbb{Z})$ of square –1. As the signature of a

manifold is an invariant of oriented cobordism, there have to be $b^-$ many pairs $\pm\alpha$ of square (–1) in $H_2(X;\mathbb{Z})$ and, in particular, the intersection form $Q$ is represented by the negative of the identity matrix (Donaldson 1983):

**Theorem 5** *The intersection form on a differentiable manifold with negative-definite intersection form is diagonal.*

Indeed, from rank 8 on there are lots of definite unimodular forms which are not diagonal. By Freedman's (1982) classification, any unimodular form is realized as the intersection form of a simply connected topological manifold. This theorem shows that most of these manifolds do not support differentiable structures.

The case $b^+(X) = 1$ is also interesting. Here, the moduli space is a smooth manifold for a generic metric, giving rise to Donaldson invariants. However, over a smooth path of metrics, there is in general no smooth cobordism of moduli spaces. So the invariants depend on the chosen metric. The singularities in the cobordisms again correspond to classes in $H_2(X;\mathbb{Z})$ with negative square. An analysis of these singularities leads to wall-crossing formulas describing how different choices of the metric do affect Donaldson invariants. The case of $\mathbb{C}P^2$ is special, as there are no elements of negative square in $H_2(\mathbb{C}P^2;\mathbb{Z})$. The Donaldson invariants for $\mathbb{C}P^2$ as well as the wall-crossing formulas turn out to be closely related to modular forms (Göttsche 2000).

## Monopoles and Seiberg–Witten Invariants

A spin$^c$-structure on an oriented Riemannian 4-manifold is a Spin$^c$(4)-principal bundle $P$ projecting to the orthonormal tangent frame bundle $\overline{P}$ over $X$ through the group homomorphism Spin$^c(4) \to SO(4)$ with kernel U(1). The group $H^2(X;\mathbb{Z})$ acts freely and transitively on the set of all spin$^c$-structures. A spin$^c$-connection is a lift to $P$ of the Levi-Civita connection on $\overline{P}$. Fixing a background spin$^c$-connection $A_0$, the monopole map

$$\mu : (A, \phi) \longmapsto \left(\mathcal{D}_A\phi, F_A^+ - \phi\phi_\circ^*, d^*a\right)$$

is defined (Witten 1994) for spin$^c$-connections $A \in A_0 + \Omega^1(X; \mathrm{i}\mathbb{R})$ and positive spinors $\phi$. Here, $\mathcal{D}_A$ denotes the complex Dirac operator associated to $A$ and $d^*a$ for $a \in \Omega^1(X;\mathrm{i}\mathbb{R})$ is the adjoint of the de Rham differential on forms. The section $\phi\phi_\circ^*$ of the traceless endomorphism bundle of positive spinors is viewed as a self-dual 2-form on $X$.

In case the first Betti number vanishes, this map – after suitable Sobolev completion – becomes a map between Hilbert spaces $\mu : \mathcal{A} \to \mathcal{C}$ which is a compact deformation of a linear Fredholm map. The Weitzenböck formula can be used to show that preimages under $\mu$ of bounded sets in $\mathcal{C}$ are bounded in $\mathcal{A}$. Furthermore, $\mu$ is U(1)-equivarant, where U(1) acts by complex multiplication on spinors and trivially on forms. If $b_1(X) > 0$, the monopole map is a map between Hilbert space bundles over the torus $H^1(X)/H^1(X;\mathbb{Z})$. These properties of the monopole map allow for an interpretation in terms of stable homotopy (Bauer 2004):

**Theorem 6** *If the first Betti number of X vanishes, then $\mu$ defines an element*

$$[\mu] \in \pi_i^{U(1)}(S^0)$$

*in an equivariant stable homotopy group of spheres. The index $i = \mathrm{ind}\,\mathcal{D}_A - H_+^2(X)$ as an element of the real representation ring* RO(U(1)) *is determind by the analytic index of the linearization of $\mu$.*

In the case $b^+(X) > 1$, these equivariant stable homotopy groups can be identified with nonequivariant stable cohomotopy groups $\pi_{st}^{b^+-1}(\mathbb{C}P^{d-1})$. Here, $d$ denotes the index of the complex Dirac operator ind $\mathcal{D}_A$. Fixing an orientation of $H_+^2(X)$ results in a Hurewicz homomorphism

$$h : \pi_{st}^{b^+-1}(\mathbb{C}P^{d-1}) \to H^{b^+-1}(\mathbb{C}P^{d-1};\mathbb{Z})$$

If $b^+(X)$ is odd, the image

$$h([\mu]) = SW(X)t^{(b^+-1)/2}$$

is an integer multiple of a power of the generator $t \in H^2(\mathbb{C}P^{d-1};\mathbb{Z})$. This integer SW($X$) is known as the Seiberg–Witten invariant (Witten 1994).

This invariant alternatively can be defined by considering the moduli space $M(a) = \mu^{-1}(a)$. Assuming $b^+ > 0$, this is a smooth oriented manifold with a free U(1)-action for generic $a \in \Omega^1(X; i\mathbb{R})$. The Seiberg–Witten invariant is the characteristic number obtainable by these data. In general, the stable homotopy invariant $[\mu]$ encodes global information about the monopole map, which cannot be recovered by only considering the moduli space. In case the spin$^c$-structure is associated to an almost-complex structure, however, there is a fortunate coincidence: the Hurewicz homomorphism in this case is an isomorphism. So for almost-complex spin$^c$-structures, the invariants $[\mu]$ and SW carry the same information.

The Seiberg–Witten invariants turn out to be directly computable for Kähler manifolds and to some degree also for symplectic manifolds (Taubes 1994). Indeed,

the following theorem follows from arguments of Witten and of Taubes:

**Theorem 7** *Let X be a 4-manifold with* $b^+ > 1$ *and* $b_1 = 0$ *which can be equipped with a Kähler or a symplectic structure. If* $[\mu]$ *is nonvanishing for a spin*$^c$*-structure on X, then the spin*$^c$*-structure is associated to an almost-complex structure. For the canonical spin*$^c$*-structure on X the Seiberg–Witten invariant is* $\pm 1$.

Seiberg–Witten invariants and Donaldson invariants are closely related: Witten gave physical arguments that an equality of the form

$$\mathbb{D} = 2^k \exp(Q/2) \cdot \sum_\alpha \mathrm{SW}(\alpha) \exp(\alpha)$$

should hold for the Donaldson series for $c = 0$ of a simply connected manifold of simple type. Here, $\alpha \in H^2(X;\mathbb{Z})$ denotes the first Chern class of the complex determinant line bundle. This first Chern class characterizes spin$^c$-structures in the simply connected case. The number $k$ is related to the signature $\sigma$ and the Euler characteristic $\chi$ of the manifold $X$ by the formula

$$4k = 11\sigma + 7\chi + 2$$

A mathematical proof of this formula is known in special cases (Feehan and Leness 2003).

As is the case for Donaldson invariants, the Seiberg–Witten invariants vanish for connected sums $X\#Y$ if both $b^+(X) > 0$ and $b^+(Y) > 0$ holds. This is not the case for the stable homotopy refinement as follows from the following theorem (Bauer 2004).

**Theorem 8** *For a connected sum* $X\#Y$ *of 4-manifolds the stable equivariant homotopy invariants are related by smash product*

$$[\mu_{X\#Y}] = [\mu_X] \wedge [\mu_Y]$$

As an example application, consider connected sums of elliptic surfaces of the form $E(2n; p, q)$. Now suppose $X$ and $X'$ are each connected sums of at most four copies of such elliptic surfaces. Then $X$ and $X'$ are diffeomorphic if and only if the summands were already diffeomorphic. This contrasts to the fact that the connected sum $E(2n; p, q)\#\mathbb{C}P^2$ is diffeomorphic to a connected sum of $4n - 1$ copies of $\mathbb{C}P^2$ and $20n - 1$ copies of $\overline{\mathbb{C}P}^2$, independently of $p$ and $q$.

As a final application, we consider the case of spin manifolds. If the manifold $X$ is spin, then the intersection form $Q$ is even, that is, $Q(\alpha, \alpha) = 0$ mod 2 for $\alpha \in H_2(X, \mathbb{Z})$. According to Rochlin's theorem, the signature of a spin 4-manifold is divisible by 16. The monopole map $\mu$ for the spin structure admits additional symmetry. It is Pin(2)-equivariant. The nonabelian group Pin(2) appears as the normalizer of the maximal torus SU(2). Methods from equivariant $K$-theory lead to Furuta's (2001) theorem:

**Theorem 9** *Let X be a spin 4-manifold. Then*

$$\chi(X) > \tfrac{5}{4}|\sigma(X)|$$

## Manifolds with Boundary

Both Donaldson invariants and Seiberg–Witten invariants to some extent satisfy formal properties which fit into a general conceptual framework known as "topological quantum field theories (TQFTs)." Such a TQFT in $3+1$ dimensions is a functor on the cobordism category of oriented 3-manifolds to the category of, say, vector spaces over a ground field: it assigns to an oriented 3-manifold $Y$ a vector space $h(Y)$. To a disjoint union it assigns

$$h(Y_1 \sqcup Y_2) = h(Y_1) \otimes h(Y_2)$$

Reversing orientation corresponds to dualizing

$$h(\overline{Y}) = h(Y)^*$$

Viewing a four-dimensional manifold $X$ with boundary $\partial X = \overline{Y}_1 \sqcup Y_2$ formally as a morphism from $Y_1$ to $Y_2$, this functor associates to $X$ a homomorphism

$$\mathcal{H}(X) : h(Y_1) \to h(Y_2)$$

that is, an element $\mathcal{H}(X) \in h(\overline{Y}_1 \sqcup Y_2)$. The most important feature is the composition law

$$\mathcal{H}(X_1 \cup_Y X_2) = \mathcal{H}(X_2) \circ \mathcal{H}(X_1)$$

So if a cobordism $X$ from $Y_1$ to $Y_2$ can be decomposed as a cobordism $X_1$ from $Y_1$ to an intermediate submanifold $Y$ and a cobordism $X_2$ from $Y$ to $Y_2$, then the homomorphism $\mathcal{H}(X)$ can be computed from $\mathcal{H}(X_1)$ and $\mathcal{H}(X_2)$ as their composition.

Donaldson invariants and Seiberg–Witten invariants fit neatly into the framework of a TQFT if one restricts to 3-manifolds which are disjoint unions of homology 3-spheres. In both the instanton and the monopole case, the vector spaces $h(Y)$ are Floer homology groups. The construction of Floer homology carries the Morse theory description of the homology of a finite-dimensional manifold over to an infinite-dimensional setting. In the instanton case, one considers the Chern–Simons function

$$\mathrm{CS}(a) = -\frac{1}{8\pi^2}\int_Y \mathrm{tr}\left(a \wedge \mathrm{d}a + \frac{2}{3} a \wedge a \wedge a\right)$$

This function is defined on the space of gauge equivalence classes of SU(2)-connections on $Y$. Note that for a homology 3-sphere, any SU(2) or PU(2)

principal bundle over $Y$ is trival. Choosing a trivialization, a connection becomes identified with a Lie-algebra-valued 1-form $a$. Critical points for the Chern–Simons functional lead to generaters in a chain complex the homology of which then gives the Floer groups. Such critical points correspond to flat connections on $Y$. The Floer homology groups $\mathrm{HF}_*(Y)$ are $\mathbb{Z}/8$-graded in the SU(2) case and $\mathbb{Z}/4$-graded in the SO(3) case. If $X$ is a 4-manifold with $b_1(X)=0$ and $b^+(X)>1$ and such that the boundary $\partial X$ is a disjoint union of homology 3-spheres, then the Donaldson invariants are linear maps

$$D_c : A(X) \longrightarrow HF_*(\partial X)$$

These invariants satisfy a composition law on the subring of $A(X)$ generated by two-dimensional homology classes (Donaldson 2002).

In the monopole case, one considers a Chern–Simons–Dirac functional

$$\mathrm{CSD}(a,\psi) = \frac{1}{2}\left(\int_Y \langle\psi, \mathcal{D}_a\psi\rangle \mathrm{dvol} - \int_Y a\wedge \mathrm{d}a\right)$$

and obtains integer graded Floer homology groups. Details and proofs of the relevant composition laws are announced.

# Gauge Theories from Strings

**P Di Vecchia**, Nordita, Copenhagen, Denmark

## Introduction

One of the most exciting properties of string theory, which led ten years ago to the formulation of the M theory as the unique theory unifying all interactions, has been the discovery that type II theories, besides a perturbative spectrum consisting of closed-string excitations, contain also a nonperturbative one consisting of "solitonic" $p$-dimensional objects called D$p$ branes. They are characterized by two important properties. They are coupled to closed-string states as the graviton, the dilaton, and the R–R $(p+1)$-form potential, and are described by a classical solution of the low-energy string effective action. Their dynamics is, on the other hand, described by open strings having the endpoints attached to their world volume and therefore satisfying Dirichlet boundary conditions in the directions transverse to their world volume. This is the reason why they are called D (Dirichlet) branes. Since the lightest open-string excitation corresponds to a gauge field, they have a gauge theory living on their world volume. This twofold description of D-branes has opened the way to study both the perturbative and nonperturbative properties of the gauge theory living on their world volume from their dynamics in terms of closed strings. With the addition of the decoupling limit, these two properties have led to the Maldacena (1998) conjecture of the equivalence between the maximally supersymmetric and conformal $\mathcal{N}=4$ super Yang–Mills and type IIB string theory on $\mathrm{AdS}_5 \times S^5$.

They have also been successfully applied to less supersymmetric and nonconformal gauge theories

that live on the world volume of fractional and wrapped branes. For general reviews of various approaches see Bertolini *et al.* (2000), Herzog *et al.* (2001), Bertolini (2003), Bigazzi *et al.* (2002), and Di Vecchia and Liccardo (2003). Also in these cases, one has constructed a classical solution of the supergravity equations of motion corresponding to these more sophisticated branes. These equations contain not only the supergravity fields present in the bulk ten-dimensional action but also boundary terms corresponding to the location of the branes. It turns out that in general the classical solution develops a naked singularity of the repulson type at short distances from the branes. This means that at short distances, it does not provide a reliable description of the branes. In the case of $\mathcal{N}=2$ supersymmetry, this can be explicitly seen because of the appearance of an enhançon located at distances slightly higher than the naked singularity (Johnson *et al.* 2000). The enhançon radius corresponds, in supergravity, to the distance where a brane probe becomes tensionless, and, in the gauge theory living on the branes, to the dynamically generated scale $\Lambda_{\mathrm{QCD}}$. Then, since short distances in supergravity correspond to large distances in the gauge theory, as implied by holography, the presence of the enhançon and of the naked singularity does not allow to get any information on the nonperturbative large-distance behavior of the gauge theory living on the D-branes. Above the radius of the enhançon, instead, the classical solution provides a good description of the branes and therefore it can be used to get information on the perturbative behavior of the gauge theory. This shows that, if we want to use the D-branes for studying the nonperturbative properties of the gauge theory living on their world volume, we must construct a classical solution that has no naked singularity at short distances in supergravity. We will see in a specific example that it will be possible to deform the classical solution, eliminating the naked singularity, and use it to describe nonperturbative properties as the gaugino condensate.

In this article, we review some of the results obtained by using fractional D3 branes of some orbifold and D5 branes wrapped on 2-cycles of some Calabi–Yau manifold. The analysis of the supersymmetric gauge theories living on the world volume of these D-branes will be based on the gauge/gravity relations that relate the gauge coupling constant and the $\theta$-angle to the supergravity fields (see, e.g., reference Di Vecchia *et al.* (2005) for a derivation of them):

$$\frac{4\pi}{g_{\mathrm{YM}}^2} = \frac{1}{g_s(2\pi\sqrt{\alpha'})^2}\int_{\mathcal{C}_2} \mathrm{d}^2\xi \mathrm{e}^{-\phi}\sqrt{\det(G_{AB}+B_{AB})} \qquad [1]$$

and

$$\theta_{\mathrm{YM}} = \frac{1}{2\pi\alpha' g_s}\int_{\mathcal{C}_2}(C_2 + C_0 B_2) \qquad [2]$$

where $\mathcal{C}_2$ is the 2-cycle where the branes are wrapped.

In the next section, we will describe the case of the fractional D3 branes of the orbifold $\mathbb{C}^2/\mathbb{Z}_2$ and show that the classical solution corresponding to a system of $N$ D3 and $M$ D7 branes reproduces the perturbative behavior of $\mathcal{N}=2$ super-QCD. Then, we will consider D5 branes wrapped on 2-cycles of a Calabi–Yau manifold described by the Maldacena–Núñez classical solution (Maldacena and Núñez 2001, Chamseddine and Volkov 1997) and show that in this case we are able to reproduce the phenomenon of gaugino condensate and to construct the complete $\beta$-function of $\mathcal{N}=1$ super Yang–Mills.

## Fractional D3 Branes of the Orbifold $\mathbb{C}^2/\mathbb{Z}_2$ and $\mathcal{N}=2$ Super-QCD

In this section, we consider fractional D3 and D7 branes of the noncompact orbifold $\mathbb{C}^2/\mathbb{Z}_2$ in order to study the properties of $\mathcal{N}=2$ super-QCD. We group the coordinates of the directions $(x^4,\ldots,x^9)$ transverse to the world volume of the D3 brane where the gauge theory lives, into three complex quantities: $z_1 = x^4 + \mathrm{i}x^5$, $z_2 = x^6 + \mathrm{i}x^7$, $z_3 = x^8 + \mathrm{i}x^9$. The nontrivial generator $h$ of $Z_2$ acts as $z_2 \to -z_2$, $z_3 \to -z_3$, leaving $z_1$ invariant. This orbifold has one fixed point, located at $z_2 = z_3 = 0$ and corresponding to a vanishing 2-cycle. Fractional D3 branes are D5 branes wrapped on the vanishing 2-cycle and therefore are, unlike bulk branes, stuck at the orbifold fixed point. By considering $N$ fractional D3 and $M$ fractional D7 branes of the orbifold $\mathbb{C}^2/\mathbb{Z}_2$, we are able to study $\mathcal{N}=2$ super-QCD with $M$ hypermultiplets. In order to do that, we need to determine the classical solution corresponding to the previous brane configuration. For the case of the orbifold $\mathbb{C}^2/Z_2$, the complete classical solution is found in Bertolini *et al.* (2002b); see also references therein and Bertolini *et al.* (2000) for a review on fractional branes. In the following, we write it explicitly for a system of $N$ fractional D3 branes with their world volume along the directions $x^0, x^1, x^2$, and $x^3$ and $M$ fractional D7 branes containing the D3 branes in their world volume and having the remaining four world-volume directions along the orbifolded ones. The metric,

the 5-form field strength, the axion, and the dilaton are given by

$$ds^2 = H^{-1/2}\eta_{\alpha\beta}\,dx^\alpha\,dx^\beta + H^{1/2}\left(\delta_{\ell m}\,dx^\ell\,dx^m + e^{-\phi}\delta_{ij}\,dx^i\,dx^j\right) \quad [3]$$

$$\widetilde{F}_{(5)} = d\left(H^{-1}\,dx^0 \wedge \cdots \wedge dx^3\right) + {}^*d\left(H^{-1}\,dx^0 \wedge \cdots \wedge dx^3\right) \quad [4]$$

$$\tau \equiv C_0 + ie^{-\phi} = i\left(1 - \frac{Mg_s}{2\pi}\log\frac{z}{\epsilon}\right)$$
$$z \equiv x^4 + ix^5 = ye^{i\theta} \quad [5]$$

where the self-dual field strength $\tilde{F}_{(5)}$ is given in terms of the NS–NS and R–R 2-forms $B_2$ and $C_2$ and of the 4-form potential $C_4$ by $\tilde{F}_{(5)} = dC_4 + C_2 \wedge dB_2$. The warp factor $H$ is a function of the coordinates $(x^4, \ldots, x^9)$ and $\epsilon$ is an infrared cutoff. We denote by $\alpha$ and $\beta$ the four directions corresponding to the world volume of the fractional D3 brane, by $\ell$ and $m$ those along the four orbifolded directions $x^6$, $x^7$, $x^8$, and $x^9$, and by $i$ and $j$ the directions $x^4$ and $x^5$ that are transverse to both the D3 and the D7 branes. The twisted fields are instead given by $B_2 = \omega_2 b, C_2 = \omega_2 c$ where $\omega_2$ is the volume form of the vanishing 2-cycle and

$$be^{-\phi} = \frac{(2\pi\sqrt{\alpha'})^2}{2}\left[1 + \frac{2N - M}{\pi}g_s\log\frac{y}{\epsilon}\right]$$
$$c + C_0 b = -2\pi\alpha'\theta g_s(2N - M) \quad [6]$$

The expression of $H$ (Kirsch and Vaman 2005) shows that the previous solution has a naked singularity of the repulson type at short distances. On the other hand, if we use a brane probe approaching from infinity the stack of branes, described by the previous classical solution, it can also be seen that the tension of the probe vanishes at a distance that is larger than that of the naked singularity. The point where the probe brane becomes tensionless is called "enhançon" (Johnson *et al.* 2000) and at this point the classical solution does not describe anymore the stack of fractional branes.

Let us now use the gauge/gravity relations given in the introduction, to determine the coupling constants of the world-volume theory from the supergravity solution. In the case of fractional D3 branes of the orbifold $\mathbb{C}^2/\mathbb{Z}_2$, that is characterized by one single vanishing 2-cycle $\mathcal{C}_2$, the gauge coupling constant given in eqn [1] reduces to

$$\frac{1}{g_{YM}^2} = \frac{1}{4\pi g_s(2\pi\sqrt{\alpha'})^2}\int_{\mathcal{C}_2} e^{-\phi}B_2 \quad [7]$$

By inserting the classical solution in eqns [7] and [2], we get the following expressions for the gauge coupling constant and the $\theta_{YM}$ angle (Bertolini *et al.* 2002b):

$$\frac{1}{g_{YM}^2} = \frac{1}{8\pi g_s} + \frac{2N - M}{16\pi^2}\log\frac{y^2}{\epsilon^2}$$
$$\theta_{YM} = -\theta(2N - M) \quad [8]$$

Notice that the gauge coupling constant appearing in the previous equation is the "bare" gauge coupling constant computed at the scale $m \sim y/\alpha'$, while the square of the bare gauge coupling constant computed at the cutoff $\Lambda \sim \epsilon/\alpha'$ is equal to $8\pi g_s$.

In the case of an $\mathcal{N} = 2$ supersymmetric gauge theory, the gauge multiplet contains a complex scalar field $\Psi$ that corresponds to the complex coordinate $z$ transverse to both the world volume of the D3 brane and the four orbifolded directions: $\Psi \sim z/2\pi\alpha'$. This is another example of holographic identification between a quantity, $\Psi$, peculiar of the gauge theory living on the fractional D3 branes and another one, the coordinate $z$, peculiar of supergravity. It allows one to obtain the gauge theory anomalies from the supergravity background. In fact, since we know how the scale and U(1) transformations act on $\Psi$, from the previous gauge/gravity relation we can deduce how they act on $z$, namely

$$\Psi \to se^{2i\alpha}\Psi \Longleftrightarrow z \to se^{2i\alpha}z \Longrightarrow y \to sy$$
$$\theta \to \theta + 2\alpha \quad [9]$$

Those transformations do not leave invariant the supergravity background in eqn [6] and when we use them in eqns [7] and [2], they generate the anomalies of the gauge theory living on the fractional D3 branes. In fact, by acting with those transformations in eqns [8], we get

$$\frac{1}{g_{YM}^2} \to \frac{1}{g_{YM}^2} + \frac{2N - M}{8\pi^2}\log s$$
$$\theta_{YM} \to \theta_{YM} - 2\alpha(2N - M) \quad [10]$$

The first equation generates the $\beta$-function of $\mathcal{N} = 2$ super-QCD with $M$ hypermultiplets given by

$$\beta(g_{YM}) = -\frac{2N - M}{16\pi^2}g_{YM}^3 \quad [11]$$

while the second one reproduces the chiral U(1) anomaly (Klebanov *et al.* 2002, Bertolini *et al.* 2002a). In particular, if we choose $\alpha = 2\pi/(2(2N - M))$, then $\theta_{YM}$ is shifted by a factor $2\pi$. But since $\theta_{YM}$ is periodic of $2\pi$, this means that the subgroup $Z_{2(2N-M)}$ is not anomalous in perfect agreement with the gauge theory results.

## Wrapped D5 Branes and $\mathcal{N}=1$ Super Yang–Mills

In this section, we will consider the classical solution corresponding to $N$ D5 branes wrapped on a 2-cycle of a noncompact Calabi–Yau space and we use it to study the properties of the gauge theory living on their world volume that can be shown to be $\mathcal{N}=1$ super Yang–Mills.

We start by writing the classical solution found in Maldacena and Núñez (2001) and Chamseddine and Volkov (1997). It has a nontrivial metric:

$$ds^2_{10} = e^{\Phi}\left[dx^2_{1,3} + \frac{e^{2h}}{\lambda^2}\left(d\tilde{\theta}^2 + \sin^2\tilde{\theta}\, d\tilde{\varphi}^2\right)\right] + \frac{e^{\Phi}}{\lambda^2}\left[d\rho^2 + \sum_{a=1}^{3}(\sigma^a - \lambda A^a)^2\right] \qquad [12]$$

a 2-form R–R potential

$$C^{(2)} = \frac{1}{4\lambda^2}\left[(\psi+\psi_0)\left(\sin\theta'\, d\theta'\wedge d\phi - \sin\tilde{\theta}\, d\tilde{\theta}\wedge d\tilde{\varphi}\right) - \cos\theta'\cos\tilde{\theta}\, d\phi\wedge d\tilde{\varphi}\right] + \frac{a}{2\lambda^2}\left[d\tilde{\theta}\wedge\sigma^1 - \sin\tilde{\theta}\, d\tilde{\varphi}\wedge\sigma^2\right] \qquad [13]$$

and a dilaton

$$e^{2\Phi} = \frac{\sinh 2\rho}{2e^h} \qquad [14]$$

where

$$\begin{aligned} e^{2h} &= \rho\coth 2\rho - \frac{\rho^2}{\sinh^2 2\rho} - \frac{1}{4} \\ e^{2k} &= e^h\frac{\sinh 2\rho}{2} \\ a &= \frac{2\rho}{\sinh 2\rho} \end{aligned} \qquad [15]$$

and

$$\begin{aligned} A^1 &= -\frac{1}{2\lambda}a(r)\, d\tilde{\theta} \\ A^2 &= \frac{1}{2\lambda}a(r)\sin\tilde{\theta}\, d\tilde{\varphi} \\ A^3 &= -\frac{1}{2\lambda}\cos\tilde{\theta}\, d\tilde{\varphi} \end{aligned} \qquad [16]$$

with $\rho \equiv \lambda r$ and $\lambda^{-2} = N g_s \alpha'$. The left-invariant 1-forms of $S^3$ are

$$\begin{aligned} \sigma^1 &= \frac{1}{2}\left[\cos\psi\, d\theta' + \sin\theta'\sin\psi\, d\phi\right] \\ \sigma^2 &= -\frac{1}{2}\left[\sin\psi\, d\theta' - \sin\theta'\cos\psi\, d\phi\right] \\ \sigma^3 &= \frac{1}{2}\left[d\psi + \cos\theta'\, d\phi\right] \end{aligned} \qquad [17]$$

with $0 \le \theta' \le \pi, 0 \le \phi \le 2\pi$, and $0 \le \psi \le 4\pi$. The variables $\tilde{\theta}$ and $\tilde{\varphi}$ describe a two-dimensional sphere and vary in the range $0 \le \tilde{\theta} \le \pi$ and $0 \le \tilde{\varphi} \le 2\pi$. Before proceeding, here we want to stress the fact that the presence of the function $a(\rho) \neq 0$ makes the solution regular everywhere. This will allow us to use it later on to describe the nonperturbative gaugino condensate property of $\mathcal{N}=1$ super Yang–Mills.

We can now use the previous solution for computing the running coupling constant and the $\theta$ parameter of $\mathcal{N}=1$ super Yang–Mills (see Di Vecchia *et al.* (2002), Bertolini and Merlatti (2003), and Mück (2003) reviewed in Bertolini (2003), Di Vecchia and Liccardo (2003), and Imeroni (2003)). In order to do that, we have to fix the cycle on which to perform the integrals in eqns [1] and [2]. It turns out that this 2-cycle is specified by

$$\tilde{\theta} = \theta' \cdot \tilde{\varphi} = -\phi, \quad \psi = 0 \qquad [18]$$

keeping $\rho$ fixed. If we now compute the gauge couplings on the previous cycle with $B_2 = C_0 = 0$, we get

$$\frac{4\pi^2}{N g^2_{YM}} = \rho\coth 2\rho + \tfrac{1}{2}a(\rho)\cos\psi \qquad [19]$$

and

$$\theta_{YM} = \frac{1}{2\pi g_s\alpha'}\int_{S^2} C_2 = -N(\psi + a(\rho)\sin\psi + \psi_0) \qquad [20]$$

where we have kept $\psi \neq 0$ for reasons that will become clear in a moment. Equation [19] shows that the coupling constant is running as a function of the distance $\rho$ from the branes. In order to obtain the correct running of the gauge theory, we have to find a relation between $\rho$ and the renormalization group scale $\mu$. This can be obtained with the following considerations. If we look at the previous solution, it is easy to see that the metric in eqn [12] is invariant under the following transformations:

$$\begin{aligned} \psi &\to \psi + 2\pi \quad \text{if } a \neq 0 \\ \psi &\to \psi + 2\epsilon \quad \text{if } a = 0 \end{aligned} \qquad [21]$$

where $\epsilon$ is an arbitrary constant. On the other hand, $C_2$ is not invariant under the previous transformations, but its flux, that is exactly equal to $\theta_{YM}$ in eqn [20], changes by an integer multiple of $2\pi$:

$$\theta_{YM} = \frac{1}{2\pi\alpha' g_s}\int_{C_2} C_2 \to \theta_{YM} + \begin{cases} -2\pi N, & \textit{if } a \neq 0 \\ -2N\epsilon, & \textit{if } a = 0, \ \epsilon = \frac{\pi k}{N} \end{cases} \qquad [22]$$

But since the physics does not change when $\theta_{YM} \to \theta_{YM} + 2\pi$, one gets that the transformation in eqn [22] is an invariance. Notice that also eqn [19] for

the gauge coupling constant is invariant under the transformation in eqn [21]. The previous considerations show that the classical solution and also the gauge couplings are invariant under the $Z_2$ transformation if $a \neq 0$, while this symmetry becomes $Z_{2N}$ if $a$ is taken to be zero. As a consequence, since in the ultraviolet $a(\rho)$ is exponentially small, we can neglect it and we have a $Z_{2N}$ symmetry, while in the infrared we cannot neglect $a(\rho)$ anymore and we have only a $Z_2$ symmetry left. This fits very well with the fact that $\mathcal{N}=1$ super Yang–Mills has a nonzero gaugino condensate $<\lambda\lambda>$ that is responsible for the breaking of $Z_{2N}$ into $Z_2$. Therefore, it is natural to identify the gaugino condensate precisely with the function $a(\rho) \neq 0$ that makes the classical solution regular also at short distances in supergravity (Di Vecchia *et al.* 2002, Apreda *et al.* 2002):

$$<\lambda\lambda> \sim \Lambda^3 = \mu^3 a(\rho) \qquad [23]$$

This provides the relation between the renormalization group scale $\mu$ and the supergravity spacetime parameter $\rho$. In the ultraviolet (large $\rho$) $a(\rho)$ is exponentially suppressed and in eqns [19] and [20] we can neglect it obtaining

$$\frac{4\pi^2}{Ng_{\mathrm{YM}}^2} = \rho \coth 2\rho \qquad [24]$$
$$\theta_{\mathrm{YM}} = -N(\psi + \psi_0)$$

The chiral anomaly can be obtained by performing the transformation $\psi \to \psi + 2\epsilon$ and getting

$$\theta_{\mathrm{YM}} \to \theta_{\mathrm{YM}} - 2N\epsilon \qquad [25]$$

This implies that the $Z_{2N}$ transformations corresponding to $\epsilon = \pi k/N$ are symmetries because they shift $\theta_{\mathrm{YM}}$ by multiples of $2\pi$.

In general, however, eqns [19] and [20] are only invariant under the $Z_2$ subgroup of $Z_{2N}$ corresponding to the transformation

$$\psi \to \psi + 2\pi \qquad [26]$$

that changes $\theta_{\mathrm{YM}}$ in eqn [20] as follows:

$$\theta_{\mathrm{YM}} \to \theta_{\mathrm{YM}} - 2N\pi \qquad [27]$$

leaving invariant the gaugino condensate:

$$<\lambda^2> = \mu^3 \frac{16\pi^2}{3Ng_{\mathrm{YM}}^2} \mathrm{e}^{-8\pi^2/Ng_{\mathrm{YM}}^2} \mathrm{e}^{\mathrm{i}\theta_{\mathrm{YM}}/N} \qquad [28]$$

Therefore, the chiral anomaly and the breaking of $Z_{2N}$ to $Z_2$ are encoded in eqns [19] and [20]. Finally, if we put $\psi = 0$ in eqn [19], we get

$$\frac{4\pi^2}{Ng_{\mathrm{YM}}^2} = \rho \coth 2\rho - \tfrac{1}{2}a(\rho) = \rho \tanh \rho \qquad [29]$$

This equation taken together with eqn [23] allows us to determine the running coupling constant as a function of $\mu$. From it, we get (Di Vecchia *et al.* 2002, Di Vecchia and Liccardo 2003) the Novikov–Shifman–Vainshtein–Zacharov (NSVZ) $\beta$-function plus nonperturbative corrections due to fractional instantons:

$$\beta(g_{\mathrm{YM}}) = -\frac{3Ng_{\mathrm{YM}}^3}{16\pi^2} \frac{1 + \dfrac{4\pi^2}{Ng_{\mathrm{YM}}^2}\sinh^{-2}\dfrac{4\pi^2}{Ng_{\mathrm{YM}}^2}}{1 - \dfrac{Ng_{\mathrm{YM}}^2}{8\pi^2} + \dfrac{1}{2}\sinh^{-2}\dfrac{4\pi^2}{Ng_{\mathrm{YM}}^2}} \qquad [30]$$

where in the ultraviolet we have approximated $\rho$ with $4\pi^2/(Ng_{\mathrm{YM}}^2) \coth 4\pi^2/(Ng_{\mathrm{YM}}^2)$.

# Gauge Theory: Mathematical Applications

**S K Donaldson**, Imperial College, London, UK

## Introduction

This article surveys some developments in pure mathematics which have, to varying degrees, grown out of the ideas of gauge theory in mathematical physics. The realization that the gauge fields of particle physics and the connections of differential geometry are one and the same has had wide-ranging consequences, at different levels. Most directly, it has led mathematicians to work on new kinds of questions, often shedding light later on well-established problems. Less directly, various fundamental ideas and techniques, notably the need to work with the infinite-dimensional gauge symmetry group, have found a place in the general world-view of many mathematicians, influencing developments in other fields. Still less directly, the work in this area – between geometry and mathematical physics – has been a prime example of the interaction between these fields which has been so fruitful since the 1970s.

The body of this article is divided into three sections: roughly corresponding to analysis, geometry, and topology. However, the different topics come together in many different ways: indeed the existence of these links between the topics is one of the most attractive features of the area.

### Gauge Transformations

For a review of the usual foundational material on connections, curvature, and related differential geometric constructions, the reader is referred to standard texts. We will, however, briefly recall the notions of gauge transformations and gauge fixing. The simplest case is that of abelian gauge theory – connections on a U(1)-bundle, say over $\boldsymbol{R}^3$. In that case the connection form, representing the connection in a local trivialization, is a pure imaginary 1-form $A$, which can also be identified with a vector field $\boldsymbol{A}$. The curvature of the connection is the 2-form $\mathrm{d}A$. Changing the local trivialization by a U(1)-valued function $g=\mathrm{e}^{\mathrm{i}\chi}$ changes the connection form to

$$\tilde{A} = A - \mathrm{d}gg^{-1} = A - \mathrm{i}\mathrm{d}\chi$$

The forms $A, \tilde{A}$ are two representations of the same geometric object: just as the same metric can be represented by different expressions in different coordinate systems. One may want to fix this choice of representation, usually by choosing $A$ to satisfy the Coulomb gauge condition $\mathrm{d}^*A=0$ (equivalently $\operatorname{div}\boldsymbol{A}=0$), supplemented by appropriate boundary conditions. Here we are using the standard Euclidean metric on $\boldsymbol{R}^3$. (Throughout this article we will work with positive-definite metrics, regardless of the fact that – at least at the classical level – the Lorentzian signature may have more obvious bearing on physics.) Arranging this choice of gauge involves solving a linear partial differential equation (PDE) for $\chi$.

The case of a general structure group $G$ is not much different. The connection form $A$ now takes values in the Lie algebra of $G$ and the curvature is given by the expression

$$F = \mathrm{d}A + \tfrac{1}{2}[A, A]$$

The change of bundle trivialization is given by a $G$-valued function and the resulting change in the connection form is

$$\tilde{A} = gAg^{-1} - \mathrm{d}gg^{-1}$$

(Our notation here assumes that $G$ is a matrix group, but this is not important.) Again, we can seek to impose the Coulomb gauge condition $\mathrm{d}^*A=0$, but now we cannot linearize this equation as before.

We can carry the same ideas over to a global problem, working on a $G$-bundle $P$ over a general

Riemannian manifold $M$. The space of connections on $P$ is an affine space $\mathcal{A}$: any two connections differ by a bundle-valued 1-form. Now the gauge group $\mathcal{G}$ of automorphisms of $P$ acts on $\mathcal{A}$ and, again, two connections in the same orbit of this action represent essentially the same geometric object. Thus, in a sense we would really like to work on the quotient space $\mathcal{A}/\mathcal{G}$. Working locally in the space of connections, near to some $A_0$, this is quite straightforward. We represent the nearby connections as $A_0 + a$, where $a$ satisfies the analog of the coulomb condition

$$d_A^* a = 0$$

Under suitable hypotheses, this condition picks out a unique representative of each nearby orbit. However, this gauge-fixing condition need not single out a unique representative if we are far away from $A_0$: indeed, the space $\mathcal{A}/\mathcal{G}$ typically has, unlike $\mathcal{A}$, a complicated topology which means that it is impossible to find any such global gauge-fixing condition. As noted above, this is one of the distinctive features of gauge theory. The gauge group $\mathcal{G}$ is an infinite-dimensional group, but one of a comparatively straightforward kind – much less complicated than the diffeomorphism groups relevant in Riemannian geometry for example. One could argue that one of the most important influences of gauge theory has been to accustom mathematicians to working with infinite-dimensional symmetry groups in a comparatively simple setting.

## Analysis and Variational Methods

### The Yang–Mills Functional

A primary object brought to mathematicians attention by physics is the Yang–Mills functional

$$\mathrm{YM}(A) = \int_M |F_A|^2 \, d\mu$$

Clearly, $\mathrm{YM}(A)$ is non-negative and vanishes if and only if the connection is flat: it is broadly analogous to functionals such as the area functional in minimal submanifold theory, or the energy functional for maps. As such, one can fit into a general framework associated with such functionals. The Euler–Lagrange equations are the Yang–Mills equations

$$d_A^* F_A = 0$$

For any solution (a Yang–Mills connection), there is a "Jacobi operator" $H_A$ such that the second variation is given by

$$\mathrm{YM}(A + ta) = \mathrm{YM}(A) + t^2 \langle H_A a, a \rangle + O(t^3)$$

The omnipresent phenomenon of gauge invariance means that Yang–Mills connections are never isolated, since we can always generate an infinite-dimensional family by gauge transformations. Thus, as explained in the last section, one imposes the gauge-fixing condition $d_A^* a = 0$. Then the operator $H_A$ can be written as

$$H_A a = \Delta_A a + [F_A, a]$$

where $\Delta_A$ is the bundle-valued "Hodge Laplacian" $d_A d_A^* + d_A^* d_A$ and the expression $[F_A, a]$ combines the bracket in the Lie algebra with the action of $\Lambda^2$ on $\Lambda^1$. This is a self-adjoint elliptic operator and, if $M$ is compact, the span of the negative eigenspaces is finite dimensional, the dimension being defined to be the index of the Yang–Mills connection $A$.

In this general setting, a natural aspiration is to construct a "Morse theory" for the functional. Such a theory should relate the topology of the ambient space to the critical points and their indices. In the simplest case, one could hope to show that for any bundle $P$ there is a Yang–Mills connection with index 0, giving a minimum of the functional. More generally, the relevant ambient space here is the quotient $\mathcal{A}/\mathcal{G}$ and one might hope that the rich topology of this is reflected in the solutions to the Yang–Mills equations.

### Uhlenbeck's Theorem

The essential foundation needed to underpin such a "direct method" in the calculus of variations is an appropriate compactness theorem. Here the dimension of the base manifold $M$ enters in a crucial way. Very roughly, when a connection is represented locally in a Coulomb gauge, the Yang–Mills action combines the $L^2$-norm of the derivative of the connection form $A$ with the $L^2$-norm of the quadratic term $[A, A]$. The latter can be estimated by the $L^4$-norm of $A$. If $\dim M \leq 4$, then the Sobolev inequalities allow the $L^4$-norm of $A$ to be controlled by the $L^2$-norm of its derivative, but this is definitely not true in higher dimensions. Thus, $\dim M = 4$ is the "critical dimension" for this variational problem. This is related to the fact that the Yang–Mills equations (and Yang–Mills functional) are conformally invariant in four dimensions. For any nontrivial Yang–Mills connection over the 4-sphere, one generates a one-parameter family of Yang–Mills connections, on which the functional takes the same value, by applying conformal transformations corresponding to dilations of $\boldsymbol{R}^4$. In such a family of connections the integrand $|F_A|^2$ – the "curvature density" – converges to a $\delta$-function

at the origin. More generally, one can encounter sequences of connections over 4-manifolds for which YM is bounded but which do not converge, the Yang–Mills density converging to $\delta$-functions. There is a detailed analogy with the theory of the harmonic maps energy functional, where the relevant critical dimension (for the domain of the map) is 2.

The result of Uhlenbeck (1982), which makes these ideas precise, considers connections over a ball $B^n \subset \mathbf{R}^n$. If the exponent $p \geq 2n$, then there are positive constants $\epsilon(p,n), C(p,n) > 0$ such that any connection with $\|F\|_{L^p(B^n)} \leq \epsilon$ can be represented in Coulomb gauge over the ball, by a connection form which satisfies the condition $d^*A = 0$, together with certain boundary conditions, and

$$\|A\|_{L_1^p} \leq C\|F\|_{L^p}$$

In this Coulomb gauge, the Yang–Mills equations are elliptic and it follows readily that, in this setting, if the connection $A$ is Yang–Mills one can obtain estimates on all derivatives of $A$.

### Instantons in Four Dimensions

This result of Uhlenbeck gives the analytical basis for the direct method of the calculus of variations for the Yang–Mills functional over base manifolds $M$ of dimension $\leq 3$. For example, any bundle over such a manifold must admit a Yang–Mills connection, minimizing the functional. Such a statement is definitely false in dimensions $\geq 5$. For example, an early result of Bourguignon and Lawson (1981) and Simons asserts that there is no minimizing connection on any bundle over $S^n$ for $n \geq 5$. The proof exploits the action of the conformal transformations of the sphere. In the critical dimension 4, the situation is much more complicated. In four dimensions, there are the renowned "instanton" solutions of the Yang–Mills equation. Recall that if $M$ is an oriented 4-manifold the Hodge $*$-operation is an involution of $\Lambda^2 T^*M$ which decomposes the two forms into self-dual and anti-self-dual parts, $\Lambda^2 T^*M = \Lambda^+ \oplus \Lambda^-$. The curvature of a connection can then be written as

$$F_A = F_A^+ + F_A^-$$

and a connection is a self-dual (respectively anti-self-dual) instanton if $F_A^-$ (respectively $F_A^+$) is 0. The Yang–Mills functional is

$$\mathrm{YM}(A) = \|F_A^+\|^2 + \|F_A^-\|^2$$

while the difference $\|F_A^+\|^2 - \|F_A^-\|^2$ is a topological invariant $\kappa(P)$ of the bundle $P$, obtained by evaluating a four-dimensional characteristic class on $[M]$. Depending on the sign of $\kappa(P)$, the self-dual or anti-self-dual connections (if any exist) minimize the Yang–Mills functional among all connections on $P$. These instanton solutions of the Yang–Mills equations are analogous to the holomorphic maps from a Riemann surface to a Kähler manifold, which minimize the harmonic maps energy functional in their homotopy class.

### Moduli Spaces

The instanton solutions typically occur in "moduli spaces." To fix ideas, let us consider bundles with structure group SU(2), in which case $\kappa(P) = -8\pi^2 c_2(P)$. For each $k > 0$, we have a moduli space $\mathcal{M}_k$ of anti-self-dual instantons on a bundle $P_k \to M^4$, with $c_2(P_k) = k$. It is a manifold of dimension $8k - 3$. The general goal of the calculus of variations in this setting is to relate three things:

1. the topology of the space $\mathcal{A}/\mathcal{G}$ of equivalence classes of connections on $P_k$;
2. the topology of the moduli space $\mathcal{M}_k$ of instantons; and
3. the existence and indices of other, nonminimal, solutions to the Yang–Mills equations on $P_k$.

In this direction, a very influential conjecture was made by Atiyah and Jones (1978). They considered the case when $M = S^4$ and, to avoid certain technicalities, work with spaces of "framed" connections, dividing by the restricted group $\mathcal{G}_0$ of gauge transformations equal to the identity at infinity. Then, for any $k$, the quotient $\mathcal{A}/\mathcal{G}_0$ is homotopy equivalent to the third loop space $\Omega^3 S^3$ of based maps from the 3-sphere to itself. The corresponding "framed" moduli space $\tilde{\mathcal{M}}_k$ is a manifold of dimension $8k$ (a bundle over $\mathcal{M}_k$ with fiber SO(3)). Atiyah and Jones conjectured that the inclusion $\tilde{\mathcal{M}}_k \to \mathcal{A}/\mathcal{G}_0$ induces an isomorphism of homotopy groups $\pi_l$ in a range of dimensions $l \leq l(k)$, where $l(k)$ increases with $k$. This would be consistent with what one might hope to prove by the calculus of variations if there were no other Yang–Mills solutions, or if the indices of such solutions increased with $k$.

The first result along these lines was due to Bourguignon and Lawson (1981), who showed that the instanton solutions are the only local minima of the Yang–Mills functional over the 4-sphere. Subsequently, Taubes (1983) showed that the index of an non-instanton Yang–Mills connection $P_k$ is at least $k+1$. Taubes' proof used ideas related to the action of the quaternions and the hyper-Kähler structure on the $\tilde{\mathcal{M}}_k$ (see the section on hyper-Kähler quotients). Contrary to some expectations, it was shown by

Sibner *et al.* (1989) that nonminimal solutions do exist; some later constructions were very explicit (Sadun and Segert 1992). Taubes' index bound gave ground for hope that an analytical proof of the Atiyah–Jones conjecture might be possible, but this is not at all straightforward. The problem is that in the critical dimension 4 a mini–max sequence for the Yang–Mills functional in a given homotopy class may diverge, with curvature densities converging to sums of $\delta$-functions as outlined above. This is related to the fact that the $\tilde{\mathcal{M}}_k$ are not compact. In a series of papers culminating in a framework for Morse theory for Yang–Mills functional, Taubes (1998) succeeded in proving a partial version of the Atiyah–Jones conjecture, together with similar results for general base manifolds $M^4$. Taubes showed that, if the homotopy groups of the moduli spaces stabilize as $k \to \infty$, then the limit must be that predicted by Atiyah and Jones. Related analytical techniques were developed for other variational problems at the critical dimension involving "critical points at infinity." The full Atiyah–Jones conjecture was established by Boyer *et al.* but using geometrical techniques: the "explicit" description of the moduli spaces obtained from the Atiyah–Drinfeld–Hitchin–Manin (ADHM) construction (see below). A different geometrical proof was given by Kirwan (1994), together with generalizations to other gauge groups.

There was a parallel story for the solutions of the Bogomolony equation over $\boldsymbol{R}^3$, which we will not recount in detail. Here the base dimension is below the critical case but the analytical difficulty arises from the noncompactness of $\boldsymbol{R}^3$. Taubes succeeded in overcoming this difficulty and obtained relations between the topology of the moduli space, the appropriate configuration space and the higher critical points. Again, these higher critical points exist but their index grows with the numerical parameter corresponding to $k$. At about the same time, Donaldson (1984) showed that the moduli spaces could be identified with spaces of rational maps (subsequently extended to other gauge groups). The analog of the Atiyah–Jones conjecture is a result on the topology of spaces of rational maps proved earlier by Segal, which had been one of the motivations for Atiyah and Jones.

### Higher Dimensions

While the scope for variational methods in Yang–Mills theory in higher dimensions is very limited, there are useful analytical results about solutions of the Yang–Mills equations. An important monotonicity result was obtained by Price (1983). For simplicity, consider a Yang–Mills connection over the unit ball $B^n \subset \boldsymbol{R}^n$. Then Price showed that the normalized energy

$$E(A, B(r)) = \frac{1}{r^{n-4}} \int_{|x| \leq r} |F|^2 \, \mathrm{d}\mu$$

decreases with $r$. Nakajima (1988) and Uhlenbeck used this monotonicity to show that for each $n$ there is an $\epsilon$ such that if $A$ is a Yang–Mills connection over a ball with $E(A, B(r)) \leq \epsilon$ then all derivatives of $A$, in a suitable gauge, can be controlled by $E(A, B(r))$. Tian (2000) showed that if $A_i$ is a sequence of Yang–Mills connections over a compact manifold $M$ with bounded Yang–Mills functional, then there is a subsequence which converges away from a set $Z$ of Haussdorf codimension at least 4 (extending the case of points in a 4-manifold). Moreover, the singular set $Z$ is a minimal subvariety, in a suitably generalized sense.

In higher dimensions, important examples of Yang–Mills connections arise within the framework of "calibrated geometry." Here, we consider a Riemannian $n$-manifold $M$ with a covariant constant calibrating form $\Omega \in \Omega_M^{n-4}$. There is then an analog of the instanton equation

$$F_A = \pm * (\Omega \wedge F_A)$$

whose solutions minimize the Yang–Mills functional. This includes the Hermitian Yang–Mills equation over a Kähler manifold (see the section on moment maps) and also certain equations over manifolds with special holonomy groups (Donaldson and Thomas 1998). For these "higher-dimensional instantons," Tian shows that the singular sets $Z$ that arise are calibrated varieties.

### Gluing Techniques

Another set of ideas from PDEs and analysis which has had great impact in gauge theory involves the construction of solutions to appropriate equations by the following general scheme:

1. constructing an "approximate solution," formed from some standard models using cutoff functions;
2. showing that the approximate solution can be deformed to a true solution by means of an implicit function theorem.

The heart of the second step usually consists of estimates for the relevant linear differential operator. Of course, the success of this strategy depends on the particular features of the problem. This approach, due largely to Taubes, has been particularly effective in finding solutions to the first-order instanton equations and their relatives. (The applicability of the approach is connected to the fact that

such solutions typically occur in moduli spaces and one can often "see" local coordinates in the moduli space by varying the parameters in the approximate solution.) Taubes applied this approach to the Bogomolny monopole equation over $\boldsymbol{R}^3$ (Jaffe and Taubes 1980) and to construct instantons over general 4-manifolds (Taubes 1982). In the latter case, the approximate solutions are obtained by transplanting standard solutions over $\boldsymbol{R}^4$ – with curvature density concentrated in a small ball – to small balls on the 4-manifold, glued to the trivial flat connection over the remainder of the manifold. These types of techniques have now become a fairly standard part of the armory of many differential geometers, working both within gauge theory and other fields. An example of a problem where similar ideas have been used is Joyce's construction of constant of manifolds with exceptional holonomy groups (Joyce 1996). (Of course, it is likely that similar techniques have been developed over the years in many other areas, but Taubes' work in gauge theory has done a great deal to bring them into prominence.)

## Geometry: Integrability and Moduli Spaces

### The Ward Correspondence

Suppose that $S$ is a complex surface and $\omega$ is the 2-form corresponding to a Hermitian metric on $S$. Then $S$ is an oriented Riemannian 4-manifold and $\omega$ is a self-dual form. The orthogonal complement of $\omega$ in $\Lambda^+$ can be identified with the real parts of forms of type $(0,2)$. Hence, if $A$ is an anti-self-dual instanton connection on a principle $\mathrm{U}(r)$-bundle over $S$ the $(0,2)$ part of the curvature of $A$ vanishes. This is the integrability condition for the $\bar{\partial}$-operator defined by the connection, acting on sections of the associated vector bundle $E \to S$. Thus, in the presence of the connection, the bundle $E$ is naturally a holomorphic bundle over $S$.

The Ward correspondence (Ward 1877) builds on this idea to give a complete translation of the instanton equations over certain Riemannian 4-manifolds into holomorphic geometry. In the simplest case, let $A$ be an instanton on a bundle over $\boldsymbol{R}^4$. Then, for any choice of a linear complex structure on $\boldsymbol{R}^4$, compatible with the metric, $A$ defines a holomorphic structure. The choices of such a complex structure are parametrized by a 2-sphere; in fact, the unit sphere in $\Lambda^+(\boldsymbol{R}^4)$. So, for any $\lambda \in S^2$ we have a complex surface $S_\lambda$ and a holomorphic bundle over $S_\lambda$. These data can be viewed in the following way. We consider the projection $\pi : \boldsymbol{R}^4 \times S^2 \to \boldsymbol{R}^4$ and the pull-back $\pi^*(E)$ to $\boldsymbol{R}^4 \times S^2$. This pullback bundle has a connection which defines a holomorphic structure along each fiber $S_\lambda \subset \boldsymbol{R}^4 \times S^2$ of the other projection. The product $\boldsymbol{R}^4 \times S^2$ is the twistor space of $\boldsymbol{R}^4$ and it is in a natural way a three-dimensional complex manifold. It can be identified with the complement of a line $L_\infty$ in $\mathbf{CP}^3$ where the projection $\boldsymbol{R}^4 \times S^2 \to S^2$ becomes the fibration of $\mathbf{CP}^3 \setminus L_\infty$ by the complex planes through $L_\infty$. One can see then that $\pi^*(E)$ is naturally a holomorphic bundle over $\mathbf{CP}^3 \setminus L_\infty$. The construction extends to the conformal compactification $S^4$ of $\boldsymbol{R}^4$. If $S^4$ is viewed as the quaternionic projective line $\mathbf{HP}^1$ and we identify $\boldsymbol{H}^2$ with $\mathbf{C}^4$ in the standard way, we get a natural map $\pi : \mathbf{CP}^3 \to \mathbf{HP}^1$. Then $\mathbf{CP}^3$ is the twistor space of $S^4$ and an anti-self-dual instanton on a bundle $E$ over $S^4$ induces a holomorphic structure on the bundle $\pi^*(E)$ over $\mathbf{CP}^3$.

In general, the twistor space $Z$ of an oriented Riemannian 4-manifold $M$ is defined to be the unit sphere bundle in $\Lambda^+_M$. This has a natural almost-complex structure which is integrable if and only if the self-dual part of the Weyl curvature of $M$ vanishes (Atiyah *et al.* 1978). The antipodal map on the 2-sphere induces an antiholomorphic involution of $Z$. In such a case, an anti-self-dual instanton over $M$ lifts to a holomorphic bundle over $Z$. Conversely, a holomorphic bundle over $Z$ which is holomorphically trivial over the fibers of the fibration $Z \to M$ (projective lines in $Z$), and which satisfies a certain reality condition with respect to the antipodal map, arises from a unitary instanton over $M$. This is the Ward correspondence, part of Penrose's twistor theory.

### The ADHM Construction

The problem of describing all solutions to the Yang–Mills instanton equation over $S^4$ is thus reduced to a problem in algebraic geometry, of classifying certain holomorphic vector bundles. This was solved by Atiyah *et al.* (1978). The resulting ADHM construction reduces the problem to certain matrix equations. The equations can be reduced to the following form. For a bundle Chern class $k$ and rank $r$, we require a pair of $k \times k$ matrices $\alpha_1, \alpha_2$, a $k \times r$ matrix $a$, and an $r \times k$ matrix $b$. Then the equations are

$$\begin{aligned} [\alpha_1, \alpha_2] &= ab \\ [\alpha_1^*, \alpha_1] + [\alpha_2^*, \alpha_2] &= aa^* - b^*b \end{aligned} \qquad [1]$$

We also require certain open, nondegeneracy conditions. Given such matrix data, a holomorphic

bundle over $\mathbf{CP}^3$ is constructed via a "monad": a pair of bundle maps over $\mathbf{CP}^3$

$$\boldsymbol{C}^k \otimes \mathcal{O}(-1)@>D_1>>\boldsymbol{C}^k \oplus \boldsymbol{C}^k \oplus \boldsymbol{C}^r@>D_2>>\boldsymbol{C}^k \otimes \mathcal{O}(1)$$

with $D_2 D_1 = 0$. That is, the rank-$r$ holomorphic bundle we construct is $\operatorname{Ker} D_2/\operatorname{Im} D_1$. The bundle maps $D_1, D_2$ are obtained from the matrix data in a straightforward way, in suitable coordinates. It is this matrix description which was used by Boyer *et al.* to prove the Atiyah–Jones conjecture on the topology of the moduli spaces of instantons. The only other case when the twistor space of a compact 4-manifold is an algebraic variety is the complex projective plane, with the nonstandard orientation. An analog of the ADHM description in this case was given by Buchdahl (1986).

### Integrable Systems

The Ward correspondence can be viewed in the general framework of integrable systems. Working with the standard complex structure on $\boldsymbol{R}^4$, the integrability condition for the $\bar{\partial}$-operator takes the shape

$$[\nabla_1 + \mathrm{i}\nabla_2, \nabla_3 + \mathrm{i}\nabla_4] = 0$$

where $\nabla_i$ are the components of the covariant derivative in the coordinate directions. So, the instanton equation can be viewed as a family of such commutator equations parametrized by $\lambda \in S^2$. One obtains many reductions of the instanton equation by imposing suitable symmetries. Solutions invariant under translation in one variable correspond to the Bogomolny "monopole equation" (Jaffe and Taubes 1980). Solutions invariant under three translations correspond to solutions of Nahm's equations,

$$\frac{\mathrm{d}T_i}{\mathrm{d}t} = \epsilon_{ijk}[T_j, T_k]$$

for matrix-valued functions $T_1, T_2, T_3$ of one variable $t$. Nahm (1982) and Hitchin (1983) developed an analog of the ADHM construction relating these two equations. This is now seen as a part of a general "Fourier–Mukai–Nahm transform" (Donaldson and Kronheimer 1990). The instanton equations for connections invariant under two translations, Hitchin's equations (Hitchin 1983), are locally equivalent to the harmonic map equation for a surface into the symmetric space dual to the structure group. Changing the signature of the metric on $\boldsymbol{R}^4$ to (2, 2), one gets the harmonic mapping equations into Lie groups (Hitchin 1990). More complicated reductions yield almost all the known examples of integrable PDEs as special forms of the instanton equations (Mason and Woodhouse 1996).

### Moment Maps: the Kobayashi–Hitchin Conjecture

Let $\Sigma$ be a compact Riemann surface. The Jacobian of $\Sigma$ is the complex torus $H^1(\Sigma, \mathcal{O})/H^1(\Sigma, \boldsymbol{Z})$: it parametrizes holomorphic line bundles of degree 0 over $\Sigma$. The Hodge theory (which was, of course, developed long before Hodge in this case) shows that the Jacobian can also be identified with the torus $H^1(\Sigma, \boldsymbol{R})/H^1(\Sigma, \boldsymbol{Z})$ which parametrizes flat U(1)-connections. That is, any holomorphic line bundle of degree 0 admits a unique compatible flat unitary connection.

The generalization of these ideas to bundles of higher rank began with Weil. He observed that any holomorphic vector bundle of degree 0 admits a flat connection, not necessarily unitary. Narasimhan and Seshadri (1965) showed that (in the case of degree 0) the existence of a flat, irreducible, unitary connection was equivalent to an algebro-geometric condition of stability which had been introduced shortly before by Mumford, for quite different purposes. Mumford introduced the stability condition in order to construct separated moduli spaces of holomorphic bundles – generalizing the Jacobian – as part of his general geometric invariant theory. For bundles of nonzero degree, the discussion is slightly modified by the use of projectively flat unitary connections. The result of Narasimhan and Seshadri asserts that there are two different descriptions of the same moduli space $\mathcal{M}^{d,r}$(Sigma): either as parametrizing certain irreducible projectively flat unitary connections (representations of $\pi_1(\Sigma)$), or parametrizing stable holomorphic bundles of degree $d$ and rank $r$. While Narasimhan and Seshadri probably did not view the ideas in these terms, another formulation of their result is that a certain nonlinear PDE for a Hermitian metric on a holomorphic bundle – analogous to the Laplace equation in the abelian case – has a solution when the bundle is stable.

Atiyah and Bott (1982) cast these results in the framework of gauge theory. (The Yang–Mills equations in two dimensions essentially reduce to the condition that the connection be flat, so they are rather trivial locally but have interesting global structure.) They made the important observation that the curvature of a connection furnishes a map

$$F : \mathcal{A} \to \mathrm{Lie}(\mathcal{G})^*$$

which is an equivariant moment map for the action of the gauge group on $\mathcal{A}$. Here the symplectic form on the affine space $\mathcal{A}$ and the map from the adjoint

bundle-valued 2-forms to the dual of the Lie algebra of $\mathcal{G}$ are both given by integration of products of forms. From this point of view, the Narasimhan–Seshadri result is an infinite-dimensional example of a general principle relating symplectic and complex quotients. At about the same time, Hitchin and Kobayashi independently proposed an extension of these ideas to higher dimensions. Let $E$ be a holomorphic bundle over a complex manifold $V$. Any compatible unitary connection on $E$ has curvature $F$ of type (1,1). Let $\omega$ be the (1,1)-form corresponding to a fixed Hermitian metric on $V$. The Hermitian Yang–Mills equation is the equation

$$F \cdot \omega = \mu 1_E$$

where $\mu$ is a constant (determined by the topological invariant $c_1(E)$). The Kobayashi–Hitchin conjecture is that, when $\omega$ is Kähler, this equation has an irreducible solution if and only if $E$ is a stable bundle in the sense of Mumford. Just as in the Riemann surface case, this equation can be viewed as a nonlinear second-order PDE of Laplace type for a metric on $E$. The moment map picture of Atiyah and Bott also extends to this higher-dimensional version. In the case when $V$ has complex dimension 2 (and $\mu$ is zero), the Hermitian Yang–Mills connections are exactly the anti-self-dual instantons, so the conjecture asserts that the moduli spaces of instantons can be identified with certain moduli spaces of stable holomorphic bundles.

The Kobayashi–Hitchin conjecture was proved in the most general form by Uhlenbeck and Yau (1986), and in the case of algebraic manifolds in Donaldson (1987). The proofs in Donaldson (1985, 1987) developed some extra structure surrounding these equations, connected with the moment map point of view. The equations can be obtained as the Euler–Lagrange equations for a nonlocal functional, related to the renormalized determinants of Quillen and Bismut. The results have been extended to non-Kähler manifolds and certain noncompact manifolds. There are also many extensions to equations for systems of data comprising a bundle with additional structure such as a holomorphic section or Higgs' field (Bradlow *et al.* 1995), or a parabolic structure along a divisor. Hitchin's equations (Hitchin 1987) are a particularly rich example.

## Topology of Moduli Spaces

The moduli spaces $\mathcal{M}_{r,d}(\Sigma)$ of stable holomorphic bundles/projectively flat unitary connections over Riemann surfaces $\Sigma$ have been studied intensively from many points of view. They have natural Kähler structures: the complex structure being visible in the holomorphic bundles guise and the symplectic form as the "Marsden–Weinstein quotient" in the unitary connections guise. In the case when $r$ and $d$ are coprime, they are compact manifolds with complicated topologies. There is an important basic construction for producing cohomology classes over these (and other) moduli spaces. One takes a universal bundle $U$ over the product $\mathcal{M} \times \Sigma$ with Chern classes

$$c_i(U) \in H^{2i}(\mathcal{M} \times \Sigma)$$

Then, for any class $\alpha \in H_p(\Sigma)$, we get a cohomology class $c_i(U)/\alpha \in H^{2i-p}(\mathcal{M})$. Thus, if $R_\Sigma$ is the graded ring freely generated by such classes, we have a homomorphism $\nu : R_\Sigma \to H^*(\mathcal{M})$. The questions about the topology of the moduli spaces which have been studied include:

1. finding the Betti numbers of the moduli space $\mathcal{M}$;
2. identifying the kernel of $\nu$;
3. giving an explicit system of generators and relations for the ring $H^*(\mathcal{M})$;
4. identifying the Pontrayagin and Chern classes of $\mathcal{M}$ within $H^*(\mathcal{M})$; and
5. evaluating the pairings

$$\int_{\mathcal{M}} \nu(W)$$

for elements $W$ of the appropriate degree in $R$.

All of these questions have now been solved quite satisfactorily. In early work, Newstead (1967) found the Betti numbers in the rank-2 case. The main aim of Atiyah and Bott was to apply the ideas of Morse theory to the Yang–Mills functional over a Riemann surface and they were able to reproduce Newstead's results in this way and extend them to higher rank. They also showed that the map $\nu$ is a surjection, so the universal bundle construction gives a system of generators for the cohomology. Newstead made conjectures on the vanishing of the Pontrayagin and Chern classes above a certain range which were established by Kirwan and extended to higher rank by Earl and Kirwan (1999). Knowing that $R_\Sigma$ maps on to $H^*(M)$, a full set of relations can (by Poincaré duality) be deduced in principle from a knowledge of the integral pairings in (5) above, but this is not very explicit. A solution to (5) in the case of rank 2 was found by Thaddeus (1992). He used results from the Verlinde theory (see section on 3-manifolds below) and the Riemann–Roch formula. Another point of view was developed by Witten (1991), who showed that the volume of the moduli space was related to the theory of torsion in algebraic topology and satisfied simple gluing axioms. These different

points of view are compared in Donaldson (1993). Using a nonrigorous localization principle in infinite dimensions, Witten (1992) wrote down a general formula for the pairings (5) in any rank, and this was established rigorously by Jeffrey and Kirwan, using a finite-dimensional version of the same localization method. A very simple and explicit set of generators and relations for the cohomology (in the rank-2 case) was given by King and Newstead (1998). Finally, the quantum cohomology of the moduli space, in the rank-2 case, was identified explicitly by Munoz (1999).

### Hyper-Kähler Quotients

Much of this story about the structure of moduli spaces extends to higher dimensions and to the moduli spaces of connections and Higgs fields. A particularly notable extension of the ideas involves hyper-Kähler structures. Let $M$ be a hyper-Kähler 4-manifold, so there are three covariant-constant self-dual forms $\omega_1, \omega_2, \omega_3$ on $M$. These correspond to three complex structures $I_1, I_2, I_3$ obeying the algebra of the quaternions. If we single out one structure, say $I_1$, the instantons on $M$ can be viewed as holomorphic bundles with respect to $I_1$ satisfying the moment map condition (Hermitian Yang–Mills equation) defined by the form $\omega_1$. Taking a different complex structure interchanges the role of the moment map and integrability conditions. This can be put in a general framework of hyper-Kähler quotients due to Hitchin *et al.* (1987). Suppose initially that $M$ is compact (so either a K3 surface or a torus). Then the $\omega_i$ components of the curvature define three maps

$$F_i : \mathcal{A} \to \mathrm{Lie}(\mathcal{G})^*$$

The structures on $M$ make $\mathcal{A}$ into a flat hyper-Kähler manifold and the three maps $F_i$ are the moment maps for the gauge group action with respect to the three symplectic forms on $\mathcal{A}$. In this situation, it is a general fact that the hyper-Kähler quotient – the quotient by $\mathcal{G}$ of the common zero set of the three moment maps – has a natural hyper-Kähler structure. This hyper-Kähler quotient is just the moduli space of instantons over $M$. In the case when $M$ is the noncompact manifold $\boldsymbol{R}^4$, the same ideas apply except that one has to work with the based gauge group $\mathcal{G}_0$. The conclusion is that the framed moduli spaces $\tilde{\mathcal{M}}$ of instantons over $\boldsymbol{R}^4$ are naturally hyper-Kähler manifolds. One can also see this hyper-Kähler structure through the ADHM matrix description. A variant of these matrix equations was used by Kronheimer to construct "gravitational instantons." The same ideas also apply to the moduli spaces of monopoles, where the hyper-Kähler metric, in the simplest case, was studied by Atiyah and Hitchin (1989).

## Low-Dimensional Topology

### Instantons and 4-Manifolds

Gauge theory has had unexpected applications in low-dimensional topology, particularly the topology of smooth 4-manifolds. The first work in this direction, in the early 1980s, involved the Yang–Mills instantons. The main issue in 4-manifold theory at that time was the correspondence between the diffeomorphism classification of simply connected 4-manifolds and the classification up to homotopy. The latter is determined by the intersection form, a unimodular quadratic form on the second integral homology group (i.e., a symmetric matrix with integral entries and determinant $\pm 1$, determined up to integral change of basis). The only known restriction was that Rohlin's theorem, which asserts that if the form is even the signature must be divisible by 16. The achievement of the first phase of the theory was to show that

1. There are unimodular forms which satisfy the hypotheses of Rohlin's theorem but which do not appear as the intersection forms of smooth 4-manifolds. In fact, no nonstandard definite form, such as a sum of copies of the $E_8$ matrix, can arise in this way.
2. There are simply connected smooth 4-manifolds which have isomorphic intersection forms, and hence are homotopy equivalent, but which are not diffeomorphic.

These results stand in contrast to the homeomorphism classification which was obtained by Freedman shortly before and which is almost the same as the homotopy classification.

The original proof of item (1) above argued with the moduli space $\mathcal{M}$ of anti-self-dual instantons SU(2) instantons on a bundle with $c_2 = 1$ over a simply connected Riemannian 4-manifold $M$ with a negative-definite intersection form (Donaldson 1983). In the model case when $M$ is the 4-sphere the moduli space $\mathcal{M}$ can be identified explicitly with the open 5-ball. Thus the 4-sphere arises as the natural boundary of the moduli space. A sequence of points in the moduli space converging to a boundary point corresponds to a sequence of connections with curvature densities converging to a $\delta$-function, as described earlier. One shows that in the general case (under our hypotheses on the 4-manifold $M$) the moduli space $\mathcal{M}$ has a similar behavior, it contains a collar $M \times (0, \delta)$

formed by instantons made using Taubes' gluing construction, described previously. The complement of this collar is compact. In the interior of the moduli space, there are a finite number of special points corresponding to U(1)-reductions of the bundle $P$. This is the way in which the moduli space "sees" the integral structure of the intersection form since such reductions correspond to integral homology classes with self-intersection –1. Neighborhoods of these special points are modeled on quotients $\mathbf{C}^3/\mathrm{U}(1)$; that is, cones on copies of $\mathbf{CP}^2$. The upshot is that (for generic Riemannian metrics on $M$) the moduli space gives a cobordism from the manifold $M$ to a set of copies of $\mathbf{CP}^2$ which can be counted in terms of the intersection form, and the result follows easily from standard topology. More sophisticated versions of the argument extended the results to rule out some indefinite intersection forms.

On the other hand, the original proofs of item (2) used "invariants" defined by instanton moduli spaces (Donaldson 1990). The general scheme exploits the same construction outlined in the previous section. We suppose that $M$ is a simply connected 4-manifold with $b^+(M) = 1 + 2p$, where $p > 0$ is an integer. (Here $b^+(M)$ is, as usual, the number of positive eigenvalues of the intersection matrix.) Ignoring some technical restrictions, there is a map

$$\nu : R_M \to H^*(\mathcal{M}_k)$$

where $R_M$ is a graded ring freely generated by the homology (below the top dimension) of the 4-manifold $M$ and $\mathcal{M}_k$ is the moduli space of anti-self-dual SU(2)-instantons on a bundle with $c_2 = k > 0$. For an element $W$ in $R_M$ of the appropriate degree, one obtains a number by evaluating, or integrating, $\nu(W)$ on $\mathcal{M}_k$. The main technical difficulty here is that the moduli space $\mathcal{M}_k$ is rarely compact, so one needs to make sense of this "evaluation." With all the appropriate technicalities in place, these invariants could be shown to distinguish various homotopy-equivalent, homeomorphic 4-manifolds. All these early developments are described in detail in the book by Donaldson and Kronheimer (1990).

### Basic Classes

Until the early 1990s, these instanton invariants could only be calculated in isolated favorable cases (although the calculations which were made, through the work of many mathematicians, led to a large number of further results about 4-manifold topology). Deeper understanding of their structure came with the work of Kronheimer and Mrowka. This work was, in large part, motivated by a natural question in geometric topology. Any homology class $\alpha \in H_2(M; \mathbf{Z})$ can be represented by an embedded, connected, smooth surface. One can define an integer $\underline{g}(\alpha)$ to be the minimal genus of such a representative. The problem is to find $\underline{g}(\alpha)$, or at least bounds on it. A well-known conjecture, ascribed to Thom, was that when $M$ is the complex projective plane the minimal genus is realized by a complex curve; that is,

$$\underline{g}(\pm dH) = \tfrac{1}{2}(d-1)(d-2)$$

where $H$ is the standard generator of $H_2(\mathbf{CP}^2)$ and $d \geq 1$.

The new geometrical idea introduced by Kronheimer and Mrowka was to study instantons over a 4-manifold $M$ with singularities along a surface $\Sigma \subset M$. For such connections, there is a real parameter: the limit of the trace of the holonomy around small circles linking the surface. By varying this parameter, they were able to interpolate between moduli spaces of nonsingular instantons on different bundles over $M$ and obtain relations between the different invariants. They also found that if the genus of $\Sigma$ is suitably small then some of the invariants are forced to vanish, thus, conversely, getting information about $\underline{g}$ for 4-manifolds with nontrivial invariants. For example, they showed that if $M$ is a K3 surface then $\underline{g}(\alpha) = (1/2)(\alpha \cdot \alpha + 2)$.

The structural results of Kronheimer and Mrowka (1995) introduced the notion of a 4-manifold of "simple type." Write the invariant defined above by the moduli space $\mathcal{M}_k$ as $I_k : R_M \to \mathbf{Q}$. Then $I_k$ vanishes except on terms of degree $2d(k)$, where $d(k) = 4k - 3(1+p)$. We can put all these together to define $\underline{I} = \sum I_k : R_M \to \mathbf{Q}$. The ring $R_M$ is a polynomial ring generated by classes $\alpha \in H_2(M)$, which have degree 2 in $R_M$, and a class $X$ of degree 4 in $R_M$, corresponding to the generator of $H_0(M)$. The 4-manifold is of simple type if

$$\underline{I}(X^2 W) = 4\underline{I}(W)$$

for all $W \in R_M$. Under this condition, Kronheimer and Mrowka showed that all the invariants are determined by a finite set of "basic" classes $K_1, \ldots, K_s \in H_2(M)$ and rational numbers $\beta_1, \ldots, \beta_s$. To express the relation, they form a generating function

$$\mathcal{D}_M(\alpha) = \underline{I}(\mathrm{e}^{\alpha}) + \underline{I}\left(\frac{X}{2}\mathrm{e}^{\alpha}\right)$$

This is *a priori* a formal power series in $H^2(M)$ but *a posteriori* the series converges and can be regarded

as a function on $H_2(M)$. Kronheimer and Mrowka's result is that

$$\mathcal{D}_M(\alpha) = \exp\left(\frac{\alpha \cdot \alpha}{2}\right) \sum_{r=1}^{s} \beta_r e^{K_r \cdot \alpha}$$

It is not known whether all simply connected 4-manifolds are of simple type, but Kronheimer and Mrowka were able to show that this is the case for a multitude of examples. They also introduced a weaker notion of "finite type," and this condition was shown to hold in general by Munoz and Froyshov. The overall result of this work of Kronheimer and Mrowka was to make the calculation of the instanton invariants for many familiar 4-manifolds a comparatively straightforward matter.

### 3-Manifolds: Casson's Invariant

Gauge theory has also entered into 3-manifold topology. In 1985, Casson introduced a new integer-valued invariant of oriented homology 3-spheres which "counts" the set $Z$ of equivalence classes of irreducible flat SU(2)-connections, or equivalently irreducible representations $\pi_1(Y) \to$ SU(2). Casson's approach (Akbulut and McCarthy 1990) was to use a Heegard splitting of a 3-manifold $Y$ into two handle bodies $Y^+, Y^-$ with a surface $\Sigma$ as common boundary. Then $\pi_1(\Sigma)$ maps onto $\pi_1(Y)$ and a flat SU(2) connection on $Y$ is determined by its restriction to $\Sigma$. Let $M_\Sigma$ be the moduli space of irreducible flat connections over $\Sigma$ (as discussed in the last section) and let $L^\pm \subset M_\Sigma$ be the subsets which extend over $Y^\pm$. Then $L^\pm$ are submanifolds of half the dimension of $\mathcal{M}_\Sigma$ and the set $Z$ can be identified with the intersection $L^+ \cap L^-$. The Casson invariant is one-half the algebraic intersection number of $L^+$ and $L^-$. Casson showed that this is independent of the Heegard splitting (and is also, in fact, an integer, although this is not obvious). He showed that when $Y$ is changed by Dehn surgery along a knot, the invariant changes by a term computed from the Alexander polynomial of the knot. This makes the Casson invariant computable in examples. (For a discussion of Casson's formula see Donaldson (1999).) Taubes showed that the Casson invariant could also be obtained in a more differential-geometric fashion, analogous to the instanton invariants of 4-manifolds (Taubes 1990).

### 3-Manifolds: Floer Theory

Independently, at about the same time, Floer (1989) introduced more sophisticated invariants – the Floer homology groups – of homology 3-spheres, using gauge theory. This development ran parallel to his introduction of similar ideas in symplectic geometry. Suppose, for simplicity, that the set $Z$ of equivalence classes of irreducible flat connections is finite. For pairs $\rho_-, \rho_+$ in $Z$, Floer considered the instantons on the tube $Y \times \boldsymbol{R}$ asymptotic to $\rho^\pm$ at $\pm\infty$. There is an infinite set of moduli spaces of such instantons, labeled by a relative Chern class, but the dimensions of these moduli spaces agree modulo 8. This gives a relative index $\delta(\rho_-, \rho_+) \in \boldsymbol{Z}/8$. If $\delta(\rho_-, \rho_+) = 1$ there is a moduli space of dimension 1 (possibly empty), but the translations of the tube act on this moduli space and, dividing by translations, we get a finite set. The number of points in this set, counted with suitable signs, gives an integer $n(\rho_-, \rho_+)$. Then, Floer considers the free abelian groups

$$C_* = \bigoplus_{\rho \in Z} \boldsymbol{Z}\langle\rho\rangle$$

generated by the set $Z$ and a map $\partial : C_* \to C_*$ defined by

$$\partial(\langle\rho_-\rangle) = \sum n(\rho_-, \rho_+)\langle\rho_+\rangle$$

Here the sum runs over the $\rho_+$ with $\delta(\rho_-, \rho_+) = 1$. Floer showed that $\partial^2 = 0$ and the homology $HF_*(Y) = \ker\partial/\mathrm{Im}\,\partial$ is independent of the metric on $Y$ (and various other choices made in implementing the construction in detail). The chain complex $C_*$ and hence the Floer homology can be graded by $\boldsymbol{Z}/8$, using the relative index, so the upshot is to define 8 abelian groups $HF_i(Y)$: invariants of the 3-manifold $Y$. The Casson invariant appears now as the Euler characteristic of the Floer homology. There has been extensive work on extending these ideas to other 3-manifolds (not homology spheres) and gauge groups, but this line of research does not yet seem to have reached a clear-cut conclusion.

Part of the motivation for Floer's work came from Morse theory, and particularly the approach to this theory expounded by Witten (1982). The Chern–Simons functional is a map

$$CS : \mathcal{A}/\mathcal{G} \to \boldsymbol{R}/\boldsymbol{Z}$$

from the space of SU(2)-connections over $Y$. Explicitly, in a trivialization of the bundle

$$\mathrm{CS}(A) = \int_Y A \wedge dA + \tfrac{3}{2} A \wedge A \wedge A$$

It appears as a boundary term in the Chern–Weil theory for the second Chern class, in a similar way as holonomy appears as a boundary term in the Gauss–Bonnet theorem. The set $Z$ can be identified with the critical points of CS and the instantons on the tube as integral curves of the gradient vector

field of CS. Floer's definition mimics the definition of homology in ordinary Morse theory, taking Witten's point of view. It can be regarded formally as the "middle-dimensional" homology of the infinite-dimensional space $\mathcal{A}/\mathcal{G}$. See Atiyah (1988) and Cohen *et al.* (1995) for discussions of these ideas.

The Floer theory interacts with 4-manifold invariants, making up a structure approximating to a $(3+1)$-dimensional topological field theory (Atiyah 1988). Roughly, the numerical invariants of closed 4-manifolds generalize to invariants for a 4-manifold $M$ with boundary $Y$ taking values in the Floer homology of $Y$. If two such manifolds are glued along a common boundary, the invariants of the result are obtained by a pairing in the Floer groups. There are, however, at the moment, some substantial technical restrictions on this picture. This theory, as well as Floer's original construction, is developed in detail by Donaldson (2002). At the time of writing, the Floer homology groups are still difficult to compute in examples. One important tool is a surgery-exact sequence found by Floer (Braam and Donaldson 1995), related to Casson's surgery formula.

### 3-Manifolds: Jones–Witten Theory

There is another, quite different, way in which ideas from gauge theory have entered 3-manifold topology. This is the Jones–Witten theory of knot and 3-manifold invariants. This theory falls outside the main line of this article, but we will say a little about it since it draws on many of the ideas we have discussed. The goal of the theory is to construct a family of $(2+1)$-dimensional topological field theories indexed by an integer $k$, assigning complex vector space $H_k(\Sigma)$ to a surface $\Sigma$ and an invariant in $H_k(\partial Y)$ to a 3-manifold-with-boundary $Y$. If $\partial Y$ is empty, the vector space $H_k(\partial Y)$ is taken to be $\mathbf{C}$, so one seeks numerical invariants of closed 3-manifolds. Witten's (1989) idea is that these invariants of closed 3-manifolds are Feynmann integrals

$$\int_{\mathcal{A}/\mathcal{G}} e^{i2\pi k \mathrm{CS}(A)} \mathcal{D}A$$

This functional integral is probably a schematic rather than a rigorous notion. The data associated with surfaces can, however, be defined rigorously. If we fix a complex structure $I$ on $\Sigma$, we can define a vector space $H_k(\Sigma, I)$ to be

$$H_k(\Sigma, I) = H^0(\mathcal{M}(\Sigma); L^k)$$

where $\mathcal{M}(\Sigma)$ is the moduli space of stable holomorphic bundles/flat unitary connections over $\Sigma$ and $L$ is a certain holomorphic line bundle over $\mathcal{M}(\Sigma)$. These are the spaces of "conformal blocks" whose dimension is given by the Verlinde formulas. Recall that $\mathcal{M}(\Sigma)$, as a symplectic manifold, is canonically associated with the surface $\Sigma$, without any choice of complex structure. The Hilbert spaces $H_k(\Sigma, I)$ can be regarded as the quantization of this symplectic manifold, in the general framework of geometric quantization: the inverse of $k$ plays the role of Planck's constant. What is not obvious is that this quantization is independent of the complex structure chosen on the Riemann surface: that is, that there is a natural identification of the vector spaces (or at least the associated projective spaces) formed by using different complex structures. This was established rigorously by Hitchin (1990) and Axelrod *et al.* (1991), who constructed a projectively flat connection on the bundle of spaces $H_k(\Sigma, I)$ over the space of complex structures $I$ on $\Sigma$. At a formal level, these constructions are derived from the construction of the metaplectic representation of a linear symplectic group, since the $\mathcal{M}_\Sigma$ are symplectic quotients of an affine symplectic space.

The Jones–Witten invariants have been rigorously established by indirect means, but it seems that there is still work to be done in developing Witten's point of view. If $Y^+$ is a 3-manifold with boundary, one would like to have a geometric definition of a vector in $H_k(\partial Y^+)$. This should be the quantized version of the submanifold $L^+$ (which is Lagrangian in $\mathcal{M}_\Sigma$) entering into the Casson theory.

### Seiberg–Witten Invariants

The instanton invariants of a 4-manifold can be regarded as the integrals of certain natural differential forms over the moduli spaces of instantons. Witten (1988) showed that these invariants could be obtained as functional integrals, involving a variant of the Feynman integral, over the space of connections and certain auxiliary fields (insofar as this latter integral is defined at all). A geometric explanation of Witten's construction was given by Atiyah and Jeffrey (1990). Developing this point of view, Witten made a series of predictions about the instanton invariants, many of which were subsequently verified by other means. This line of work culminated in 1994 where, applying developments in supersymmetric Yang–Mills QFT, Seiberg and Witten introduced a new system of invariants and a precise prediction as to how these should be related to the earlier ones.

The Seiberg–Witten invariants (Witten 1994) are associated with a $\mathrm{Spin}^c$ structure on a 4-manifold $M$. If $M$ is simply connected this is specified by a class $K \in H^2(M; \mathbf{Z})$ lifting $w_2(M)$. One has spin bundles

$S^+, S^- \to M$ with $c_1(S^\pm) = K$. The Seiberg–Witten equation is for a spinor field $\phi$ – a section of $S^+$ and a connection $A$ on the complex line bundle $\Lambda^2 S^+$. This gives a connection on $S^+$ and hence a Dirac operator

$$D_A : \Gamma(S^+) \to \Gamma(S^-)$$

The Seiberg–Witten equations are

$$D_A\phi = 0, \qquad F_A^+ = \sigma(\phi)$$

where $\sigma : S^+ \to \Lambda^+$ is a certain natural quadratic map. The crucial differential-geometric feature of these equations arises from the Weitzenbock formula

$$D_A^* D_A \phi = \nabla_A^* \nabla_A \phi + \frac{R}{4}\phi + \rho(F^+)\phi$$

where $R$ is the scalar curvature and $\rho$ is a natural map from $\Lambda^+$ to the endomorphisms of $S^+$. Then $\rho$ is adjoint to $\sigma$ and

$$\langle \rho(\sigma(\phi))\phi, \phi\rangle = |\phi|^4$$

It follows easily from this that the moduli space of solutions to the Seiberg–Witten equation is compact. The most important invariants arise when $K$ is chosen so that

$$K \cdot K = 2\chi(M) + 3\,\mathrm{sign}(M)$$

where $\chi(M)$ is the Euler characteristic and sign$(M)$ is the signature. (This is just the condition for $K$ to correspond to an almost-complex structure on $M$.) In this case, the moduli space of solutions is zero dimensional (after generic perturbation) and the Seiberg–Witten invariant SW$(K)$ is the number of points in the moduli space, counted with suitable signs.

Witten's conjecture relating the invariants, in its simplest form, is that when $M$ has simple type the classes $K$ for which SW$(K)$ is nonzero are exactly the basic classes $K_r$ of Kronheimer and Mrowka and that

$$\beta_r = 2^{C(M)}\mathrm{SW}(K_r)$$

where $C(M) = 2 + (1/4)(7\chi(M) + 11\,\mathrm{sign}(M))$. This asserts that the two sets of invariants contain exactly the same information about the 4-manifold.

The evidence for this conjecture, via calculations of examples, is very strong. A somewhat weaker statement has been proved rigorously by Feehan and Leness (2003). They use an approach suggested by Pidstragatch and Tyurin, studying moduli spaces of solutions to a nonabelian version of the Seiberg–Witten equations. These contain both the instanton and abelian Seiberg–Witten moduli spaces, and the strategy is to relate the topology of these two sets by standard localization arguments. (This approach is related to ideas introduced by Thaddeus (1994) in the case of bundles over Riemann surfaces.) The serious technical difficulty in this approach stems from the lack of compactness of the nonabelian moduli spaces. The more general versions of Witten's conjecture (Moore and Witten 1997) (e.g., when $b^+(M) = 1$) contain very complicated formulas, involving modular forms, which presumably arise as contributions from the compactification of the moduli spaces.

## Applications

Regardless of the connection with the instanton theory, one can go ahead directly to apply the Seiberg–Witten invariants to 4-manifold topology, and this has been the main direction of research since the 1990s. The features of the Seiberg–Witten theory which have led to the most prominent developments are the following.

1. The reduction of the equations to two dimensions is very easy to understand. This has led to proofs of the Thom conjecture and wide-ranging generalizations (Ozsvath and Szabo 2000).
2. The Weitzenboch formula implies that, if $M$ has positive scalar curvature, then solutions to the Seiberg–Witten equations must have $\phi = 0$. This has led to important interactions with four-dimensional Riemannian geometry (Lebrun 1996).
3. In the case when $M$ is a symplectic manifold, there is a natural deformation of the Seiberg–Witten equations, discovered by Taubes (1996), who used it to show that the Seiberg–Witten invariants of $M$ are nontrivial. More generally, Taubes showed that for large values of the deformation parameter the solutions of the deformed equation localize around surfaces in the 4-manifold and used this to relate the Seiberg–Witten invariants to the Gromov theory of pseudoholomorphic curves. These results of Taubes have completely transformed the subject of four-dimensional symplectic geometry.

Bauer and Furuta (2004) have combined the Seiberg–Witten theory with more sophisticated algebraic topology to obtain further results about 4-manifolds. They consider the map from the space of connections and spinor fields defined by the formulas on the left-hand side of the equations. The general idea is to obtain invariants from the homotopy class of this map, under a suitable notion of homotopy. A technical complication arises from the gauge group action, but this can be reduced to the action of a single U(1). Ignoring this issue, Bauer and Furuta have obtained invariants in the stable homotopy groups $\lim_{N\to\infty} \pi_{N+r}(S^N)$, which reduce to the ordinary numerical invariants when $r = 1$. Using these invariants, they obtain results about connected sums of

4-manifolds, for which the ordinary invariants are trivial. Using refined cobordism invariants ideas, Furuta made great progress towards resolving the question of which intersection forms arise from smooth, simply connected 4-manifolds. A well-known conjecture is that, if such a manifold is spin, then the second Betti number satisfies

$$b_2(M) \geq \tfrac{11}{8}|\mathrm{sign}(M)|$$

Furuta (2001) proved that $b_2(M) \geq (10/8)|\mathrm{sign}(M)| + 2$.

An important and very recent achievement, bringing together many different lines of work, is the proof of "Property P" in 3-manifold topology by Kronheimer and Mrowka (2004). This asserts that one cannot obtain a homotopy sphere (counter-example to the Poincaré conjecture) by +1-surgery along a nontrivial knot in $S^3$. The proof uses work of Gabai and Eliashberg to show that the manifold obtained by 0-framed surgery is embedded in a symplectic 4-manifold; Taubes' results to show that the Seiberg–Witten invariants of this 4-manifold are nontrivial; Feehan and Leness' partial proof of Witten's conjecture to show that the same is true for the instanton invariants; and the gluing rule and Floer's exact sequence to show that the Floer homology of the +1-surgered manifold is nontrivial. It follows then from the definition of Floer homology that the fundamental group of this manifold is not trivial; in fact, it must have an irreducible representation in SU(2).

# General Relativity: Experimental Tests

**C M Will**, Washington University, St. Louis, MO, USA

## Introduction

Einstein's general theory of relativity has become the foundation for our understanding of the gravitational interaction. Four decades of high-precision experiments have verified the theory with ever-increasing precision, with no confirmed evidence of a deviation from its predictions. The theory is now the standard framework for much of astronomy, with its searches for black holes, neutron stars, gravitational waves, and the origin and fate of the universe.

Yet modern developments in particle theory suggest that it may not be the entire story, and that

modification of the basic theory may be required at some level. String theory generally predicts a proliferation of gravity-like fields that could result in alterations of general relativity (GR) reminiscent of the Brans–Dicke theory of the 1960s. In the presence of extra dimensions, the gravity of the four-dimensional "brane" of a higher-dimensional world could be somewhat different from a pure four-dimensional GR. However, any theoretical speculation along these lines must still abide by the best current empirical bounds. This article will review experimental tests of GR and the theoretical implications of the results.

## The Einstein Equivalence Principle

The Einstein equivalence principle is a modern generalization of Einstein's 1907 idea of an equivalence between gravity and acceleration, or between free fall and an absence of gravity. It states that: (1) test bodies fall with the same acceleration independently of their internal structure or composition (weak equivalence principle, or WEP); (2) the outcome of any local nongravitational experiment is independent of the velocity of the freely falling reference frame in which it is performed (local Lorentz invariance, or LLI); and (3) the outcome of any local nongravitational experiment is independent of where and when in the universe it is performed (local position invariance, or LPI).

This principle is fundamental to gravitational theory, for it is possible to argue that, if EEP is valid, then gravitation and geometry are synonymous. In other words, gravity must be described by a "metric theory of gravity," in which (1) spacetime is endowed with a symmetric metric, (2) the trajectories of freely falling bodies are geodesics of that metric, and (3) in local freely falling reference frames, the nongravitational laws of physics are those written in the language of special relativity (see Will (1993) for further details).

GR is a metric theory of gravity, but so are many others, including the scalar–tensor theory of Brans and Dicke and many of its modern descendents, some of which are inspired by string theory.

### Tests of the Weak Equivalence Principle

To test the WEP, one compares the acceleration of two laboratory-sized bodies of different composition in an external gravitational field. Although legend suggests that Galileo may have demonstrated this principle to his students at the Leaning Tower of Pisa, and Newton tested it by means of pendulum experiments, the first true high-precision experiments were done at the end of the nineteenth century by the Hungarian physicist Baron Roland von Eötvös and colleagues.

Eötvös employed a torsion balance, in which (schematically) two bodies of different composition are suspended at the ends of a rod that is supported horizontally by a fine wire or fiber. One then looks for a difference in the horizontal accelerations of the two bodies as revealed by a slight rotation of the rod. The source of the horizontal gravitational force could be the Sun, a large mass in or near the laboratory, or, as Eötvös recognized, the Earth itself. A measurement or limit on the fractional difference in acceleration between two bodies yields a quantity $\eta \equiv 2|a_1 - a_2|/|a_1 + a_2|$, called the "Eötvös ratio." Eötvös' experiments showed that $\eta$ was smaller than a few parts in $10^9$, and later classic experiments in the 1960s and 1970s by Dicke and Braginsky improved the bounds by several orders of magnitude. Additional experiments were carried out during the 1980s as part of a search for a putative "fifth force," that was motivated in part by a re-analysis of Eötvös' original data.

The best limit on $\eta$ currently comes from experiments carried out during the 1985–2000 period at the University of Washington (called the "Eöt-Wash" experiments), which used a sophisticated torsion balance tray to compare the accelerations of bodies of different composition toward the Earth, the Sun, and the galaxy. Another strong bound comes from ongoing laser ranging to reflectors deposited on the Moon during the Apollo program in the 1970s (lunar laser ranging, LLR), which routinely determines the Earth–Moon distance to millimeter accuracies. The data may be used to check the equality of acceleration of the Earth and Moon toward the Sun. The results from laboratory and LLR experiments are (Will 2001):

$$\eta_{\text{Eöt-Wash}} < 4 \times 10^{-13}, \qquad \eta_{\text{LLR}} < 5 \times 10^{-13} \qquad [1]$$

LLR also shows that gravitational binding energy falls with the same acceleration as ordinary matter to $1.3 \times 10^{-3}$ (test of the Nordtvedt effect – see the section "Bounds on the PPN parameters" and Table 1).

Many of the high-precision, low-noise methods that were developed for tests of WEP have been adapted to laboratory tests of the inverse-square law of Newtonian gravitation at millimeter scales and below. The goal of these experiments is to search for additional gravitational interactions involving massive particles or for the presence of large extra dimensions. The challenge of these experiments is to distinguish gravitation-like interactions from electromagnetic and quantum-mechanical effects. No deviations from

**Table 1** Current limits on the PPN parameters

| *Parameter* | *Effect* | *Limit* | *Remarks* |
|---|---|---|---|
| $\gamma - 1$ | (i) Shapiro delay | $2.3 \times 10^{-5}$ | Cassini tracking |
| | (ii) Light deflection | $4 \times 10^{-4}$ | VLBI |
| $\beta - 1$ | (i) Perihelion shift | $3 \times 10^{-3}$ | $J_2 = 10^{-7}$ from helioseismology |
| | (ii) Nordtvedt effect | $2.3 \times 10^{-4}$ | LLR plus bounds on other parameters |
| $\xi$ | Anisotropy in Newton's $G$ | $10^{-3}$ | Gravimeter bounds on anomalous Earth tides |
| $\alpha_1$ | Orbit polarization for moving systems | $10^{-4}$ | Lunar laser ranging |
| $\alpha_2$ | Anomalous spin precession for moving bodies | $4 \times 10^{-7}$ | Alignment of solar axis relative to ecliptic |
| $\alpha_3$ | Anomalous self-acceleration for spinning moving bodies | $2 \times 10^{-20}$ | Pulsar spindown timing data |
| $\eta$[a] | Nordtvedt effect | $9 \times 10^{-4}$ | Lunar laser ranging |
| $\zeta_1$ | | $2 \times 10^{-2}$ | Combined PPN bounds |
| $\zeta_2$ | Anomalous self-acceleration for binary systems | $4 \times 10^{-5}$ | Timing data for PSR 1913 + 16 |
| $\zeta_3$ | Violation of Newton's third law | $10^{-8}$ | Lunar laser ranging |
| $\zeta_4$ | | | Not independent |

[a]Here $\eta = 4\beta - \gamma - 3 - 10\xi/3 - \alpha_1 + 2\alpha_2/3 - 2\zeta_1/3 - \zeta_2/3$.

Newton's inverse-square law have been found to date at distances between 10 μm and 10 mm.

### Tests of Local Lorentz Invariance

Although special relativity itself never benefited from the kind of "crucial" experiments, such as the perihelion advance of Mercury and the deflection of light, that contributed so much to the initial acceptance of GR and to the fame of Einstein, the steady accumulation of experimental support, together with the successful integration of special relativity into quantum mechanics, led to its being accepted by mainstream physicists by the late 1920s, ultimately to become part of the standard toolkit of every working physicist.

But in recent years new experiments have placed very tight bounds on any violations of the Lorentz invariance, which underlies special relativity. A simple way of interpreting this new class of experiments is to suppose that a coupling of some external gravitation-like field (not the metric) to the electromagnetic interactions results in an effective change in the speed of electromagnetic radiation, $c$, relative to the limiting speed of material test particles, $c_0$; in other words, $c \neq c_0$. It can be shown that such a Lorentz-noninvariant electromagnetic interaction would cause shifts in the energy levels of atoms and nuclei that depend on the orientation of the quantization axis of the state relative to our velocity relative to the rest of the universe, and on the quantum numbers of the state, resulting in orientation dependences of the fundamental frequencies of such atomic clocks. The magnitude of these "clock anisotropies" would be proportional to $\delta \equiv |(c_0/c)^2 - 1|$, which vanishes if Lorentz invariance holds (see Will (1993) and Haugan and Will (1987) for details).

The earliest clock anisotropy experiments were carried out around 1960 independently by Hughes and Drever, although their original motivation was somewhat different. Dramatic improvements were made in the 1980s using laser-cooled trapped atoms and ions. This technique made it possible to reduce the broadening of resonance lines caused by collisions, leading to the impressive bound $|\delta| > 10^{-21}$ (Will 2001).

Other recent tests of Lorentz invariance violation include comparisons of resonant cavities with atomic clocks, tests of dispersion and birefringence in the propagation of high-energy photons from astrophysical sources, threshold effects in elementary particle collisions, and anomalies in neutrino oscillations. Mattingly (2005) gives a thorough and up-to-date review of both the theoretical frameworks for studying these effects and the experimental results.

### Tests of Local Position Invariance

LPI requires, among other things, that the internal binding energies of atoms and nuclei be independent of location in space and time, when measured against some standard atom. This means that a comparison of the rates of two different kinds of atomic clocks should be independent of location or epoch, and that the frequency shift between two identical clocks at different locations is simply a consequence of the apparent Doppler shift between a pair of inertial frames momentarily comoving with the clocks at the moments of emission and reception, respectively. The relevant parameter $\alpha$ appears in the formula for the frequency shift,

$$\Delta f/f = (1 + \alpha)\Delta\Phi/c^2 \quad [2]$$

where $\Phi$ is the Newtonian gravitational potential. If LPI holds, $\alpha = 0$. An early test of this was the Pound–Rebka experiment of 1960, which measured the frequency shift of gamma rays from radioactive iron nuclei in a tower at Harvard University. The best bounds come from a 1976 experiment in which a hydrogen maser atomic clock was launched to 10 000 km altitude on a Scout rocket and its frequency compared via telemetry with an identical clock on the ground, and a 1993 experiment in which two different kinds of atomic clocks were intercompared as a function of the varying solar gravitational field as seen on Earth (a "null" redshift experiment). The results are (Will 2001):

$$\alpha_{\text{Maser}} < 2 \times 10^{-4}, \qquad \alpha_{\text{Null}} < 10^{-3} \qquad [3]$$

Recent "clock comparison" tests of LPI include experiments done at the National Institute of Standards and Technology (NIST) in Boulder and at the Observatory of Paris, to look for cosmological variations in clock rates. The NIST experiment compared laser-cooled mercury ions with neutral cesium atoms over a two-year period, while the Paris experiment compared laser-cooled cesium and rubidium atomic fountains over five years; the results showed that the fine-structure constant is constant in time to a part in $10^{15}$ per year. A better bound of $6 \times 10^{-17}\,\text{yr}^{-1}$ comes from analysis of fission yields of the Oklo natural reactor, which occurred in Africa two billion years ago.

## Solar-System Tests

### The Parametrized Post-Newtonian Framework

It was once customary to discuss experimental tests of GR in terms of the "three classical tests," the gravitational redshift (which is really a test of the EEP, not of GR itself; see the section on tests of LPI), the perihelion advance of Mercury (the first success of the theory), and the deflection of light (whose measurement in 1919 made Einstein a celebrity). However, the proliferation of additional experimental tests and of well-motivated alternative metric theories of gravity made it desirable to develop a more general theoretical framework for analyzing both experiments and theories. This "parametrized post-Newtonian (PPN) framework" dates back to Eddington in 1922, but was fully developed by Nordtvedt and Will in the period 1968–72 (see Will (1993) for details).

When attention is confined to metric theories of gravity and, further, the focus is on the slow-motion, weak-field limit appropriate to the solar system and similar systems, it turns out that, in a broad class of metric theories, only the numerical values of a set of coefficients in the spacetime metric vary from theory to theory. The resulting PPN framework contains ten parameters: $\gamma$, related to the amount of spatial curvature generated by mass; $\beta$, related to the degree of nonlinearity in the gravitational field; $\xi$, $\alpha_1$, $\alpha_2$, and $\alpha_3$, which determine whether the theory violates LPI or LLI in gravitational experiments; and $\zeta_1$, $\zeta_2$, $\zeta_3$, and $\zeta_4$, which describe whether the theory has appropriate momentum conservation laws. In GR, $\gamma = 1$, $\beta = 1$, and the remaining parameters all vanish. In the scalar–tensor theory of Brans–Dicke, $\gamma = (1 + \omega_{\text{BD}})/(2 + \omega_{\text{BD}})$, where $\omega_{\text{BD}}$ is an adjustable parameter.

A number of well-known relativistic effects can be expressed in terms of these PPN parameters:

**Deflection of light**

$$\Delta\theta = \left(\frac{1+\gamma}{2}\right)\frac{4GM}{dc^2} = \left(\frac{1+\gamma}{2}\right) \times 1.7505\,\frac{R_\odot}{d}\ \text{arcsec} \qquad [4]$$

where $d$ is the distance of closest approach of a ray of light to a body of mass $M$, and where the second line is the deflection by the Sun, with radius $R_\odot$.

**Shapiro time delay**

$$\Delta t = \left(\frac{1+\gamma}{2}\right)\frac{4GM}{c^3}\ln\left[\frac{(r_1 + \boldsymbol{x}_1 \cdot \boldsymbol{n})(r_2 - \boldsymbol{x}_2 \cdot \boldsymbol{n})}{d^2}\right] \qquad [5]$$

where $\Delta t$ is the excess travel time of a round-trip electromagnetic tracking signal, $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ are the locations relative to the body of mass $M$ of the emitter and receiver of the round-trip signal ($r_1$ and $r_2$ are the respective distances), and $\boldsymbol{n}$ is the direction of the outgoing tracking signal.

**Perihelion advance**

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = \left(\frac{2+2\gamma-\beta}{3}\right)\frac{GM}{Pa(1-e^2)c^2} = \left(\frac{2+2\gamma-\beta}{3}\right) \times 42.98\ \text{arcsec}/100\,\text{yr} \qquad [6]$$

where $P$, $a$, and $e$ are the period, semimajor axis, and eccentricity of the planet's orbit, respectively; the second line is the value for Mercury.

**Nordtvedt effect**

$$\frac{m_{\text{G}} - m_{\text{I}}}{m_{\text{I}}} = \left(4\beta - \gamma - 3 - \tfrac{10}{3}\xi - \alpha_1 + \tfrac{2}{3}\alpha_2 - \tfrac{2}{3}\zeta_1 - \tfrac{1}{3}\zeta_2\right)\frac{|E_{\text{g}}|}{m_{\text{I}}c^2} \qquad [7]$$

where $m_{\text{G}}$ and $m_{\text{I}}$ are, respectively, the gravitational and inertial masses of a body such as the Earth or

Moon, and $E_g$ is its gravitational binding energy. A nonzero Nordtvedt effect would cause the Earth and Moon to fall with a different acceleration toward the Sun. In GR, this effect vanishes.

### Precession of a gyroscope

$$\frac{dS}{dt} = (\Omega_{FD} + \Omega_{Geo}) \times S$$
$$\Omega_{FD} = -\frac{1}{2}\left(1+\gamma+\frac{\alpha_1}{4}\right)\frac{G}{r^3c^2}(J - 3nn \cdot J)$$
$$= \frac{1}{2}\left(1+\gamma+\frac{\alpha_1}{4}\right) \times 0.041 \,\text{arcsec yr}^{-1}$$
$$\Omega_{Geo} = -\frac{1}{2}(1+2\gamma)v \times \frac{Gmn}{r^2c^2}$$
$$= \frac{1}{3}(1+2\gamma) \times 6.6 \,\text{arcsec yr}^{-1} \qquad [8]$$

where $S$ is the spin of the gyroscope, and $\Omega_{FD}$ and $\Omega_{Geo}$ are, respectively, the precession angular velocities caused by the dragging of inertial frames (Lense–Thirring effect) and by the geodetic effect, a combination of Thomas precession and precession induced by spatial curvature; $J$ is the angular momentum of the Earth, and $v$, $n$, and $r$ are, respectively, the velocity, direction, and distance of the gyroscope. The second line in each case is the corresponding value for a gyroscope in polar Earth orbit at about 650 km altitude (Gravity Probe B).

## Bounds on the PPN Parameters

Four decades of high-precision experiments, ranging from the standard light-deflection and perihelion-shift tests, to LLR, planetary and satellite tracking tests of the Shapiro time delay, and geophysical and astronomical observations, have placed bounds on the PPN parameters that are consistent with GR. The current bounds are summarized in Table 1 (Will 2001).

To illustrate the dramatic progress of experimental gravity since the dawn of Einstein's theory, Figure 1 shows a history of results for $(1+\gamma)/2$, from the 1919 solar eclipse measurements of Eddington and his colleagues (which made Einstein a celebrity), to modern-day measurements using very long baseline radio interferometry (VLBI), advanced radar tracking of spacecraft, and the astrometry satellite Hipparcos. The most recent results include a 2003 measurement of the Shapiro delay, performed by tracking the "Cassini" spacecraft on its way to Saturn, and a 2004 measurement of the bending of light via analysis of VLBI data on 541 quasars and compact radio galaxies distributed over the entire sky.

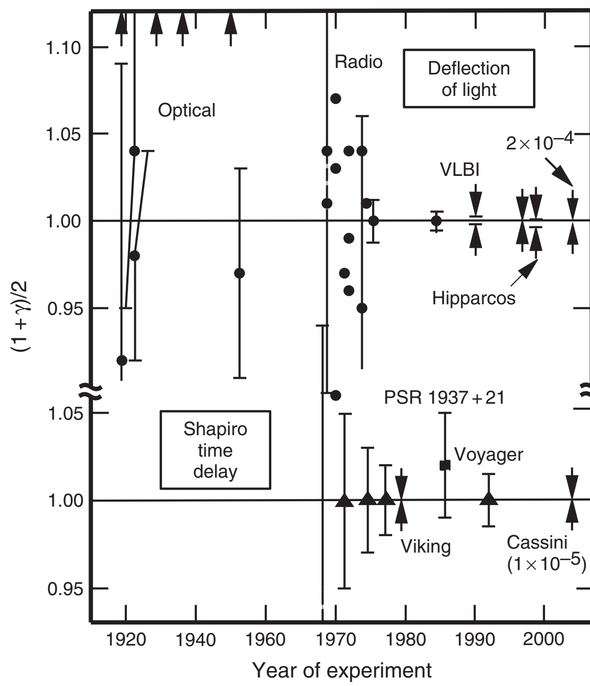

**Figure 1** Measurements of the coefficient $(1+\gamma)/2$ from observations of the deflection of light and of the Shapiro delay in propagation of radio signals near the Sun. The GR prediction is unity. "Optical" denotes measurements of stellar deflection made during solar eclipse, and "Radio" denotes interferometric measurements of radio-wave deflection. "Hipparcos" denotes the European optical astrometry satellite. Arrows denote values well off the chart from one of the 1919 eclipse expeditions and from others through 1947. Shapiro delay measurements using the Cassini spacecraft on its way to Saturn yielded tests at the 0.001% level, and light deflection measurements using VLBI have reached 0.02%.

The perihelion advance of Mercury, the first of Einstein's successes, is now known to agree with observation to a few parts in $10^3$. During the 1960s there was controversy about this test when reports of an excess solar oblateness implied an unacceptably large Newtonian contribution to the perihelion advance. However, it is now known from helioseismology, the study of short-period vibrations of the Sun, that the oblateness is of the order of a part in $10^7$, as expected from standard solar models, much too small to affect Mercury's orbit, within the observational errors.

## Gravity Probe B

The NASA Relativity Mission called Gravity Probe B (GPB) recently completed its mission to measure the Lense–Thirring and geodetic precessions of gyroscopes in Earth's orbit. Launched on 20 April 2004 for a 16-month mission, it consisted of four spherical rotors coated with a thin layer of superconducting niobium, spinning at 70–100 Hz, in a spacecraft filled with liquid helium, containing a telescope continuously pointed

toward a distant guide star (IM Pegasi). Superconducting current loops encircling each rotor were designed to measure the change in direction of the rotors by detecting the change in magnetic flux through the loop generated by the London magnetic moment of the spinning superconducting film. The spacecraft was in a polar orbit at 650 km altitude. The primary science goal of GPB was a 1% measurement of the 41 marcsec $yr^{-1}$ frame dragging or Lense–Thirring effect caused by the rotation of the Earth; its secondary goal was to measure to six parts in $10^5$ the larger 6.6 arcsec $yr^{-1}$ geodetic precession caused by space curvature.

## The Binary Pulsar

The binary pulsar PSR 1913 + 16, discovered in 1974, provided important new tests of GR. The pulsar, with a pulse period of 59 ms, was observed to be in orbit about an unseen companion (now generally thought to be a dead pulsar), with a period of $\sim$8 h. Through precise timing of apparent variations in the pulsar "clock" caused by the Doppler effect, the important orbital parameters of the system could be measured with exquisite precision. These included nonrelativistic "Keplerian" parameters, such as the eccentricity $e$, and the orbital period (at a chosen epoch) $P_b$, as well as a set of relativistic "post-Keplerian" (PK) parameters. The first PK parameter, $\langle\dot{\omega}\rangle$, is the mean rate of advance of periastron, the analog of Mercury's perihelion shift. The second, denoted $\gamma'$, is the effect of special relativistic time dilation and the gravitational redshift on the observed phase or arrival time of pulses, resulting from the pulsar's orbital motion and the gravitational potential of its companion. The third, $\dot{P}_b$, is the rate of decrease of the orbital period; this is taken to be the result of gravitational radiation damping (apart from a small correction due to the acceleration of the system in our rotating galaxy). Two other parameters, $s$ and $r$, are related to the Shapiro time delay of the pulsar signal if the orbital inclination is such that the signal passes in the vicinity of the companion; $s$ is a direct measure of the orbital inclination sin $i$. According to GR, the first three PK effects depend only on $e$ and $P_b$, which are known, and on the two stellar masses, which are unknown. By combining the observations of PSR 1913 + 16 (see Table 2) with the GR predictions, one obtains both a measurement of the two masses and a test of GR, since the system is overdetermined. The results are

$$m_1 = 1.4414 \pm 0.0002 M_\odot, \qquad m_2 = 1.3867 \pm 0.0002 M_\odot$$
$$\dot{P}_b^{GR}/\dot{P}_b^{OBS} = 1.0013 \pm 0.0021 \qquad [9]$$

Other relativistic binary pulsars may provide even more stringent tests. These include the relativistic neutron star/white dwarf binary pulsar J1141-6545, with a 0.19 day orbital period, which may ultimately lead to a very strong bound on the phenomenon of dipole gravitational radiation, predicted by many alternative theories of gravity, but not by GR; and the remarkable "double pulsar" J0737-3039, a binary system with two detected pulsars, in a 0.10 day orbit seen almost edge on and a periastron advance of 17° per year. For further discussion of binary pulsar tests, see Stairs (2003).

## Gravitational-Wave Tests

The detection of gravitational radiation by either laser interferometers or resonant cryogenic bars will usher in a new era of gravitational-wave astronomy (Barish and Weiss 1999). Furthermore, it will yield new and interesting tests of GR in its radiative regime (Will 1999).

GR predicts that gravitational waves possess only two polarization modes independently of the source; they are transverse to the direction of propagation and quadrupolar in their effect on a detector. Other theories of gravity may predict up to four additional modes of polarization. A suitable array of gravitational antennas could delineate or limit the number of modes present in a given wave. If distinct evidence were found of any mode other than the two transverse quadrupolar modes of GR, the result would be disastrous for the theory.

**Table 2** Parameters of the binary pulsars PSR 1913 + 16 and J0737-3039

| *Parameter* | *Symbol* | *Value*[a] *in PSR*1913 + 16 | *Value*[a] *in* J0737-3039 |
|---|---|---|---|
| *Keplerian parameters* | | | |
| Eccentricity | $e$ | 0.6171338(4) | 0.087779(5) |
| Orbital period | $P_b$ (day) | 0.322997448930(4) | 0.102251563(1) |
| *Post-Keplerian parameters* | | | |
| Periastron advance | $\langle\dot{\omega}\rangle$(°$yr^{-1}$) | 4.226595(5) | 16.90(1) |
| Redshift/time dilation | $\gamma'$ (ms) | 4.2919(8) | 0.382(5) |
| Orbital period derivative | $\dot{P}_b(10^{-12})$ | −2.4184(9) | |
| Shapiro delay ( sin $i$) | $s$ | | 0.9995(4) |

[a]Numbers in parentheses denote errors in last digit.

According to GR, gravitational waves propagate with the same speed, $c$, as light. In other theories, the speed could differ from $c$ because of coupling of gravitation to "background" gravitational fields, or propagation of the waves into additional spatial dimensions. Another way in which the speed of gravitational waves could differ from $c$ is if gravitation were propagated by a massive field (a massive graviton), in which case $v_g$ would be given by, in a local inertial frame,

$$\frac{v_g^2}{c^2} = 1 - \frac{m_g^2 c^4}{E^2} \approx 1 - \frac{c^2}{f^2 \lambda_g^2} \qquad [10]$$

where $m_g$, $E$, and $f$ are the graviton rest mass, energy, and frequency, respectively, and $\lambda_g = h/m_g c$ is the graviton Compton wavelength (it is assumed that $\lambda_g \gg c/f$).

The most obvious way to measure the speed of gravitational waves is to compare the arrival times of a gravitational wave and an electromagnetic wave from the same event (e.g., a supernova). For a source at a distance of 600 million light years (a typical distance for the currently operational detectors), and a difference in times on the order of seconds, the bound on the difference $|1 - v_g/c|$ could be as small as a part in $10^{17}$. It is worth noting that a 2002 report that the speed of gravity had been measured by studying light from a quasar as it propagated past Jupiter was fundamentally flawed. That particular measurement was not sensitive to the speed of gravity.

## Conclusions

The past four decades have witnessed a systematic, high-precision experimental verification of Einstein's theories. Relativity has passed every test with flying colors. A central theme of future work will be to test strong-field gravity in the vicinity of black holes and neutron stars, and to see how well GR works on cosmological scales. Gamma-ray, X-ray, microwave, infrared, neutrino, and gravitational-wave astronomy will all play a critical role in probing these largely unexplored aspects of GR.

GR is now the "standard model" of gravity. But, as in particle physics, there may be a world beyond the standard model. Quantum gravity, strings, and branes may lead to testable effects beyond Einstein's GR. Searches for such effects using laboratory experiments, particle accelerators, space instrumentation, and cosmological observations are likely to continue for some time to come.

# General Relativity: Overview

**R Penrose**, University of Oxford, Oxford, UK

## The Principle of Equivalence

The special theory of relativity is founded on two basic principles: that the laws of physics should be independent of the uniform motion of an inertial frame of reference, and that the speed of light should have the same constant value in any such frame. In the years between 1905 and 1915, Einstein pondered deeply on what was, to him, a profound enigma, which was the issue of why these laws retain their proper form only in the case of an inertial frame. In special relativity, as had been the case in the earlier dynamics of Galilei–Newton, the laws indeed retain their basic form only when the reference frame is unaccelerated (which includes it being nonrotating). It demonstrated a particular prescience on the part of Einstein that he should have demanded the seemingly impossible requirement that the very same dynamical laws should hold also in an accelerating (or even rotating) reference frame. The key realization came to him late in 1907, when sitting in his chair in the Bern

patent office he had the "happiest thought" in his life, namely that if a person were to fall freely in a gravitational field, then he would not notice that field at all while falling. The physical point at issue is Galileo's early insight (itself having roots even earlier from Simon Stevin in 1586 or Ioannes Philiponos in the fifth or sixth century) that the acceleration induced by gravity is independent of the body upon which it acts. Accordingly, if two neighboring bodies are accelerated together in the same gravitational field, then the motion of one body, in the (nonrotating) reference frame of the other, will be as though there were no gravitational field at all. To put this another way, the effect of a gravitational force is just like that of an accelerating reference system, and can be eliminated by free fall. This is now known as the "principle of equivalence."

It should be made clear that this is a particular feature of only the gravitational field. From the perspective of Newtonian dynamics, it is a consequence of the seemingly accidental fact that the concept of (passive) "mass" $m$ that features in Newton's law of gravitational attraction, where the attractive force due to the gravitational field of another body, of mass $M$, has the form

$$\frac{GmM}{r^2}$$

is the same as – or, at least, proportional to – the inertial mass $m$ of the body which is being acted upon. Thus, the impedance to acceleration of a body and the strength of the attractive force on that body are, in the case of gravity (and only in the case of gravity), in proportion to one another, so that the acceleration of a body in a gravitational field is independent of its mass (or, indeed, of any other localized magnitude) possessed by it. (The fact that the active gravitational mass, here given by the quantity $M$, is also in proportion to its own passive gravitational mass – from Newton's third law – may be regarded as a feature of the general Lagrangian/Hamiltonian framework of physics. But see Bondi (1957).) Other forces of nature do not have this property. For example, the electrostatic force on a charged body, by an electric field, acts in proportion to the electric charge on that body, whereas, the impedance to acceleration is still the inertial mass of that body, so the acceleration induced depends on the charge-to-mass ratio. Accordingly, it is the gravitational field alone which is equivalent to an acceleration.

Einstein's fundamental idea, therefore, was to take the view that the "relativity principle" could as well be applied to accelerating reference frames as to inertial ones, where the same physical laws would apply in each, but where now the perceived gravitational field would be different in the two frames. In accordance with this perspective, Einstein found it necessary to adopt a different viewpoint from the Newtonian one, both with regard to the notion of "gravitational force" and to the very notion of an "inertial frame." According to the Newtonian perspective, it would be appropriate to describe the action of the Earth's gravitational field, near some specific place on the Earth's surface, in terms of a "Newtonian inertial frame" in which the Earth is "fixed" (here we ignore the Earth's rotation and the Earth's motion about the Sun), and we consider that there is a constant gravitational field of force (directed towards the Earth's center). But the Einsteinian perspective is to regard that frame as noninertial where, instead, it would be a frame which falls freely in the Earth's (Newtonian) gravitational field that would be regarded as a suitable "Einsteinian inertial frame." Generally, to be inertial in Einstein's sense, the frame would refer to free fall under gravity, so that the Newtonian field of gravitational force would appear to have disappeared – in accordance with his "happiest thought" that Einstein had had in the Bern patent office. We see that the concept of a gravitational field must also be changed in the passage from Newton's to Einstein's viewpoint. For in Newton's picture we indeed have a "gravitational force" directed towards the ground with a magnitude of $gm$, where $m$ is the mass of the body being acted upon and $g$ is the "acceleration due to gravity" at the Earth's surface, whereas in Einstein's picture we have specifically eliminated this "gravitational force" by the choice of "Einsteinian inertial frame."

It might at first seem puzzling that the gravitational field has appeared to have been removed altogether by this device, and it is natural to wonder how gravitational effects can have any physical role to play at all from this point of view! However, this would be to go too far, as the Newtonian gravitational field may vary from place to place – as it does, indeed, in the case of the Earth's field, since it is directed towards the Earth's center, which is a different spatial direction at different places on the Earth's surface. Our considerations up to this point really refer only to a small neighborhood of a point. One might well take the view that a "frame" ought really to describe things also at widely separated places at once, and the considerations of the paragraphs above do not really take this into consideration.

## The Tidal Effect

To proceed further, it will be helpful to consider an astronaut A in free fall, high above the Earth's surface. Let us first adopt a Newtonian perspective.

We shall be concerned only with the instantaneous accelerations due to gravity in the neighborhood of A, so it will be immaterial whether we regard the astronaut as falling to the ground or – more comfortably! – in orbit about the Earth.

Let us imagine that the astronaut is initially surrounded, nearby, by a sphere of particles, with A at the centre, which are taken to be initially at rest with respect to A (see Figure 1). To a first approximation, all the particles will share the same acceleration as the astronaut, so they will seem to the astronaut to hover motionless all around. But now let us be a little more precise about the accelerations. Those particles which are initially located in a vertical line from A, that is, either directly below A, at B, or directly above A, at T, will have, like A, an acceleration which is in the direction AO, where O is the Earth's center. But for the bottom point B, the acceleration will be slightly greater than that at A, and for the top point T, the acceleration will be slightly less than the acceleration at A, because of the slightly differing distances from O. Thus, relative to A, both will initially accelerate away from A. With regard to particles in the sphere which are initially in a circle in the horizontal plane through A, the direction to O will now be somewhat inwards, so that the particles at these points $H_i$ will accelerate, relative to A, slightly inwards. Accordingly, the entire sphere of particles will begin to get distorted into a prolate spheroid (elongated ellipsoid of revolution). This is referred to as the tidal distortion, for the good reason that it is precisely the same physical effect which is responsible for the tides in the Earth's oceans, where for this illustration we are to think of the Earth's center as being at A, the Moon (or Sun) to be situated at O, and the sphere of particles to represent the surface of the water of the Earth's oceans.

It is not hard to calculate (reverting, now, to our original picture) that, as a reflection of Newton's inverse-square law of gravitational attraction, the amount of (small) outward vertical displacement from A (at B and T) will be twice the inward horizontal displacement (over the circle of points $H_i$); accordingly, the sphere will initially be distorted into an ellipsoid of the same volume. This depends upon there being no gravitating matter inside the sphere. The presence of such matter would contribute a volume-reducing effect in proportion to the total mass surrounded. (An extreme case illustrating this would occur if we take our sphere of particles to surround the entire Earth, where the volume-reducing effect would be manifest in the accelerations towards the ground at all points of the surrounding sphere.)

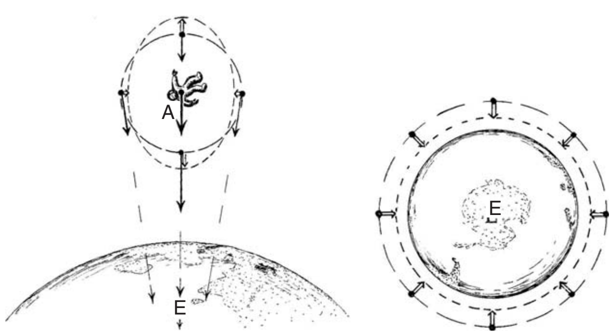

**Figure 1** (a) Tidal effect. The astronaut A surrounded by a sphere of nearby particles initially at rest with respect to A. In Newtonian terms, they have an acceleration towards the Earth's center E, varying slightly in direction and magnitude (single-shafted arrows). By subtracting A's acceleration from each, we obtain the accelerations relative to A (double-shafted arrows); this relative acceleration is slightly inward for those particles displaced horizontally from A, but slightly outward for those displaced vertically from A. Accordingly, the sphere becomes distorted into a (prolate) ellipsoid of revolution, with symmetry axis in the direction AE. The initial distortion preserves volume. (b) Now move A to the Earth's center E and the sphere of particles to surround E just above the atmosphere. The acceleration (relative to A = E) is inward all around the sphere, with an initial volume reduction acceleration $4\pi GM$, where $M$ is the total mass surrounded. ## Gravity as Curved Spacetime

It is appropriate to take a spacetime view of these phenomena (Figure 2). The distortions that we have been considering are, in fact, direct manifestations

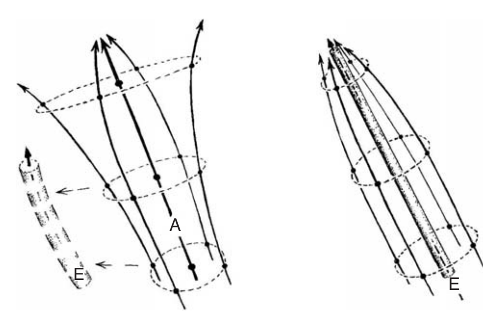

**Figure 2** Spacetime versions of Figure 1 in terms of the relative distortion of neighboring geodesics. (a) Geodesic deviation in empty space (basically Weyl curvature) as seen in the world lines of A and surrounding particles (one spatial dimension suppressed), as might be induced from the gravitational field of a nearby body E. (b) The corresponding inward acceleration (basically Ricci curvature) due to the mass density within the bundle of geodesics. Reproduced with permission from Penrose R (2004) *The Road to Reality: A Complete Guide to the Laws of the Universe*. London: Jonathan Cape.

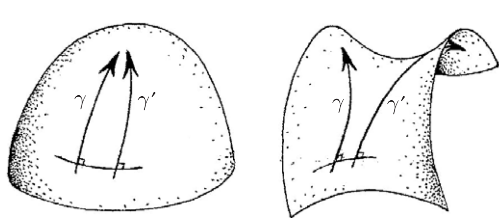
of spacetime curvature, according to Einstein's viewpoint. We are to think of the world line of a particle, falling freely under gravity (Einsteinian inertial motion), as described as some kind of geodesic in spacetime. We shall be coming to this more completely shortly, but for the moment it will be helpful to picture the behavior of geodesics within an ordinary curved 2-surface S (Figure 3). If S has positive (Gaussian) curvature, then there will be a tendency for geodesics on S to bend towards each other, so that a pair of infinitesimally separated geodesics which are initially parallel will begin to get closer together as we move along them; if S has negative (Gaussian) curvature, then there will be a corresponding tendency for geodesics on S to bend away from each other. This is what happens in two dimensions, where the intrinsic curvature at a point is given by a single number. However, we are now concerned with a four-dimensional space, where the notion of curvature requires many more components. We see in **Figure 2** that we are indeed to expect mixtures of convergence and divergence of geodesics, which suggests that there are both positive and negative curvature components involved, the positive curvature being in the horizontally displaced directions from A and the negative curvature in the vertically displaced directions. In a curved space of dimension 4, as is the case for a curved spacetime, we can expect 20 independent components of curvature at each point altogether. In the present situation, the others would be called into play when differing velocities of A are considered.

Let us see how we are to accommodate the above considerations within the standard framework of differential geometry. So far, we have not really deviated from Newtonian theory, even though we have been considering "geodesics" in a four-dimensional spacetime. In fact, it is perfectly legitimate to view Newtonian theory in this way (*see* Newtonian



(a) (b)

**Figure 3** Geodesic deviation when M is a 2-surface (a) of positive (Gaussian) curvature, when the geodesics $\gamma, \gamma''$ bend towards each other, and (b) of negative curvature, when they bend apart. Reproduced with permission from Penrose R (2004) *The Road to Reality: A Complete Guide to the Laws of the Universe*. London: Jonathan Cape.

Limit of General Relativity), although the 4-geometry description is somewhat more complicated than one might wish. This is due to the fact that the infinite speed at which gravitation is taken to act in Newtonian theory demands that the "metric" of Newtonian spacetime is degenerate. (In effect, one would have a degenerate "dual metric" $G^{ab}$, of matrix rank 3, which plays a role in defining spatial displacements and a very degenerate "metric" $G_{ab}$, of matrix rank 1, which defines temporal differences, where $G^{ab}G_{bc} = 0$; *see* Newtonian Limit of General Relativity.) Accordingly, there is no unique notion of "geodesic" defined by the metric in Newtonian theory.

It is striking that although the insights provided by the principle of equivalence are to some considerable extent independent of special relativity (since we see from the paragraphs prior to the preceding one that a curved-spacetime-geometry view of gravity is natural in the light of the equivalence principle alone), it is the nondegenerate metric $g_{ab}$, (and its inverse $g^{ab}$) that special relativity gives us locally, which leads to an elegant spacetime theory of gravity. Although the metric $g_{ab}$ is Lorentzian (with preferred choice of signature $+---$ here) rather than positive definite, so that the spacetime is not strictly a Riemannian one, the change of signature makes little difference to the local formalism. In particular, the fact that the metric defines a unique (torsion-free) connection preserving it is unaffected by the signature. This connection is the one defined by Christoffel's symbols

$$\Gamma_{ac}{}^{b} = \tfrac{1}{2} g^{db}(\partial_c g_{da} + \partial_a g_{cd} - \partial_d g_{ca})$$

where $\partial_a$ stands for coordinate derivative $\partial/\partial x^a$, so that the covariant derivative of a vector $V^a$ is given by

$$\nabla_a V^b = \partial_a V^b + V^c \Gamma_{ac}{}^{b}$$

(Here the standard "physicist's conventions" are being used, whereby notation such as "$g_{ab}$" and "$V^a$" can be used interchangeably either for the sets of components of the metric tensor $\boldsymbol{g}$ and the vector $\boldsymbol{V}$, respectively, or alternatively for the entire geometrical metric tensor $\boldsymbol{g}$ or vector $\boldsymbol{V}$, in each case; moreover, the summation convention is being assumed, or this can alternatively be understood in terms of abstract indices. (For the abstract-index notation for tensors, see Penrose and Rindler (1984), especially Chapters 2 and 4. Sign and index-ordering conventions used here follow those given in that book. Many other authors use conventions which differ from these in various, usually minor respects.))

## Physical Interpretation of the Metric

Some words of clarification are needed, as to the meaning of the metric tensor $g_{ab}$ in relativity theory. In the early discussions by Einstein and others, the spacetime metric tended to be interpreted in terms of little "rulers" placed on a curved manifold. Although this is natural in the Riemannian (positive-definite) case, it is not quite so appropriate for the Lorentzian geometry of spacetime manifolds. An ordinary physical ruler has a spacetime description as a timelike strip, and it does not naturally express the spatial separation between two spacelike-separated events. In order for a ruler to measure such a spacelike separation, it would be necessary for the two events to be simultaneous in the ruler's rest frame, and for this to be assured, some further mechanism would be needed, such as Einstein's procedure for ensuring simultaneity by the use of light signals from the two events to be received simultaneously at their midpoint on the ruler. Clearly this complicates the issue, and it turns out to be much preferable to concentrate on temporal displacements rather than spatial ones.

The idea that spacetime geometry should really be regarded as "chronometry," in this way, has been stressed by a number of distinguished expositors of relativity theory, most notably John L Synge (1956, 1960) and Hermann Bondi (1961, 1964, 1967). Where needed, spatial displacements can then be defined by the use of temporal ones together with light signals. This has the additional advantage that in modern technology, the measurement of (proper) time far surpasses that of distance in accuracy, to the extent that the meter is now defined simply by the requirement that there are exactly 299792458 of them in a light-second! The proper time interval between two nearby events is, indeed, measured by a clock which encounters both events, moving inertially between the two, and very precise atomic and nuclear clocks are now a common feature of current technology. The physical role of the metric $g_{ab}$ is most clearly seen in the formula

$$\tau = \int_p^q (g_{ab}\,\mathrm{d}x^a\,\mathrm{d}x^b)$$

which measures the (proper) time interval $\tau$ between an event $p$ and a later event $q$ on its world line, the integral being taken along this curve, and where now that curve need not be a geodesic, so that accelerating (noninertial) motion of the clock is allowed. The metric (with choice of signature $+---$ so that it is the timelike displacements that are directly provided as real numbers) is very precisely specified by this physical requirement, and this tells us that the pseudo-Riemannian (Lorentzian) structure of spacetime is far from being an arbitrary construction, but is given to us by Nature with enormous precision. (Some theorists prefer to use the alternative spacetime signature $-+++$, because this more directly relates to familiar Newtonian concepts, these being normally described in spatial terms. The difference is essentially just a notational one, however. It may be remarked that the 2-spinor formalism (*see* Spinors and Spin Coefficients) fits in much more readily with the $+---$ signature being used here.) It may be noted, also that this time measure is ultimately fixed by quantum principles and the masses of the elementary ingredients involved (e.g., particle masses) via the Einstein and Planck relations $E=mc^2$ and $E=h\nu$, so that there is a natural frequency associated with a given mass, via $\nu=mc^2/h$ ($c$ being the speed of light and $h$ being Planck's constant).

## Riemann Curvature and Geodesic Deviation

The unique torsion-free (Christoffel–Levi-Civita) connection $\nabla_a$ is, via this physically determined metric, also fixed accordingly by these physical considerations, as is the notion of a geodesic, and therefore so also is the curvature. The 20-independent-component Riemann curvature tensor $R_{abcd}$ may be defined by

$$(\nabla_a\nabla_b - \nabla_b\nabla_a)V^d = R_{abc}{}^d V^c$$

with normal index-raising/lowering conventions, so that $R_{abcd}=R^e_{abc}g_{ed}$, etc., and we have the standard classical formula

$$R_{abc}{}^d = \partial_a\Gamma_{cb}{}^d - \partial_b\Gamma_{ca}{}^d + \Gamma_{cb}{}^e\Gamma_{ea}{}^d - \Gamma_{ca}{}^e\Gamma_{eb}{}^d$$

The symmetries $R_{abcd}=R_{cdab}=-R_{bacd}$, $R_{abcd}+R_{bcad}+R_{cabd}=0$ reduce the number of independent components of $R_{abcd}$ to 20 (from a potential $4^4=64$). Of these, 10 are locally fixed by the kind of physical requirement indicated above, that in order to express something that agrees closely with Newton's inverse-square law we require that there should be a net inward curving of free world lines (the timelike geodesics that represent local inertial motions, or "free fall" under gravity). Let us see how this requirement is satisfied in Einstein's general relativity.

What we find, from Newton's theory, is that a system of test particles which, at some initial time constitutes a closed 2-surface at rest surrounding some gravitating matter, will begin to accelerate in such a way that the volume surrounded is initially reduced in proportion to the total mass surrounded.

This volume reduction is a direct consequence of Poisson's equation $\nabla^2\Phi = -4\pi\rho$ ($\Phi$ being the gravitational potential and $\rho$ the mass density) and of Newton's second law, which tell us that the second time derivative of the free-fall volume of our initially stationary closed surface of test particles is indeed $-4\pi GM$, where $M$ is the total gravitating mass surrounded (and $G$ is Newton's constant, as above). In Einstein's theory, we can basically carry this over to our four-dimensional Lorentzian spacetime. We do, however, find that such a general statement as this does not exactly hold. Instead of referring to 3-volumes of any size, we must restrict attention to infinitesimal volumes.

The basic mathematical tool is the equation of "geodesic deviation," namely the "Jacobi equation":

$$\mathrm{D}^2 u^d = R_{abc}{}^d t^a u^b t^c$$

where D describes "propagation derivative"

$$\mathrm{D} = t^a \nabla_a$$

along a timelike geodesic $\gamma$, where $t^a$ is a unit timelike tangent vector to $\gamma$ (so $t_a t^a = g_{ab} t^a t^b = 1$) which is (consequently) parallel-propagated along $\gamma$,

$$\mathrm{D}t^a = 0$$

(When acting on a scalar quantity defined along $\gamma$, we can read "D" as "$\mathrm{d}/\mathrm{d}\tau$," where $\tau$ measures proper time along $\gamma$.) The vector $u^a$ is what is called a connecting vector between the geodesic $\gamma$ and some "neighboring geodesic" $\gamma'$. We think of the vector $u^a$ as "connecting" a point $p$ on $\gamma$ to some neighboring point $p'$ on $\gamma'$, where it is usual to take $u^a$ to be orthogonal to $t^a$ (i.e., $u_a t^a = 0$). The derivative $\mathrm{D}u^a$ measures the rate of change of $u^a$, as $p$ and $p'$ move together into the future along $\gamma$. Mathematically, we express this as the vanishing of the Lie derivative of $u^a$ with respect to $t^a$ (with $t_a$ extended to a unit vector field which is tangent both to $\gamma$ and to $\gamma'$). By taking three independent vectors $u^a$ at $p$, we can form a spatial 3-volume element $W$ and investigate how this propagates along $\gamma$. We find

$$\mathrm{D}^2 W = W R_{ab} t^a t^b$$

where the Ricci tensor $R_{ab} (= R_{ba})$ is here defined by

$$R_{ab} = R_{acb}{}^c$$

## The Einstein Field Equations

In view of what has been said above, with regard to the way that the acceleration of volume behaves in Newtonian theory, it would be natural to "identify" $R_{ab} t^a t^b$ with ($-4\pi G\times$) the (active gravitational) mass density, with respect to the time direction $t^a$. In (special) relativity theory we expect to identify mass density with $c^{-2}\times$ energy density (by $E = mc^2$) and to take energy density as just one component (the time–time component) of a symmetric tensor $T_{ab}$, called the "energy tensor," and for simplicity we now take $c = 1$. The tensor quantity $T_{ab}$ is to incorporate the contributions to the local mass/energy density of all particles and fields other than gravity itself. Since we would require this to work for all choices of time-direction $t^a$, it would be natural, accordingly, to make the identification

$$R_{ab} = -4\pi G T_{ab}$$

Indeed, this was Einstein's initial choice for a gravitational field equation. However, this will actually not do, as Einstein later realized. The trouble comes from the Bianchi identity

$$\nabla_a R_{bcde} + \nabla_b R_{cade} + \nabla_c R_{abde} = 0$$

from which we deduce

$$\nabla^a \left(R_{ab} - \tfrac{1}{2} R g_{ab}\right) = 0$$

where

$$R = R_a{}^a$$

This causes trouble in connection with the standard requirement on the energy tensor, that it satisfy the local "conservation law"

$$\nabla^a T_{ab} = 0$$

The latter equation is an essential requirement in special relativity, since it expresses the conservation of energy and momentum for fields in flat spacetime. In standard Minkowski coordinates, each of $T_{a0}, T_{a1}, T_{a2}, T_{a3}$ satisfies an equation just like the $\nabla^a J_a = 0$ of the charge–current vector $J_a$ of Maxwell's theory of electromagnetism, with now $\nabla_a = \partial_a = \partial/\partial x^a$, which expresses global conservation of charge. Similarly to the way that $J_a$ encapsulates density and flux of electric charge, $T_{a0}$ encapsulates density and flux of energy, and $T_{a1}, T_{a2}, T_{a3}$ encapsulate the same for the three components of momentum. So the equation $\nabla^a T_{ab} = 0$ is essential in special relativity, for similarly expressing global conservation of energy and momentum. We find (referring to a local inertial frame) that, when we pass to general relativity, this equation should still hold, with $\nabla_a$ now standing for covariant derivative. But the initially proposed field equation $R_{ab} = -4\pi G T_{ab}$ would now give us $\nabla^a R_{ab} = 0$, which combined with the geometrically necessary $\nabla^a (R_{ab} - (\frac{1}{2}) R g_{ab}) = 0$, tells us that $R$ is constant. In turn this implies the physically unacceptable requirement that $T = T_a^a$ is constant (since we have $R = -4\pi GT$).

Einstein eventually became convinced (by 1915) of the modified field equations

$$R_{ab} - \tfrac{1}{2}Rg_{ab} = -8\pi G T_{ab}$$

(the "8" rather than "4" being now needed to fit in with the Newtonian limit) and it is these that are now commonly referred to as "Einstein's field equations." (Some authors prefer to use the singular form "field equation," especially if the formula is to be read as an abstract-index expression rather than a family of component equations, since the tensors involved are really single entities.) It may be noted that the formula can be rewritten as

$$R_{ab} = -8\pi G\left(T_{ab} - \tfrac{1}{2}Tg_{ab}\right)$$

from which we deduce that in Einstein's theory the source of gravity is not simply the mass (or equivalently energy) density, but there is an additional contribution from the pressure (momentum flux, i.e., space–space components of $T_{ab}$). This can have significant implications for the instability of very large and massive stars in highly relativistic regimes, where increases in pressure can, paradoxically, actually increase the tendency for a star to collapse, owing to its contribution to the attractive effect of its gravity.

In 1917, Einstein put forward a slight modification of his field equations – basically the only modification that can be made without fundamentally changing the foundations of his theory – by introducing the very tiny cosmological constant $\Lambda$. The modified equations are

$$R_{ab} - \tfrac{1}{2}Rg_{ab} + \Lambda g_{ab} = -8\pi G T_{ab}$$

and the source of gravity, or active gravitational mass is now

$$\rho + P_1 + P_2 + P_3 - \frac{\Lambda}{4\pi G}$$

where (with respect to a local Lorentzian orthonormal frame, units being chosen so that $c = 1$) $\rho = T_{00}$ is the mass/energy density and $P_1 = T_{11}, P_2 = T_{22}, P_3 = T_{33}$ are the principal pressures. The $\Lambda$-term, for positive $\Lambda$, provides a repulsive contribution to the gravitational effect, but it is extremely tiny (and totally ignorable) on all ordinary scales, beginning to show itself only at the most vast of observed cosmological distances (since the effect of $\Lambda$ adds up relentlessly at larger and larger distances). Einstein originally introduced the term in order to have the possibility of a static universe, where the attractive gravitational effect of the totality of ordinary matter would be balanced, overall, by $\Lambda$. But the discovery of the expansion of the universe (by Hubble and others) led Einstein to abandon the cosmological term. However, since 1998 (initially from the supernova observations of Brian Schmidt and Robert Kirschner, and Saul Perlmutter, *see* Perlmutter *et al.* (1998)), cosmological evidence has mounted in favor of the presence of a very small positive $\Lambda$-term, which has resulted in the expansion of the universe beginning to accelerate. While the presence of Einstein's constant $\Lambda$-term is consistent with observations, and remains the simplest explanation of this observed acceleration, many cosmologists prefer to allow for what would amount to a "varying $\Lambda$," and refer to it as "dark energy."

## Energy Conservation and Related Matters

One of the features of Einstein's general relativity theory that had been deeply puzzling to a good many of Einstein's contemporaries, and which may be said to be still not fully resolved, even today, is "energy conservation," in the presence of a dynamical gravitational field. We have noted that the energy tensor $T_{ab}$ is to incorporate the contributions of all particles and fields other than gravity. But what about gravity itself? There are many physical situations in which energy can be transferred back and forth from gravitational systems to nongravitational ones (most strikingly in the example of the emission of gravitational waves; *see* Gravitational Waves). The conservation of energy would make no sense without an understanding of how energy can be stored in a gravitational field. At first sight we seem to see no role for a gravitational contribution to energy in Einstein's theory, since the conservation law $\nabla^a T_{ab} = 0$ seems to be a self-contained expression of energy conservation with no direct contribution from the gravitational field in the tensor $T_{ab}$. However, this is illusory, since the formulation of a global conservation law from the local covariant expression $\nabla^a T_{ab} = 0$ does not work in curved spacetime (basically because, unlike the charge–current quantity $J_a$ of Maxwell's electrodynamical theory, the extra index on $T_{ab}$ prevents it from being regarded as a 1-form). We may take the view that the energy of gravitation enters nonlocally into the equation, so that the failure of $T_{ab}$ to provide a global conservation law on its own is an expression of the gravitational contributions of energy not being taken into account. This is no doubt a correct attitude to take, but it is a difficult one to express comprehensively in a mathematical form. Einstein himself provided a partial understanding, but at the expense of introducing concepts known as "pseudotensors" whose meaning was too tied up with arbitrary choices of coordinate systems to provide an overall picture. In modern approaches, the most clear-cut results come from the study of asymptotically flat or asymptotically de Sitter spacetimes (de Sitter space being the empty universe which takes over the role of Minkowski space when

there is a positive cosmological constant $\Lambda$; *see* Cosmology: Mathematical Aspects).

The important role of the "Weyl conformal tensor"

$$C_{abcd} = R_{abcd} - \tfrac{1}{2}(R_{ac}g_{bd} - R_{bc}g_{ad} + R_{bd}g_{ac} - R_{ad}g_{bc}) + \tfrac{1}{6}R(g_{ac}g_{bd} - g_{bc}g_{ad})$$

should also be pointed out. This tensor retains all the symmetries of the full Riemann tensor, but has the Ricci tensor contribution removed, so that all its contractions vanish, as is exemplified by

$$C_{abc}{}^{a} = 0$$

It describes the conformal part of the curvature, that is, that part that survives under conformal rescalings of the metric;

$$g_{ab} \mapsto \Omega^2 g_{ab}$$

where $\Omega$ is a smooth (positive) function of position. The tensor $C_{abc}{}^{d}$ is itself invariant under these conformal rescalings. This has importance in the asymptotic analysis of gravitational fields (*see* Asymptotic Structure and Conformal Infinity). We may take the view that $C_{abcd}$ describes the degrees of freedom in the free gravitational field, whereas $R_{ab}$ contains the information of the sources of gravity. This is analogous to the Maxwell tensor $F_{ab}$ describing the degrees of freedom in the free electromagnetic field, whereas $J_a$ contains the information of the sources of electromagnetism.

From the observational point of view, general relativity stands in excellent shape, with full agreement with all known relevant data, starting with the anomalous perihelion advance of the planet Mercury observed by LeVerrier in the mid-nineteenth century, through clock-slowing, light-bending (lensing) and time-delay effects, and the necessary corrections to GPS positioning systems, to the precise orbiting of double neutron-star systems, with energy loss due to the emission of gravitational waves. The effects of gravitational lensing now play vital roles in modern cosmology. To get some idea of the precision in Einstein's theory, we may take note of the fact that the double neutron-star system PSR 1913+16 has been observed for some 30 years, and the agreement between observation and theory overall is to about one part in $10^{14}$.

# Generic Properties of Dynamical Systems

**C Bonatti**, Université de Bourgogne, Dijon, France

## Introduction

The state of a concrete system (from physics, chemistry, ecology, or other sciences) is described using (finitely many, say $n$) observable quantities (e.g., positions and velocities for mechanical systems, population densities for echological systems, etc.). Hence, the state of a system may be represented as a point $x$ in a geometrical space $\mathbb{R}^n$. In many cases, the quantities describing the state are related, so that the phase space (space of all possible states) is a submanifold $M \subset \mathbb{R}^n$. The time evolution of the system is represented by a curve $x_t, t \in \mathbb{R}$ drawn on the phase space $M$, or by a sequence $x_n \in M$, $n \in \mathbb{Z}$, if we consider discrete time (i.e., every day at the same time, or every January 1st).

Believing in determinism, and if the system is isolated from external influences, the state $x_0$ of the system at the present time determines its evolution. For continuous-time systems, the infinitesimal

evolution is given by a differential equation or vector field $dx/dt = X(x)$; the vector $X(x)$ represents velocity and direction of the evolution. For a discrete-time system, the evolution rule is a function $F: M \to M$; if $x$ is the state at time $t$, then $F(x)$ is the state at the time $t+1$. The evolution of the system, starting at the initial data $x_0$, is described by the orbit of $x_0$, that is, the sequence $\{(x_n)_{n\in\mathbb{Z}} \mid x_{n+1} = F(x_n)\}$ (discrete time) or the maximal solution $x_t$ of the differential equation $ax/dt = X(x)$ (continuous time).

**General problem** *Knowing the initial data and the infinitesimal evolution rule, what can we tell about the long-time evolution of the system?*

The dynamics of a dynamical system (differential equation or function) is the behavior of the orbits, when the time tends to infinity. The aim of "dynamical systems" is to produce a general procedure for describing the dynamics of any system. For example, Conley's theory presented in the next section organizes the global dymamics of a general system using regions concentrating the orbit accumulation and recurrence and splits these regions in elementary pieces: the chain recurrence classes.

We focus our study on $C^r$-diffeomorphisms $F$ (i.e., $F$ and $F^{-1}$ are $r$ times continuously derivable) on a compact smooth manifold $M$ (most of the notions and results presented here also hold for vector fields). Even for very regular systems ($F$ algebraic) of a low-dimensional space ($\dim(M) = 2$), the dynamics may be chaotic and very unstable: one cannot hope for a precise description of all systems. Furthermore, neither the initial data of a concrete system nor the infinitesimal-evolution rule are known exactly: fragile properties describe the evolution of the theoretical model, and not of the real system. For these reasons, we are mostly interested in properties that are persistent, in some sense, by small perturbations of the dynamical system. The notion of small perturbations of the system requires a topology on the space $\mathrm{Diff}^r(M)$ of $C^r$-diffeomorphisms: two diffeomorphisms are close for the $C^r$-topology if all their partial derivatives of order $\leq r$ are close at each point of $M$. Endowed with this topology, $\mathrm{Diff}^r(M)$ is a complete metric space.

The open and dense subsets of $\mathrm{Diff}^r(M)$ provide the natural topological notion of "almost all" $F$. Genericity is a weaker notion: by Baire's theorem, if $\mathcal{O}_i, i \in \mathbb{N}$, are dense and open subsets, the intersection $\bigcap_{i\in\mathbb{N}} \mathcal{O}_i$ is a dense subset. A subset is called residual if it contains such a countable intersection of dense open subsets. A property $\mathcal{P}$ is generic if it is verified on a residual subset. By a practical abuse of language, one says:

"$C^r$-generic diffeomorphisms verify $\mathcal{P}$"

A countable intersection of residual sets is a residual set. Hence, if $\{\mathcal{P}_i\}, i \in \mathbb{N}$, is a countable family of generic properties, generic diffeomorphisms verify simultanuously all the properties $\mathcal{P}_i$.

A property $\mathcal{P}$ is $C^r$-robust if the set of diffeomorphisms verifying $\mathcal{P}$ is open in $\mathrm{Diff}^r(M)$. A property $\mathcal{P}$ is locally generic if there is an (nonempty) open set $\mathcal{O}$ on which it is generic, that is, there is residual set $\mathcal{R}$ such that $\mathcal{P}$ is verified on $\mathcal{R} \cap \mathcal{O}$.

The properties of generic dynamical systems depend mostly on the dimension of the manifold $M$ and of the $C^r$-topology considered, $r \in \mathbb{N} \cup \{+\infty\}$ (an important problem is that $C^r$-generic diffeomorphisms are not $C^{r+1}$ ):

- On very low dimensional spaces (diffeomorphisms of the circle and vector fields on compact surfaces) the dynamics of generic systems (indeed in a open and dense subset of systems) is very simple (called Morse–Smale) and well understood; see the subsection "Generic properties of the low-dimensional systems."
- In higher dimensions, for $C^r$-topology, $r > 1$, one has generic and locally generic properties related to the periodic orbits, like the Kupka–Smale property (see the subsection "Kupka–Smale theorem") and the Newhouse phenomenon (see the subsection "Local $C^2$-genericity of wild behavior for surface diffeomorphisms"). However, we still do not know if the dynamics of $C^r$-generic diffeomorphisms is well approached by their periodic orbits, so that one is still far from a global understanding of $C^r$-generic dynamics.
- For the $C^1$-topology, perturbation lemmas show that the global dynamics is very well approximated by periodic orbits (see the section "$C^1$-generic systems: global dynamics and periodic orbits"). One then divides generic systems in "tame" systems, with a global dynamics analoguous to hyperbolic dynamics, and "wild" systems, which present infinitely many dynamically independent regions. The notion of dominated splitting (see the section "Hyperbolic properties of $C^1$-generic diffeormorphisms") seems to play an important role in this division.

## Results on General Systems

### Notions of Recurrence

Some regions of $M$ are considered as the heart of the dynamics:

- $\mathrm{Per}(F)$ denotes the set of periodic points $x \in M$ of $F$, that is, $F^n(x) = x$ for some $n > 0$.
- A point $x$ is recurrent if its orbit comes back arbitrarily close to $x$, infinitely many times. $\mathrm{Rec}(F)$ denotes the set of recurrent points.
- The limit set $\mathrm{Lim}(F)$ is the union of all the accumulation points of all the orbits of $F$.

- A point $x$ is "wandering" if it admits a neighborhood $U_x \subset M$ disjoint from all its iterates $F^n(U_x), n > 0$. The nonwandering set $\Omega(F)$ is the set of the nonwandering points.
- $\mathcal{R}(F)$ is the set of chain recurrent points, that is, points $x \in M$ which look like periodic points if we allow small mistakes at each iteration: for any $\varepsilon > 0$, there is a sequence $x = x_0, x_1, \ldots, x_k = x$ where $d(f(x_i), x_{i+1}) < \varepsilon$ (such a sequence is an $\varepsilon$-pseudo-orbit).

A periodic point is recurrent, a recurrent point is a limit point, a limit point is nonwandering, and a nonwandering point is chain recurrent:

$$\mathrm{Per}(F) \subset \mathrm{Rec}(F) \subset \mathrm{Lim}(F) \subset \Omega(F) \subset \mathcal{R}(F)$$

All these sets are invariant under $F$, and $\Omega(F)$ and $\mathcal{R}(F)$ are compact subsets of $M$. There are diffeomorphisms $F$ for which the closures of these sets are distinct:

- A rotation $x \mapsto x + \alpha$ with irrational angle $\alpha \in \mathbb{R}\backslash\mathbb{Q}$ on the circle $S^1 = \mathbb{R}/\mathbb{Z}$ has no periodic points but every point is recurrent.
- The map $x \mapsto x + (1/4\pi)(1 + \cos(2\pi x))$ induces on the circle $S^1$ a diffeomorphism $F$ having a unique fixed point at $x = 1/2$; one verifies that $\Omega(F) = \{1/2\}$ and $\mathcal{R}(F)$ is the whole circle $S^1$.

An invariant compact set $K \subset M$ is transitive if there is $x \in K$ whose forward orbit is dense in $K$. Generic points $x \in K$ have their forward and backward orbits dense in $K$: in this sense, transitive sets are dynamically indecomposable.

#### Conley's Theory: Pairs Attractor/Repeller and Chain Recurrence Classes

A trapping region $U \subset M$ is a compact set whose image $F(U)$ is contained in the interior of $U$. By definition, the intersection $A = \bigcap_{n \geq 0} F^n(U)$ is an attractor of $F$: any orbit in $U$ "goes to $A$." Denote by $V$ the complement of the interior of $U$: it is a trapping region for $F^{-1}$ and the intersection $R = \bigcap_{n \geq 0} F^{-n}(V)$ is a repeller. Each orbit either is contained in $A \cup R$, or "goes from the repeller to the attractor." More precisely, there is a smooth function $\psi: M \to [0, 1]$ (called Lyapunov function) equal to 1 on $R$ and 0 on $A$, and strictly decreasing on the other orbits:

$$\psi(F(x)) < \psi(x) \quad \text{for } x \notin A \cup R$$

So, the chain recurrent set is contained in $A \cup R$. Any compact set contained in $U$ and containing the interior of $F(U)$ is a trapping region inducing the same attracter and repeller pair $(A,R)$; hence, the set of attracter/repeller pairs is countable. We denote by $(A_i, R_i, \psi_i), i \in \mathbb{N}$, the family of these pairs endowed with an associated Lyapunov function. Conley (1978) proved that

$$\mathcal{R}(F) = \bigcap_{i \in \mathbb{N}} (A_i \cup R_i)$$

This induces a natural partition of $\mathcal{R}(F)$ in equivalence classes: $x \sim y$ if $x \in A_i \Leftrightarrow y \in A_i$. Conley proved that $x \sim y$ iff, for any $\varepsilon > 0$, there are $\varepsilon$-pseudo orbits from $x$ to $y$ and vice versa. The equivalence classes for $\sim$ are called chain recurrence classes.

Now, considering an average of the Lyapunov functions $\psi_i$ one gets the following result: there is a continuous function $\varphi: M \to \mathbb{R}$ with the following properties:

- $\varphi(F(x)) \leq \varphi(x)$ for every $x \in M$, (i.e., $\varphi$ is a Lyapunov function);
- $\varphi(F(x)) = \varphi(x) \Leftrightarrow x \in \mathcal{R}(F)$;
- for $x, y \in \mathcal{R}(F)$, $\quad \varphi(x) = \varphi(y) \Leftrightarrow x \sim y$; and
- the image $\varphi(\mathcal{R}(F)$ is a compact subset of $\mathbb{R}$ with empty interior.

This result is called the "fundamental theorem of dynamical systems" by several authors (see Robinson (1999)).

Any orbit is $\varphi$-decreasing from a chain recurrence class to another chain reccurence class (the global dynamics of $F$ looks like the dynamics of the gradient flow of a function $\phi$, the chain recurrence classes supplying the singularities of $\phi$). However, this description of the dynamics may be very rough: if $F$ preserves the volume, Poincaré's recurrence theorem implies that $\Omega(F) = \mathcal{R}(F) = M$; the whole $M$ is the unique chain recurrence class and the function $\varphi$ of Conley's theorem is constant.

Conley's theory provides a general procedure for describing the global topological dynamics of a system: one has to characterize the chain recurrence classes, the dynamics in restriction to each class, the stable set of each class (i.e., the set of points whose positive orbits goes to the class), and the relative positions of these stable sets.

## Hyperbolicity

Smale's hyperbolic theory is the first attempt to give a global vision of almost all dynamical systems. In this section we give a very quick overview of this theory. For further details, *see* Hyperbolic Dynamical Systems.

#### Hyperbolic Periodic Orbits

A fixed point $x$ of $F$ is hyperbolic if the derivative $DF(x)$ has no (neither real nor complex) eigenvalue with modulus equal to 1. The tangent space at $x$

splits as $T_xM = E^s \oplus E^u$, where $E^s$ and $E^u$ are the $DF(x)$-invariant spaces corresponding to the eigenvalues of moduli $<1$ and $>1$, respectively. There are $C^r$-injectively immersed $F$-invariant submanifolds $W^s(x)$ and $W^u(x)$ tangent at $x$ to $E^s$ and $E^u$; the stable manifold $W^s(x)$ is the set of points $y$ whose forward orbit goes to $x$. The implicit-function theorem implies that a hyperbolic fixed point $x$ varies (locally) continuously with $F$; (compact parts of) the stable and unstable manifolds vary continuously for the $C^r$-topology when $F$ varies with the $C^r$-topology.

A periodic point $x$ of period $n$ is hyperbolic if it is a hyperbolic fixed point of $F^n$ and its invariant manifolds are the corresponding invariant manifolds for $F^n$. The stable and unstable manifold of the orbit of $x$, $W^s_{orb}(x)$ and $W^u_{orb}(x)$, are the unions of the invariant manifolds of the points in the orbit.

### Homoclinic Classes

Distinct stable manifolds are always disjoint; however, stable and unstable manifolds may intersect. At the end of the nineteenth century, Poincaré noted that the existence of transverse homoclinic orbits, that is, transverse intersection of $W^s_{orb}(x)$ with $W^u_{orb}(x)$ (other than the orbit of $x$), implies a very rich dynamical behavior: indeed, Birkhoff proved that any transverse homoclinic point is accumulated by a sequence of periodic orbits (see Figure 1). The homoclinic class $H(x)$ of a periodic orbit is the closure of the transverse homoclinic point associated to $x$:

$$H(p) = \overline{W^s_{orb}(x) \pitchfork W^u_{orb}(x)}$$

There is an equivalent definition of the homoclinic class of $x$: we say that two hyperbolic periodic points $x$ and $y$ are homoclinically related if $W^s_{orb}(x)$ and $W^u_{orb}(x)$ intersect transversally $W^u_{orb}(y)$ and $W^s_{orb}(y)$, respectively; this defines an equivalence relation in $\mathrm{Per}_{hyp}(F)$ and the homoclinic classes are the closure of the equivalence classes.

The homoclinic classes are transitive invariant compact sets canonically associated to the periodic orbits. However, for general systems, homoclinic classes are not necessarily disjoint.

For more details, *see* Homoclinic Phenomena.

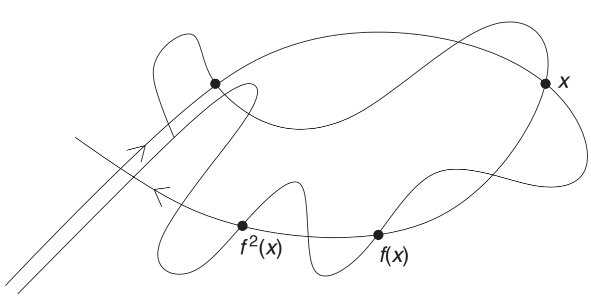

**Figure 1** A transverse homoclinic orbit.

### Smale's Hyperbolic Theory

A diffeomorphism $F$ is *Morse–Smale* if $\Omega(F) = \mathrm{Per}(F)$ is finite and hyperbolic, and if $W^s(x)$ is tranverse to $W^u(y)$ for any $x, y \in \mathrm{Per}(F)$. Morse–Smale diffeomorphisms have a very simple dynamics, similar to the one of the gradient flow of a Morse function; apart from periodic points and invariant manifolds of periodic saddles, each orbit goes from a source to a sink (hyperbolic periodic repellers and attractors). Furthermore, Morse–Smale diffeomorphisms are $C^1$-*structurally stable*, that is, any diffeomorphism $C^1$-close to $F$ is conjugated to $F$ by a homeomorphism: the topological dynamics of $F$ remains unchanged by small $C^1$-perturbation. Morse–Smale vector fields were known (Andronov and Pontryagin, 1937) to characterize the structural stability of vector fields on the sphere $S^2$. However, a diffeomorphism having transverse homoclinic intersections is robustly not Morse–Smale, so that Morse–Smale diffeomorphisms are not $C^r$-dense, on any compact manifold of dimension $\geq 2$. In the early 1960s, Smale generalized the notion of hyperbolicity for nonperiodic sets in order to get a model for homoclinic orbits. The goal of the theory was to cover a whole dense open set of all dynamical systems.

An invariant compact set $K$ is hyperbolic if the tangent space $TM|_K$ of $M$ over $K$ splits as the direct sum $TM_K = E^s \oplus E^u$ of two $DF$-invariant vector bundles, where the vectors in $E^s$ and $E^u$ are uniformly contracted and expanded, respectively, by $F^n$, for some $n > 0$. Hyperbolic sets persist under small $C^1$-perturbations of the dynamics: any diffeomorphism $G$ which is $C^1$-close enough to $F$ admits a hyperbolic compact set $K_G$ close to $K$ and the restrictions of $F$ and $G$ to $K$ and $K_G$ are conjugated by a homeomorphism close to the identity. Hyperbolic compact sets have well-defined invariant (stable and unstable) manifolds, tangent (at the points of $K$) to $E^s$ and $E^u$ and the (local) invariant manifolds of $K_G$ vary locally continuously with $G$.

The existence of hyperbolic sets is very common: if $y$ is a transverse homoclinic point associated to a hyperbolic periodic point $x$, then there is a transitive hyperbolic set containing $x$ and $y$.

Diffeomorphisms for which $\mathcal{R}(F)$ is hyperbolic are now well understood: the chain recurrence classes are homoclinic classes, finitely many, and transitive, and admit a combinatorical model (subshift of finite type). Some of them are

attractors or repellers, and the basins of the attractors cover a dense open subset of $M$. If, furthermore, all the stable and unstable manifolds of points in $\mathcal{R}(f)$ are transverse, the diffeomorphism is $C^1$-structurally stable (Robbin 1971, Robinson 1976); indeed, this condition, called "axiom A + strong transversality," is equivalent to the $C^1$-structural stability (Mañé 1988).

In 1970, Abraham and Smale built examples of robustly non-axiom A diffeomorphisms, when $\dim M \geq 3$: the dream of a global understanding of dynamical systems was postponed. However, hyperbolicity remains a key tool in the study of dynamical systems, even for nonhyperbolic systems.

## $C^r$-Generic Systems

### Kupka–Smale Theorem

Thom's transversality theorem asserts that two submanifolds can always be put in tranverse position by a $C^r$-small perturbations. Hence, for $F$ in an open and dense subset of $\mathrm{Diff}^r(M), r \geq 1$, the graph of $F$ in $M \times M$ is transverse to the diagonal $\Delta = \{(x,x), x \in M\}$: $F$ has finitely many fixed points $x_i$, depending locally continuously on $F$, and 1 is not an eigenvalue of the differential $DF(x_i)$. Small local perturbations in the neighborhood of the $x_i$ avoid eigenvalue of modulus equal to 1: one gets a dense and open subset $\mathcal{O}_1^r$ of $\mathrm{Diff}^r(M)$ such that every fixed point is hyperbolic. This argument, adapted for periodic points, provides a dense and open set $\mathcal{O}_n^r \subset \mathrm{Diff}^r(M)$, such that every periodic point of period $n$ is hyperbolic. Now $\bigcap_{n\in\mathbb{N}} \mathcal{O}_n^r$ is a residual subset of $\mathrm{Diff}^r(M)$, for which every periodic point is hyperbolic.

Similarly, the set of diffeomorphisms $F \in \bigcap_{i=0}^n \mathcal{O}_i^r(M)$ such that all the disks of size $n$, of invariant manifolds of periodic points of period less that $n$, are pairwise transverse, is open and dense. One gets the Kupka–Smale theorem (see Palis and de Melo (1982) for a detailed exposition): *for $C^r$-generic diffeomorphisms $F \in \mathrm{Diff}^r(M)$, every periodic orbit is hyperbolic and $W^s(x)$ is transverse to $W^u(y)$ for $x, y \in Per(F)$.*

### Generic Properties of Low-Dimensional Systems

Poincaré–Denjoy theory describes the topological dynamics of all diffeomorphisms of the circle $S^1$ (*see* Homeomorphisms and Diffeomorphisms of the Circle). Diffeomorphisms in an open and dense subset of $\mathrm{Diff}_+^r(S^1)$ have a nonempty finite set of periodic orbits, all hyperbolic, and alternately attracting (sink) or repelling (source). The orbit of a nonperiodic point comes from a source and goes to a sink. Two $C^r$-generic diffeomorphisms of $S^1$ are conjugated iff they have same rotation number and same number of periodic points.

This simple behavior has been generalized in 1962 by Peixoto for vector fields on compact orientable surfaces $S$. Vector fields $X$ in a $C^r$-dense and open subset are Morse–Smale, hence structurally stable (see Palis and de Melo (1982) for a detailed proof). Peixoto gives a complete classification of these vector fields, up to topological equivalence.

Peixoto's argument uses the fact that the return maps of the vector field on transverse sections are increasing functions: this helped control the effect on the dynamics of small "monotonous" perturbations, and allowed him to destroy any nontrivial recurrences. Peixoto's result remains true on nonorientable surfaces for the $C^1$-topology but remains an open question for $r > 1$: is the set of Morse–Smale vector fields $C^2$-dense, for $S$ nonorientable closed surface?

### Local $C^2$-Genericity of Wild Behavior for Surface Diffeomorphisms

The generic systems we have seen above have a very simple dynamics, simpler than the general systems. This is not always the case. In the 1970s, Newhouse exhibited a $C^2$-open set $\mathcal{O} \subset \mathrm{Diff}^2(S^2)$ (where $S^2$ denotes the two-dimensional sphere), such that $C^2$-generic diffeomorphisms $F \in \mathcal{O}$ have infinitely many hyperbolic periodic sinks. In fact, $C^2$-generic diffeomorphisms in $\mathcal{O}$ present many other pathological properties: for instance, it has been recently noted that they have uncountably many chain recurrence classes without periodic orbits. Densely (but not generically) in $\mathcal{O}$, they present many other phenomena, such as strange (Henon-like) attractors (*see* Lyapunov Exponents and Strange Attractors).

This phenomenon appears each time that a diffeomorphism $F_0$ admits a hyperbolic periodic point $x$ whose invariant manifolds $W^s(x)$ and $W^u(x)$ are tangent at some point $p \in W^s(x) \cap W^u(x)$ ($p$ is a homoclinic tangency associated to $x$). Homoclinic tangencies appear locally as a codimension-1 submanifold of $\mathrm{Diff}^2(S^2)$; they are such a simple phenomenon that they appear in very natural contexts. When a small perturbation transforms the tangency into tranverse intersections, a new hyperbolic set $K$ with very large fractal dimensions is created. The local stable and unstable manifolds of $K$, each homeomorphic to the product of a Cantor set by a segment, present tangencies in a $C^2$-robust way, that is, for $F$ in some $C^2$-open set $\mathcal{O}$ (see **Figure 2**). As a consequence, for a $C^2$-dense subset of $\mathcal{O}$, the

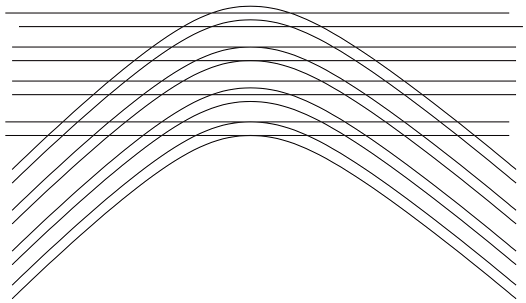

**Figure 2** Robust tangencies.

invariant manifolds of the point $x$ present some tangency (this is not generic, by Kupka–Smale theorem). If the Jacobian of $F$ at $x$ is $<1$, each tangency allows to create one more sink, by an arbitrarily small perturbation. Hence, the sets of diffeomorphisms having more than $n$ hyperbolic sinks are dense open subsets of $\mathcal{O}$, and the intersection of all these dense open subsets is the announced residual set. See Palis and Takens (1993) for details on this deep argument.

## $C^1$-Generic Systems: Global Dynamics and Periodic Orbits

See Bonatti *et al.* (2004), Chapter 10 and Appendix A, for a more detailed exposition and precise references.

### Perturbations of Orbits: Closing and Connecting Lemmas

In 1968, Pugh proved the following Lemma.

**Closing lemma** *If $x$ is a nonwandering point of a diffeomorphism $F$, then there are diffeomorphisms $G$ arbitrarily $C^1$-close to $F$, such that $x$ is periodic for $G$.*

Consider a segment $x_0, \ldots, x_n = F^n(x_0)$ of orbit such that $x_n$ is very close to $x_0 = x$; one would like to take $G$ close to $F$ such that $G(x_n) = x_0$, and $G(x_i) = F(x_i) = x_{i+1}$ for $i \neq n$. This idea works for the $C^0$-topology (so that the $C^0$-closing lemma is easy). However, if one wants $G$ $\varepsilon$-$C^1$-close to $F$, one needs that the points $x_i, i \in \{1, \ldots, n-1\}$, remain at distance $d(x_i, x_0)$ greater than $C(d(x_n, x_0)/\varepsilon)$, where $C$ bounds $\|Df\|$ on $M$. If $C/\varepsilon$ is very large, such a segment of orbit does not exist. Pugh solved this difficulty in two steps: the perturbation is first spread along a segment of orbit of $x$ in order to decrease this constant; then a subsegment $y_0, \ldots, y_k$ of $x_0, \ldots, x_n$ is selected, verifying the geometrical condition.

For the $C^2$ topology, the distances $d(x_i, x_0)$ need to remain greater than $\sqrt{d(x_n, x_0)/\varepsilon} \gg d(x_n, x_0)$. This new difficulty is why the $C^2$-closing lemma remains an open question.

Pugh's argument does not suffice to create homoclinic point for a periodic orbit whose unstable manifold accumulates on the stable one. In 1998, Hayashi solved this problem proving the

**Connecting lemma** (Hayashi 1997) *Let $y$ and $z$ be two points such that the forward orbit of $y$ and the backward orbit of $z$ accumulate on the same nonperiodic point $x$. Fix some $\varepsilon > 0$. There is $N > 0$ and a $\varepsilon$-$C^1$-perturbation $G$ of $F$ such that $G^n(y) = z$ for some $n > 0$, and $G \equiv F$ out of an arbitrary small neighborhood of $\{x, F(x), \ldots, F^N(x)\}$.*

Using Hayashi's arguments, we (with Crovisier) proved the following lemma:

**Connecting lemma for pseudo-orbits** (Bonatti and Crovisier 2004) *Assume that all periodic orbits of $F$ are hyperbolic; consider $x, y \in M$ such that, for any $\varepsilon > 0$, there are $\varepsilon$-pseudo-orbits joining $x$ to $y$; then there are arbitrarily small $C^1$-perturbations of $F$ for which the positive orbit of $x$ passes through $y$.*

### Densities of Periodic Orbits

As a consequence of the perturbations lemma above, we (Bonatti and Crovisier 2004) proved that for $F$ $C^1$-generic,

$$\mathcal{R}(F) = \Omega(F) = \overline{\mathrm{Per}_{\mathrm{hyp}}(F)}$$

where $\overline{\mathrm{Per}_{\mathrm{hyp}}(F)}$ denotes the closure of the set of hyperbolic periodic points.

For this, consider the map $\Psi: F \mapsto \Psi(F) = \overline{\mathrm{Per}_{\mathrm{hyp}}(F)}$ defined on $\mathrm{Diff}^1(M)$ and with value in $\mathcal{K}(M)$, space of all compact subsets of $M$, endowed with the Hausdorff topology. $\mathrm{Per}_{\mathrm{hyp}}(F)$ may be approximated by a finite set of hyperbolic periodic points, and this set varies continuously with $F$; so $\mathrm{Per}_{\mathrm{hyp}}(F)$ varies lower-semicontinuously with $F$: for $G$ very close to $F$, $\mathrm{Per}_{\mathrm{hyp}}(G)$ cannot be very much smaller than $\mathrm{Per}_{\mathrm{hyp}}(F)$. As a consequence, a result from general topology asserts that, for $C^1$-generic $F$, the map $\Psi$ is continuous at $F$. On the other hand, $C^1$-generic diffeomorphisms are Kupka–Smale, so that the connecting lemma for pseudo-orbits may apply: if $x \in \mathcal{R}(F), x$ can be turned into a hyperbolic periodic point by a $C^1$-small perturbation of $F$. So, if $x \notin \overline{\mathrm{Per}_{\mathrm{hyp}}(F)}, F$ is not a continuity point of $\Psi$, leading to a contradiction.

Furthermore, Crovisier proved the following result: "for $C^1$-generic diffeomorphisms, each chain recurrence class is the limit, for the Hausdorff distance, of a sequence of periodic orbits."

This good approximation of the global dynamics by the periodic orbits will now allow us to better understand the chain recurrence classes of $C^1$-generic diffeomorphisms.

### Chain Recurrence Classes/Homoclinic Classes of $C^1$-Generic Systems

Tranverse intersections of invariant manifolds of hyperbolic orbits are robust and vary locally continuously with the diffeomorphisms $F$. So, the homoclinic class $H(x)$ of a periodic point $x$ varies lower-semicontinuously with $F$ (on the open set where the continuation of $x$ is defined). As a consequence, for $C^r$-generic diffeomorphisms ($r \geq 1$), each homoclinic class varies continuously with $F$. Using the connecting lemma, Arnaud (2001) proved the following result: "for Kupka–Smale diffeomorphisms, if the closures $\overline{W^u_{orb}}(x)$ and $\overline{W^s_{orb}}(x)$ have some intersection point $z$, then a $C^1$-pertubation of $F$ creates a tranverse intersection of $\overline{W^u_{orb}}(x)$ and $\overline{W^s_{orb}}(x)$ at $z$." So, if $z \notin H(x)$, then $F$ is not a continuity point of the function $F \mapsto H(x, F)$. Hence, for $C^1$-generic diffeomorphisms $F$ and for every periodic point $x$,

$$H(x) = \overline{W^u_{orb}}(x) \cap \overline{W^s_{orb}}(x)$$

In the same way, $\overline{W^u_{orb}}(x)$ and $\overline{W^s_{orb}}(x)$ vary locally lower-semicontinuously with $F$ so that, for $F$ $C^r$-generic, the closures of the invariant manifolds of each periodic point vary locally continuously. For Kupka–Smale diffeomorphisms, the connecting lemma for pseudo-orbits implies: "if $z$ is a point in the chain recurrence class of a periodic point $x$, then a $C^1$-small perturbation of $F$ puts $z$ on the unstable manifold of $x$"; so, if $z \notin \overline{W^u_{orb}}(x)$, then $F$ is not a continuity point of the function $F \mapsto \overline{W^u_{orb}}(x, F)$. Hence, for $C^1$-generic diffeomorphisms $F$ and for every periodic point $x$, the chain recurrence class of $x$ is contained in $\overline{W^u_{orb}}(x) \cap \overline{W^s_{orb}}(x)$, and, therefore, coincides with the homoclinic class of $x$. This argument proves:

> For a $C^1$-generic diffeomorphism $F$, each homoclinic class $H(x)$ is a chain recurrence class of $F$ (of Conley's theory): a chain recurrence class containing a periodic point $x$ coincides with the homoclinic class $H(x)$. In particular, two homoclinic classes are either disjoint or equal.

### Tame and Wild Systems

For generic diffeomorphisms, the number $N(F) \in \mathbb{N} \cup \{\infty\}$ of homoclinic classes varies lower-semicontinuously with $F$. One deduces that $N(F)$ is locally constant on a residual subset of $\text{Diff}^1(M)$ (Abdenur 2003).

A local version (in the neighborhood of a chain recurrence class) of this argument shows that, for $C^1$-generic diffeomorphisms, any isolated chain recurrence classe $C$ is robustly isolated: for any diffeomorphism $G$, $C^1$-close enough to $F$, the intersection of $\mathcal{R}(G)$ with a small neighborhood of $C$ is a unique chain recurrence class $C_G$ close to $C$.

One says that a diffeomorphism is "tame" if each chain recurrence class is robustly isolated. We denote by $\mathcal{T}(M) \subset \text{Diff}^1(M)$ the ($C^1$-open) set of tame diffeomorphisms and by $\mathcal{W}(M)$ the complement of the closure of $\mathcal{T}(M)$. $C^1$-generic diffeomorphisms in $\mathcal{W}(M)$ have infinitely many disjoint homoclinic classes, and are called "wild" diffeomorphisms.

Generic tame diffeomorphisms have a global dynamics analogous to hyperbolic systems: the chain recurrence set admits a partition into finitely many homoclinic classes varying continuously with the dynamics. Every point belongs to the stable set of one of these classes. Some of the homoclinic classes are (transitive) topological attractors, and the union of the basins covers a dense open subset of $M$, and the basins vary continuously with $F$ (Carballo Morales 2003). It remains to get a good description of the dynamics in the homoclinic classes, and particularly in the attractors. As we shall see in the next section, tame behavior requires some kind of weak hyperbolicity. Indeed, in dimension 2, tame diffeomorphisms satisfy axiom A and the noncycle condition.

As of now, very little is known about wild systems. One knows some semilocal mechanisms generating locally $C^1$-generic wild dynamics, therefore proving their existence on any manifold with dimension $\dim(M) \geq 3$ (the existence of wild diffeomorphisms in dimension 2, for the $C^1$-topology, remains an open problem). Some of the known examples exhibit a universal dynamics: they admit infinitely many disjoint periodic disks such that, up to renormalization, the return maps on these disks induce a dense subset of diffeomorphisms of the disk. Hence, these locally generic diffeomorphisms present infinitely many times any robust property of diffeomorphisms of the disk.

### Ergodic Properties

A point $x$ is well closable if, for any $\varepsilon > 0$ there is $G$ $\varepsilon$-$C^1$-close to $F$ such that $x$ is periodic for $G$ and $d(F^i(x), G^i(x)) < \varepsilon$ for $i \in \{0, \ldots, p\}$, $p$ being the period of $x$. As an important refinement of Pugh's closing lemma, Mañé proved the following lemma:

**Ergodic closing lemma** *For any F-invariant probability, almost every point is well closable.*

As a consequence, “for $C^1$-generic diffeomorphisms, any ergodic measure $\mu$ is the weak limit of a sequence of Dirac measures on periodic orbits, which converges also in the Hausdorff distance to the support of $\mu$.”

It remains an open problem to know if, for $C^1$-generic diffeomorphisms, the ergodic measures supported in a homoclinic class are approached by periodic orbits in this homoclinic class.

### Conservative Systems

The connecting lemma for pseudo-orbits has been adapted for volume preserving and symplectic diffeomorphisms, replacing the condition on the periodic orbits by another generic condition on the eigenvalues. As a consequence, one gets: “$C^1$-generic volume-preserving or symplectic diffeomorphisms are transitive, and $M$ is a unique homoclinic class.”

Notice that the KAM theory implies that this result is wrong for $C^4$-generic diffeomorphisms, the persistence of invariant tori allowing to break robustly the transitivity.

The Oxtoby–Ulam (1941) theorem asserts that $C^0$-generic volume-preserving homeomorphisms are ergodic. The ergodicity of $C^1$-generic volume-preserving diffeomorphisms remains an open question.

## Hyperbolic Properties of $C^1$-Generic Diffeomorphisms

For a more detailed exposition of hyperbolic properties of $C^1$-generic diffeomorphisms, the reader is referred to Bonatti *et al.* (2004, chapter 7 and appendix B).

### Perturbations of Products of Matrices

The $C^1$-topology enables us to do small perturbations of the differential $DF$ at a point $x$ without perturbing either $F(x)$ or $F$ out of an arbitrarily small neighborhood of $x$. Hence, one can perturb the differential of $F$ along a periodic orbit, without changing this periodic orbit (Frank’s lemma). When $x$ is a periodic point of period $n$, the differential of $F^n$ at $x$ is fundamental for knowing the local behavior of the dynamics. This differential is (up to a choice of local coordinates) a product of the matrices $DF(x_i)$, where $x_i = F^i(x)$. So, the control of the dynamical effect of local perturbations along a periodic orbit comes from a problem of linear algebra: “consider a product $\mathcal{A} = A_n \circ A_{n-1} \circ \cdots \circ A_1$ of $n \gg 0$ bounded linear ismorphisms of $\mathbb{R}^d$; how do the eigenvalues and the eigenspaces of $\mathcal{A}$ vary under small perturbations of the $A_i$?”
